**Abstract.** The Last Interglacial (LIG; ca. 125 ka) is a period of interest for climate research as it is the most recent period of the Earth's history when the boreal climate was warmer than at present. Previous research, based on models and geological evidence, suggests that the LIG may have featured enhanced patterns of ocean storminess, but this remains hotly debated. Here, we apply state-of-the-art climate and hydrodynamic modeling to simulate changes in extreme sea levels caused by storm surges, under LIG and pre-industrial climate forcings. Significantly higher seasonal LIG sea level extremes emerge for the Gulf of Carpentaria, parts of Indonesia, the Mediterranean Sea and northern Africa, the Gulf of Saint Lawrence, the Persian Gulf, Pakistan, northwest India, and islands of the Pacific Ocean and of the Caribbean. Lower LIG sea level extremes emerge for the Baltic and North Seas, the Bay of Bengal, China and Vietnam. Some of these anomalies are clearly associated with anomalies in seasonal sea level pressure minima, and potentially also originate from anomalies in the meridional position and intensity of the predominant wind bands. In a qualitative comparison, LIG sea level extremes seem generally higher than those projected for future warmer climates. These results help to constrain the interpretation of coastal archives of LIG sea level indicators.

## 1 Introduction

Storm surges are temporary changes in sea level driven by strong winds and low atmospheric pressures (Resio and Westerink, 2008). In combination with tides and waves, they are the main driver of sea level extremes along the world's coasts (Enríquez et al., 2020; Kirezci et al., 2020; Muis et al., 2016). The genesis and intensity of low-pressure systems depend on large-scale patterns of atmospheric circulation, on sea surface temperature, and on water vapor content of the low atmosphere. These processes that drive storm surges may adjust with ongoing climatic change. Climate reanalysis datasets of the last decades show signs of changes in the atmospheric circulation (Staten et al., 2018) that are potentially due to global warming (e.g., Francis and Skific, 2015). These changes are expected to continue in the future, as sea surface temperatures (Bindoff, 2019) and water vapor content (Takahashi et al., 2016) are projected to increase. As a result, the region of tropical cyclone formation is expected to expand (Harvey et al., 2020), and the Atlantic coast of Europe may see more frequent landfall of tropical cyclones (Haarsma et al., 2013). Ensembles of climate models project a future poleward shift of boreal extra-tropical cyclones, and a decrease in their occurrence (Chang et al., 2012). For the boreal mid-latitudes, the most recent generation of global climate models associate future global warming with a southern shift of winter storm tracks, and weakening of summer storm tracks (Harvey et al., 2020). However, projections of both tropical and extra-tropical cyclone occurrence remain contentious (Catto et al., 2019; Shaw et al., 2016; Yamada et al., 2017).

To understand the implications of different climate states on the occurrence of storm surges, we can look at past periods in earth's history, for example during the warmer conditions of the Last Interglacial (LIG). Since geological proxies do not have the stratigraphic and temporal resolution needed to address storms and cyclones directly, a proposed method to examine these phenomena in the past is climate modelling (Raible et al., 2021). For example, by modeling a set of starkly different past climatic conditions, Koh and Brierley (2015) reveal that the potential for

50 generation of tropical cyclones only changes regionally. Specifically for the LIG, Kaspar et al. (2007) found a strengthening of the winter mid-latitude storm tracks, along with a northward shift and an extension to the east.

### 1.1 The Last Interglacial

One period of particular interest for paleoclimate sciences is the Last Interglacial, spanning from 129 to 116 ka. This was the last period of the Earth's past when large parts of the globe were characterized by a climate slightly warmer than at present, at least in the Northern Hemisphere (CAPE\_Members, 2006; Hoffman et al., 2017; McKay et al., 2011; Shackleton et al., 2020; Turney et al., 2020b; Turney and Jones, 2010). On average, LIG polar temperatures were several degrees higher than pre-industrial (Jouzel et al., 2007; Neem\_Community\_Members, 2013), and ice sheets were smaller (Rohling et al., 2019; Turney et al., 2020a), with sea levels higher than today (Dutton et al., 2015a; Dutton et al., 2015b; Dyer et al., 2021; Kopp et al., 2009). Although key differences in the forcing of LIG and future climates prevent the use of the LIG as a direct analog for the future (Lunt et al., 2013; Otto-Bliesner et al., 2013), its similarity with projected future thermal changes in some regions (especially the Northern Hemisphere) makes it a relevant process-analog for warmer climate conditions.

To date, patterns of LIG storminess are much less explored than temperature, ice sheet, and sea-level. Hansen et al. (2016) suggested that the (late) LIG may have been characterized by anomalous storminess in the Atlantic, and more generally in the subtropics. The notion of higher storminess is rooted in geological observations of so-called "superstorm" deposits emplaced during the LIG along the coasts of the Bahamas (Hearty, 1997; Hearty et al., 1998) and Bermuda (Hearty and Tormey, 2017). These are large boulders and storm ridges whose size and position suggest that they were deposited by storms of higher intensity than recorded in human history. However, there are still debates around the origin of these proxies (Myroie, 2008, 2018; Vimpere et al., 2019) and the type of storm that created them (Hearty and Tormey, 2018; Rovere et al., 2017; Rovere et al., 2018; Scheffers and Kelletat, 2020). Recent modeling work has shown that the LIG might have seen higher-than-today sea surface temperatures, and more frequent and stronger tropical cyclones over the western North Atlantic (Yan et al., 2021). From proxies, reconstructions of storminess are only indirect, and are inferred from variables linked to storm tracks, such as precipitation (Scussolini et al., 2019) and river runoff (Scussolini et al., 2020), and seasonal gradients in precipitation and temperature (Salonen et al., 2021). Possible changes in LIG storm tracks might affect the probabilities of storm surges at the coastline, but this effect has not been quantified.

### 1.2 Application of modeling to LIG storm surges

Compared to previous generations, the present generation of General Circulation Models (GCMs) is much more capable of simulating present-day boreal storm tracks and jet stream (Belmonte Rivas and Stoffelen, 2019; Dullaart et al., 2020; Roberts et al., 2020), with a reduction of almost 50% in root-mean-square error (Harvey et al., 2020). However, GCMs still have a positive bias in the intensity, and a southern bias in the position of the zonal winds associated with summer storm tracks (Roberts et al., 2020). Further, the intensity of the strongest tropical cyclones seems to still be underestimated (ibid.). GCMs indicate significant changes in storm tracks under different climate change scenarios (Haarsma et al., 2013; Harvey et al., 2020), possibly resulting in a poleward shift in areas of

85 cyclone activity (Mori et al., 2019), and implying that future changes in storminess may contribute to higher coastal sea level extremes (Vousdoukas et al., 2018).

In this paper, we explore the influence of the LIG atmospheric climate on global patterns of storm surges. We examine changes in storm surge levels between climates of the LIG and the Pre-Industrial (PI), and link them to changes in mean and extremes of atmospheric circulation. To achieve this, we employ meridional and zonal wind speed and sea level pressure from simulations of LIG and PI climate with a global climate model to force a global hydrodynamic model to simulate the extreme water levels along coastlines resulting from storm surges.

## 2 Methods

### 2.1 Climate simulations

The LIG and PI climates are simulated with the state-of-the-art coupled climate model CESM, version 1.2 (Hurrell et al., 2013). The model includes the Community Atmosphere Model (CAM5), Community Land Model (CLM4.0), the Parallel Ocean Program (POP2.1), and the Community Ice Code (CICE4). We use a horizontal resolution of 95  $0.93^\circ \times 1.25^\circ$  in the atmosphere (30 vertical levels and a finite volume core) and land, and a nominal  $1^\circ$  resolution in the ocean (60 vertical levels) and sea-ice models with a grid reflecting a displaced North Pole. Both the LIG and PI experiments are an equilibrium simulations. The LIG simulation represents conditions at 127 ka, the timing of maximum positive anomaly in Northern Hemisphere insolation. It is forced with changes in atmospheric greenhouse-gas values (275 ppm  $\text{CO}_2$ , 685 ppb  $\text{CH}_4$  and 255 ppb  $\text{N}_2\text{O}$ ) and in the orbital parameters (eccentricity = 100  $0.039378$ , obliquity =  $24.040^\circ$  and perihelion – 180 = 275.41), following Otto-Bliesner et al. (2017). The PI simulation includes greenhouse and orbital forcing of AD 1850. All other boundary conditions, such as the land-sea mask, continental ice sheets, and vegetation are the same in the PI and LIG simulations. From the last 20 years of multi-centennial equilibrium simulation of the PI and of the LIG, we save 6-hourly values of sea-level pressure and 105 of zonal and meridional wind speed at 10 m elevation, i.e.,  $u_{10}$  and  $v_{10}$ . These values constitute input in the next modeling step.

### 2.2 Hydrodynamic simulations

We use the atmospheric outputs from the climate model to force the Global Tide and Surge Model Version 3.0 (GTSMv3.0). GTSM is a depth-averaged hydrodynamic model with global coverage. The model uses the Delft3D 110 Flexible Mesh software (Kernkamp et al., 2011), and has a spatially varying resolution that ranges from 50 km in the deep ocean to 2.5 km along the coast. The Charnock (1955) relation with a drag coefficient of 0.0041 is used to estimate the wind stress at the ocean surface. A combination of different datasets is used for the bathymetry: EMODnet at 250 m resolution around Europe (Consortium\_EMODnet\_Bathymetry, 2018) and the General Bathymetric Chart of the Ocean with 30 arc seconds resolution for the rest of the globe (GEBCO, 2014). The bathymetry under the permanent ice shelves in Antarctica is represented by Bedmap2 (Fretwell et al., 2013). For 115 further details, see Muis et al. (2020) and Wang et al. (2021). We execute GTSM including only storm-surge processes and exclude astronomical tidal forcing. Time series of surge levels are stored at a 10-minute temporal

120 resolution for 23,815 output locations. This set of locations was developed by Muis et al. (2020), and includes  
output every 25-50 km along the global coast. We note that results in the extra-tropical latitudes must be considered  
more reliable than in the tropics. This is because the spatial resolution of the climate forcing does not allow GTSM to  
simulate tropical cyclones with realistic frequency and magnitude (Roberts et al., 2020).

### 2.3 Analysis

125 In the analysis of the modeling results, we consider seasons separately, except otherwise noted: December-January-  
February (DJF), March-April-May (MAM), June-July-August (JJA), and September-October-November (SON). To  
adequately compare seasonal results between the LIG and PI periods, we account for the effect of changes in the  
earth's orbit across geological time upon the definition of seasons, and we apply the angular (i.e., celestial)  
definition of calendar (Bartlein and Shafer, 2019). For variables from the climate model simulations - sea level  
pressure, meridional and zonal wind speed, absolute wind speed - we calculate the climatological average and the  
seasonal maxima and minima of values sustained for 1-day, 2-days, 3-days and 5-days. To obtain a proxy of surface  
130 storminess, we calculate eddy kinetic energy (EKE) from the zonal (u) and meridional (v) wind speeds at 10 m, by  
filtering out frequencies outside of the 2.5-6 day interval with a Butterworth passband filter, as in, e.g., Pfliegerer et  
al. (2019). From the value of sea levels resulting from storm surges along the global coastline, we subtracted values  
of the local sea level averaged across the whole PI and LIG simulations, as these are slightly different between  
simulations (Fig. S1). We then calculate extreme values of sea levels for several return periods (from 2-year to 20-  
135 year), based on seasonal maxima of daily maxima. The calculation of extreme values of sea levels for different  
return periods is based on the Weibull formula for plotting positions (e.g., Makkonen, 2006):

$$RP = (n+1)/m \quad (1)$$

Where  $RP$  is the return period (in years) of the event with rank  $m$  in the ordered annual/seasonal maxima time series  
of length  $n$ . We do not fit extreme value distributions to the maxima and extrapolate values along fitted curves. This  
140 approach is adequate since we only consider anomalies in return periods from 2-year to 20-year, a period which is  
encompassed by the length of our time series.

To estimate the uncertainty around the estimated values for the various return periods of sea level extremes, we use  
bootstrapping with 599 repetitions to obtain the 5% and 95% confidence bounds (Wilcox, 2010).

## 145 3 Results

### 3.1 Atmospheric variables

The most notable anomalies in sea level pressure between the LIG and the PI climate simulations occur during JJA  
(Fig. 1). Both seasonal mean and seasonal minimum LIG values are then much lower over Northern Africa, Europe,  
Central and Northern Asia, and secondarily over Northern America; and much higher over the northernmost sector

150 of the Pacific Ocean. Across all seasons, seasonal LIG minima of sea level pressure deviate from the PI more strongly than seasonal means of sea level pressure.

In the LIG climate simulation, the boundary between westerly and easterly winds of the boreal mid-latitudes slightly shifts poleward during JJA (Fig. S2). Conversely, it shifts equatorward during DJF. Further, LIG equatorial easterlies during JJA are weaker over the Atlantic and stronger over the western Pacific Ocean sectors. Meridional  
155 wind patterns show that LIG Atlantic circulation is on average more zonal during JJA, and slightly less zonal during DJF (Fig. S3). Several other seasonal anomalies in zonal and meridional winds speed emerge that we do not mention here.

Atmospheric storminess, as portrayed by EKE, is strongest over the Southern Ocean and oceanic sectors to its north, over the northern Pacific and Atlantic Oceans, and over the Arctic Ocean, with substantial seasonal differences.  
160 While these broad patterns apply both to the LIG simulation (Fig. 2A) and to the PI simulation (not shown), strong seasonal anomalies in EKE emerge over oceanic sectors adjacent to coastal areas, where anomalies have potential implications for extreme sea levels. These are mainly the extratropical north Atlantic Ocean, the northwestern and northeastern Pacific Ocean, the southern Indian Ocean, and the southeastern Atlantic Ocean.

### 3.2 Sea level extremes

165 In the following, we present and discuss sea level extremes due to storm surges, modeled with GTSM, at the return period of 10-year as generally representative of extremes at return periods between 2-year and 20-year (shown in Fig. S4-S6). In both simulations of the LIG (Fig. 3) and of the PI (not shown), the highest values of extreme sea levels are reached at the coast of Northern Europe, northern North America, northern Asia, and at the Gulf of Carpentaria in northern Australia (especially during DJF and MAM), of Patagonia and, secondarily, of southern  
170 Australia (especially during MAM and JJA) and of the northern Persian Gulf (especially during JJA and SON). The high values in these regions are linked to the presence of a wide and shallow continental shelf combined with the season of higher storminess.

Figure 4 maps the significant anomalies in sea level extremes, expressed both in absolute value and as a percentage. Anomalies are significant at the 95<sup>th</sup> confidence level in 8.5% of locations for DJF, in 9.6% for MAM, in 29.5% for  
175 JJA, in 8.4% for SON. Annual anomalies are significant in 9.9% of locations (Fig. 5). Considerably higher LIG surge levels, i.e., positive anomalies, emerge: in the area of the Gulf of Carpentaria (northern Australia) and parts of Indonesia, with anomalies around +0.6 m during DJF; the Mediterranean Sea and northern Africa, with anomalies up to +0.2 m during JJA, representing about +100% increase from PI values; around the area of the Gulf of Saint Lawrence in northeast America with MAM anomalies that reach +0.4 m, corresponding to about +50%; at the  
180 Persian Gulf, with JJA anomalies up to +0.5 m, corresponding to +80%; at the coast of Pakistan and northwest India, with SON anomalies up to +0.4 m, corresponding to more than +100%. Considerable negative anomalies are found: at the Baltic and North Seas, with anomalies around -0.3 m, with the most profound decrease during DJF; at the Bay of Bengal, with DJF anomalies reaching -0.4 m, corresponding to -80%; at the coast of China and Vietnam, with JJA anomalies reaching -0.5 m, corresponding to around -60%. Across a large number of islands of the Pacific

185 Ocean and of the Caribbean, significant anomalies are modest in absolute values, but reach around +100% during DJF and MAM over the Pacific, +60% during JJA over the Caribbean, and -50% during JJA, albeit in different ocean sectors.

### 3.3 Correspondence between anomalies in atmospheric variables and sea level extremes

190 Our results reveal widespread coherence between anomalies of atmospheric storminess and of sea level extremes at the coast (Fig. 2 and 4). Typically, higher LIG EKE values coincide with higher LIG sea level extremes in adjacent coastlines, and conversely. During DJF, lower LIG EKE values coincide with lower LIG sea level extremes: over a vast area of the Norwegian, North and Baltic Seas, over the western North Atlantic, Gulf of Mexico and the Caribbean Sea, and over the Bay of Bengal. Conversely, higher LIG EKE values coincide with higher LIG sea level extremes over the area of the Indonesian archipelago and northern Australia. During MAM, higher LIG EKE values  
195 coincide with higher LIG sea level extremes: over the western North Atlantic, over the western South Atlantic, over parts of the tropical western Pacific Ocean. During JJA, higher LIG EKE values coincide with higher LIG sea level extremes: in the Indian Ocean sector around southeastern Africa and Mozambique, over the northeastern sector of the Pacific Ocean, over parts of the northern Indian Ocean, the Persian Gulf, Red Sea and parts of the Mediterranean Sea. Conversely, lower LIG EKE values coincide with lower LIG sea level extremes over the northeastern and  
200 western sectors of the northern Pacific Ocean. During SON, higher LIG EKE values coincide with higher LIG sea level extremes: in the Indian Ocean sector around southeastern Africa and Mozambique, over parts of Indonesian archipelago and in parts of the Caribbean Sea. Conversely, lower LIG EKE values coincide with lower LIG sea level extremes over parts of the South and East China Sea, and over parts of northwestern Europe.

Coherence between anomalies of sea level pressure and of sea level extremes. Across seasons, negative LIG  
205 anomalies of minima of sea-level pressure often correspond with sea-level extremes higher in the LIG than in the PI (Fig. 1B and 4). This holds true: during JJA, over the Mediterranean, northern Africa and Arabian Peninsula, the eastern coast of North America, the Caribbean Islands, the Persian Gulf, Mozambique and Madagascar; during MAM, over the area of the Gulf of Saint Lawrence; and, during DJF, over northern Australia and Indonesia. Conversely, lower LIG sea-level extremes often coincide with areas where LIG seasonal pressure minima are  
210 higher. There are clear deviations from this anti-correlation: e.g., during JJA, over northern Europe; during SON, at the coast of Pakistan and northwest India; during JJA, over parts of the eastern Indian Ocean and Indonesia.

Clear links do not emerge between anomalies of zonal or meridional wind speeds and of sea level extremes. As an exception, during JJA, the latitudinal position of maximum intensity of the LIG easterlies over the Caribbean Sea shifts northwards, coinciding with higher LIG sea level extremes.

215

## 4 Discussion

In some regions, sea level extremes from storm surges in the LIG and PI climates generally differ from those modeled for the recent decades by Muis et al. (2016), based on climate reanalysis (Fig. S7): they are higher than the

220 recent decades in Patagonia, in the Gulf of Carpentaria, and they are lower than recent decades at some coasts of  
South Asia. Anomalies between LIG and PI are larger than between projected warmer climate of the late 21<sup>st</sup>  
century and the recent decades, as modeled by Muis et al. (2020) and Vousdoukas et al. (2018). Nevertheless, the  
validity of a comparison with those studies is limited by differences in the climate models and reference climate  
benchmarks employed, such that it is not possible to separate the effect of differences in climate forcing and of  
different models. More in general, a comparison of surges between the LIG and possible futures has to take into  
225 account fundamental differences in the forcing of the two climates: the LIG deviates from the PI due to higher  
boreal summer insolation, and the future deviates from the PI and the modern climate due to higher greenhouse gas  
concentration. On the other hand, spatial patterns of warming during JJA in the Northern Hemisphere are similar  
across simulations of the LIG and of warmer futures, as evident from the fact that boreal summer sea surface  
temperature patterns in the LIG simulation somewhat resemble those of the projected futures (Fig. S8). A qualitative  
230 comparison of results for the summer of the Northern Hemisphere is therefore meaningful. It is important to note, in  
this context, that it is during JJA that the largest values are reached in anomalies of temperature (Fig. S8; see also  
Otto-Bliesner et al. (2021)), and also of sea level extremes (Fig. 4), when anomalies are significant in three times as  
many locations as for the other seasons (29.5% of locations).

#### 4.1 Implication for paleo sea level proxies

235 Our results have implications also on the interpretation of certain geological facies that are used to reconstruct LIG  
relative sea level, i.e., the local absolute elevation of paleo sea level, still uncorrected for post-depositional effects  
such as due to Glacial Isostatic Adjustment and tectonics. Reconstructions of paleo relative sea level from field data  
often use the uniformitarianism approach, i.e., the assumption that processes acted essentially with the same  
intensity in the past as they do in the present (Lyell, 1830). In the practice of sea level reconstruction, this concept  
240 often entails using modern analogs to calculate the relationship between the measured elevation of a paleo relative  
sea level proxy and the paleo sea level. Different levels attained by storm surges in the LIG might affect the  
interpretation of wave-built relative sea level proxies such as beach deposits or beach ridges. Beach ridges are  
widespread along the Atlantic coasts of South America (Patagonia) and the Gulf Coast of the U.S. (Gowan et al.,  
2021; Simms, 2021). In our models, both areas show variations in the order of up to a few tens of centimeters in the  
245 LIG annual sea level extremes, which do not reach statistical significance (Fig. 5). LIG beach deposits are instead  
widely distributed globally, and our results contain annual anomalies that reach multiple tens of centimeters at  
several other locations, e.g., in the Western Mediterranean (Cerrone et al., 2021). We surmise that it may be possible  
that, at these locations, the uniformitarianism principle may not be directly applicable to beach deposits and beach  
ridges. For proxies correlated to LIG extreme storm deposits, like those reported in Bermuda and the Bahamas  
250 (Hearty, 1997; Hearty et al., 1998; Hearty and Tormey, 2017), our results may help disentangle in which areas it  
may be of interest to combine our storm surge models with wave modeling, to unravel whether higher surges may  
have also been coupled with higher waves.

#### 4.2 Limitations and future research

It is known that the modelling of extreme sea levels based on global climate models is prone to large spatial biases (Muis et al., 2020). While regional studies have attempted to correct for such biases (Marsooli et al., 2019), global studies have not. However, if we assume biases to equally affect the PI and the LIG simulations, the anomalies between results based on the two simulations, which we report here, should not be impacted by the presence of biases. Nevertheless, there are considerable uncertainties associated with the meteorological forcing that we use here, and there are several research directions that could be explored in future research. First, the resolution of the CESM1.2 model, although high in the context of state-of-the-art GCMs, is not fully storm-resolving. Higher resolution would improve spatial gradients in pressure and wind speeds, and much increase the representation of tropical storms. Second, the length of the GCM simulations (20 years) is relatively short for assessing changes in the probabilities of extremes, especially on account of the large internal variability. Increasing the length of the simulations would make the detection of changes in extreme value statistics more robust. Third, future research should account for the model bias and uncertainty by performing hydrodynamic simulations based on an ensemble of climate models, such as the ensemble of LIG experiments analyzed in Otto-Bliesner et al. (2021). Higher confidence could be placed on anomalies in LIG storm surges that emerge as robust across the ensemble.

An important assumption that underlies our analysis is that we only consider climatic changes and do not account for changes in mean sea level that originate from different extents of polar ice sheets and from steric processes. The generation of a storm surge is influenced by changes in bathymetry, coastal geometry, and geomorphic features such as river deltas, barrier islands, and bays, which all interact and can modulate the height of the storm surge (Islam et al., 2021). Moreover, storm surges are influenced by variations in water depth as well as the sea-air momentum exchange, and as such they can be modulated by (non-linear) interaction effects with tides and waves (Idier et al., 2019). This has been shown in regional studies that use fully coupled hydrodynamic models, such as Arns et al. (2017). At the global scale, interaction effects are typically excluded and considered to be negligible compared to the other sources of uncertainty (Dullaart et al., 2020; Vousdoukas et al., 2018), although Arns et al. (2020) have used statistical modelling to show that interaction effects can modulate extreme sea levels. The starkly different climate of the LIG, however, warrants exploration of this set of interactions, which could be accomplished by: 1) including LIG mean sea level anomalies such as resulting from a GIA modeling approach and from inclusion of steric effects and changes in ocean circulation; 2) running GTSM simulations, with inclusion of such mean sea level anomalies with activation of the tidal component of the model; and 3) including wave modeling, globally or for specific regions of interest. This is computationally expensive, but it seems like the near-ideal approach to investigate drivers behind observed changes at key paleo sea level indicators sites.

#### 5 Conclusions

We report the first results of simulations of storm surge under climatic conditions representing the Last Interglacial and the pre-industrial periods. These reveal that a naturally (orbitally) forced warmer climate implies significant seasonal and annual anomalies in sea level extremes along the coastline of many global areas. Those anomalies can be linked to changes in patterns of atmospheric storminess in our climate simulations. For some locations, anomalies

of sea level extremes reach multiple tens of centimeters, and are considerable in terms of percentage change. These  
290 insights can inform the interpretation of existing and upcoming future paleo sea level indicators. Lastly, we suggest  
research avenues to improve the realism of modeled sea level extremes for the LIG by including other relevant  
processes in the modeling framework.

#### Author contribution

PS, SM, AR, PJW and JCJHA designed the study. PB carried out the climate model simulations. JD and SM carried  
295 out the hydrodynamic simulations. PS and JD processed and analyzed the datasets. PS prepared the figures. PS, SM  
and AR lead the writing of the manuscript. All authors contributed to the interpretation of results and writing of the  
manuscript.

#### Competing interests
