10 **Abstract**

11 Coastal flooding is driven by both high tides and/or storm surge, the latter being caused by strong
12 winds and low pressure in tropical and extratropical. The combination of storm surge and the
13 astronomical tide is defined as the storm tide. To gain understanding into the threat imposed by
14 coastal flooding and to identify areas that are especially at risk, now and in the future, it is crucial to
15 accurately model coastal inundation and assess the coastal flood hazard. Most models capable of
16 simulating coastal inundation at the global scale follow a simple planar approach, often referred to as
17 bathtub models. The main limitations of this type of model are that they implicitly assume an infinite
18 flood duration and do not capture relevant physical processes. In this study we develop a method to
19 generate hydrographs called HGRAPHER, and provide a global dataset of storm tide hydrographs.
20 These hydrographs represent the typical shape of an extreme storm tide at a certain location along
21 the global coastline. We test the sensitivity of the HGRAPHER method with respect to two main
22 assumptions that determine the shape of the hydrograph, namely the surge event sampling threshold
23 and coincidence in time of the surge and tide maxima. These hydrographs can be used to move away
24 from planar to more advanced dynamic inundation modelling techniques at large scales.

25 **1 Introduction**

26 Over the course of the 21st century, coastal populations will be increasingly at risk of flooding due to
27 sea level rise (SLR) (Oppenheimer et al., 2019). In addition, as a result of increasing exposure, the
28 number of people living in coastal areas below 10 m elevation worldwide is projected to increase from
29 over 600 million people today to more than 1 billion people by 2050 under all Shared Socioeconomic
30 Pathways scenarios (Merkens et al., 2016). Global flood models can inform risk assessments that help
31 to identify which areas are potentially exposed to flooding under both current and future climate
32 conditions (Ward et al., 2015). Coastal flooding is generally driven by strong winds and low pressure
33 in tropical (TCs) and extratropical cyclones (ETCs), which generate a storm surge (Resio and Westerink,
34 2008). The combination of storm surge and the tide is defined as the storm tide (Colle et al., 2010).
35 Flood models can be used to model coastal inundation resulting from extreme storm tides.

36 Coastal inundation models have varying levels of complexity. Global models generally follow a simple
37 planar approach (Brown et al., 2018; Dullaart et al., 2021a; Kirezci et al., 2020; Lincke and Hinkel, 2018;
38 Muis et al., 2016). These models, often referred to as bathtub models, assume that any land that is
39 below a specific static water level and that is connected to the sea will be inundated. The main
40 limitation of the planar approach is that it assumes an infinite flood duration and does not capture the
41 physical hydrodynamic processes (e.g. temporal evolution of a storm surge) that drive coastal

42 flooding. This can be partly addressed by accounting for water-level attenuation (Vafeidis et al., 2019;
43 Haer et al., 2018; Tiggeloven et al., 2020). Local to regional-scale models generally apply a
44 (hydro)dynamic modelling approach that captures the physical processes that drive flooding (Lewis et
45 al., 2013; Pasquier et al., 2019; Vousdoukas et al., 2018). Model comparisons at regional scale have
46 shown that in terms of flood extent and depth the dynamic modelling approach is more accurate than
47 the planar approach. Generally, the planar approach overestimates the flood extent due to the
48 assumption that flood propagation is only limited by topography, and that high water levels are
49 maintained for an infinite duration (Stephens et al., 2021). The main reasons for applying the planar
50 approach at the global scale, instead of the dynamic approach, are the simplicity of setting up a planar
51 model, low computational costs, and limited requirements for input data.

52 Due to the advances in high-performance computing and the development of reduced-physics
53 dynamic inundation models (Leijnse et al., 2021; Yin et al., 2016; Bates et al., 2010), there is the
54 potential to improve global flood mapping and step away from using the planar approaches for global
55 coastal inundation modelling. However, global flood maps are often derived for a specific return
56 period (RP), for example a flood map corresponding to the 1 in 100-year water level. While planar
57 models only need information about the height of the extreme water level, dynamic models also need
58 information about the duration. The temporal evolution of an extreme water level, composed of tide
59 and surge, is referred to as the hydrograph (Chbab, 2015; Sebastian et al., 2014; Salisbury and Hagen,
60 2007). Throughout this study we use the term hydrograph to refer to the storm tide hydrograph.
61 Hydrograph characteristics that determine the flood severity are, among others, the maximum storm
62 tide level, base duration, and overall shape. For example, when the water level is elevated for a longer
63 period of time the water will propagate further inland. Currently, a global dataset of hydrographs that
64 can be applied for dynamic inundation modelling for specific RPs is lacking. Vousdoukas et al. (2016)
65 made a first step towards dynamic inundation modelling at the continental-scale for Europe. In this
66 study, the temporal evolution of extreme water levels is incorporated by the use of a generic empirical
67 formulation. The surge hydrograph is assumed to be an isosceles triangle with a duration based on a
68 linear fit relationship between modelled surge heights and the half event duration. In reality the rising
69 and falling limb of the surge hydrograph can have a distinct shape that have different durations, and
70 varies from location to location (MacPherson et al., 2019). The tidal component is represented by
71 taking the highest tidal level from a 10-year period. Instead, a time-varying value could be used to
72 include tidal variation, including the spring-neap cycle, in a more accurate way. While some advances
73 have been made in modelling storm tide hydrographs, the current understanding of the temporal
74 evolution of sea levels during extremes is limited.

75 The aim of this study is to address this research gap by developing and applying a globally-applicable
76 method (HGRAPHER) to generate hydrographs. In doing so, we pave the way for global coastal flood
77 mapping using dynamic models. First, we review the various methods available to define a hydrograph
78 and their main assumptions. Second, building on the literature, we present the new open-source
79 HGRAPHER method with a global dataset of hydrographs for 23,226 locations along the world's
80 coastline. As input, we use storm surge and tide simulations (1979-2018) from the Global Tide and
81 Surge Model (GTSM) forced with the ERA5 climate reanalysis (Muis et al., 2020). Third, the sensitivity
82 of the HGRAPHER method is tested with respect to two main assumptions that determine the shape
83 of the hydrograph, namely: 1) using normal high tide or spring tide; and 2) the coincidence of the surge
84 and tide maximum or a time offset between the two maximums. Last, we discuss the limitations of
85 our methodology and ways forward.

86 2 Available methods to generate hydrographs

87 In this section we give an overview of four hydrograph generating methods. The reason for including
 88 these studies on hydrographs in this review, from the wide variety of studies that exists on this topic,
 89 is that they all have a clearly distinct methodology. Based on this review, we can select the hydrograph
 90 generating method that best fits our study goals. All four methods use multi-year water level time
 91 series from tide gauge stations or model simulations as input, but they differ in terms of input
 92 parameter used, the way the surge hydrograph is computed, and how tide and surge levels are
 93 combined. Table 1 summarizes the main characteristics of the four methods.

94 **Table 1:** Main characteristics of four hydrograph methods

study	study area	hydrograph method		
		input parameter	surge hydrograph	combine tide and surge
Chbab, 2015	Dutch coast	surge residual	averaging	linearly
Environment Agency, 2018	United Kingdom coast	skew surge	fit distribution	joint probability method
MacPherson et al., 2019	German Baltic Sea coast	storm tide	parametric	not required
Vousdoukas et al., 2016	European coast	surge and wave setup	best linear fit relationship	constant value for tide

95
 96 The first method by Chbab (2015) starts by computing the residual water level. The surge residual is
 97 the difference between the predicted tide and the storm tide level (*Fig. 1*). Predicted tides are
 98 estimated by harmonic analyses to determine the amplitude and phase of the different tidal
 99 constituents. To define the surge hydrograph, events are selected from the residual time series by
 100 means of the Peaks-Over-Threshold (POT) method using 0.5 m as a threshold. The 36-hour period
 101 before and after the surge maximum is extracted. The final step to obtain the surge hydrograph is
 102 normalizing and averaging all 72-hour time series of surge levels. The surge hydrograph is added
 103 linearly to the average tidal cycle where the surge maximum is assumed to coincide with the tide
 104 maximum. To generate a hydrograph corresponding to a specific RP, the unitless surge hydrograph is
 105 scaled to a certain water level. For example, if the average maximum tide is 1 metre and the 100-year
 106 storm tide is 3 metres, the surge hydrograph is multiplied by 2. In areas with a large tidal range and a
 107 wide and shallow continental shelf, tide-surge interaction may induce a time offset between the two
 108 maxima (*Fig. 1*). For example, in the North Sea the surge maximum generally occurs 2.5 hours before
 109 the tidal maximum (Chbab, 2015; Horsburgh and Wilson, 2007). This is because a storm surge
 110 increases the depth and thereby modulates the influence of bottom friction and the speed of the tidal
 111 wave (Pugh, 1996; Rego and Li, 2010). The time offset can be taken into account by computing the
 112 time offset between the surge and tidal maxima for all surge events above the POT 99th percentile
 113 (POT99). Subsequently, the average offset is used to shift the surge time series relative to the tidal
 114 maximum.

115

Figure 1: schematic of the residual, offset, and skew surge. Time series of the tide (grey line), and the tide including meteorological effects (black line) are shown.

116 The second method, developed by the U.K. Environment Agency (2018) starts by computing the skew
 117 surge. Skew surge (Fig. 1) refers to the difference between the maximum storm tide level and
 118 maximum tidal level within a tidal cycle, irrespective of their timing (Williams et al., 2016). An
 119 important reason for using skew surge instead of the surge residual is that the latter can arise due to
 120 tide-surge interaction (Idier et al., 2019). In contrast to the surge residual, for the skew surge there is
 121 no need to account for timing offsets. To generate the skew surge hydrograph, the 15 most extreme
 122 skew surges are selected. Both the high and low water skew surge values are extracted for each storm
 123 event. Subsequently, the high and low water skew surge values are interpolated to a 15-minute
 124 timeseries and normalized. Then, the duration of each of the 15 surges at particular percentiles (i.e.
 125 10%, 20% and so on) are calculated. The maximum duration at each percentile is used to compute the
 126 skew surge hydrograph. The study by U.K. Environment Agency does not combine the skew surge
 127 hydrograph with tidal level time series.

128 The third method by MacPherson et al. (2019) starts by identifying storm tide events. To do this, a
 129 POT method is used. Using POT is preferred over annual maxima because the number of events
 130 extracted is typically higher with POT resulting in a more robust representation of the local storm tide
 131 characteristics in the hydrograph. Then, each event is characterized through a parameterization
 132 scheme. A total of 17 parameters are calculated such as peak water level, event duration, and the flow
 133 (rising limb) and ebb (falling limb) curve shape. Subsequently, synthetic hydrographs are generated
 134 through Monte Carlo simulations using the obtained parameters. This means that for a single return
 135 period multiple storm tide hydrographs are available with different shapes but the same maximum
 136 water level.

137 The fourth method by Vousdoukas et al. (2016) starts by computing the high tide water level (HTWL).
 138 The HTWL is calculated as a constant water level that consists of the mean sea level (MSL) and the
 139 maximum tide elevation taken from a 10-year time series. The HTWL is then combined with time-
 140 varying storm surge levels and wave setup to obtain total water levels. Time series of storm surge
 141 levels (1979-2014) are taken from Vousdoukas et al. (2016b) and wave setup is approximated by 20%
 142 of the significant wave height, both based on the ERA-Interim global climate reanalysis (Dee et al.,
 143 2011). To obtain information about the temporal evolution of an extreme event, extreme events are
 144 identified in the available time series of surge and wave setup. For each identified event the duration
 145 and peak water level are extracted. Subsequently, a best linear fit relationship between the duration
 146 and peak water level is estimated. To conclude, the combined hydrograph consists of the HTWL
 147 combined with a symmetric triangle shaped time series on top of it representing the surge and wave
 148 setup for a certain return period.

149 Comparing the four methods, we find that the hydrograph generating methods that are developed for
150 application at smaller scales are tailored towards the local water level characteristics. This makes them
151 less suitable for application at larger scales. For example, in the study by Chbab (2015) a threshold of
152 0.5 m is used to identify extreme surge events in time series. However, at the global scale surge levels
153 exceeding 0.5 m do not occur in some regions such as the south of the Caribbean. The hydrograph
154 generating method developed by U.K. Environment Agency (2018) is developed for regions that
155 experience a substantial tidal range such as the U.K., as it is based on skew surge values. However, the
156 complete global coastline does not experience such high tides. In addition, MacPherson et al., (2019)
157 developed a method that is applicable in areas with a small tidal range, making it well suited for the
158 German Baltic Sea coast but inapplicable at larger scales. The last study that we discussed (Vousdoulas
159 et al., 2016a) takes a more simple approach to define hydrographs for continental Europe. The tidal
160 component is represented by a constant value and is combined with a triangle shaped time-varying
161 storm surge. Overall, the study by Vousdoulas et al. (2016a) is a step towards modelling inundation
162 at larger scales using hydrographs. However, substantial improvements can be made to the
163 hydrograph generating method. To this end, we will build on Chbab (2015) because, most importantly,
164 the method used in this study does take a time-varying surge and tide component into account. In
165 addition, instead of representing the surge by a triangle shape in the combined hydrograph like
166 Vousdoulas et al. (2016a), the method from Chbab (2015) allows the rising and falling limb of the
167 hydrograph to have different shapes. This results in a more accurate representation of the shape of
168 the storm surge in the combined hydrograph.

169 3 Methods

170 Figure 1 summarizes the main steps of the HGRAPHER hydrograph generating model. Storm tide
171 levels, tidal time series, and storm tide RPs are used as input. First, extreme events are identified in
172 the surge time series and used to compute a normalized surge hydrograph. Second, the average tide
173 signal is computed from the tidal time series. Third, the hydrograph is generated by combining the
174 average tide signal with the normalized surge hydrograph. To create the final hydrograph, this generic
175 shape is scaled to an absolute water level height for specific RPs based on the COAST-RP dataset
176 (Dullaart et al., 2021b).

177 3.1 Input data

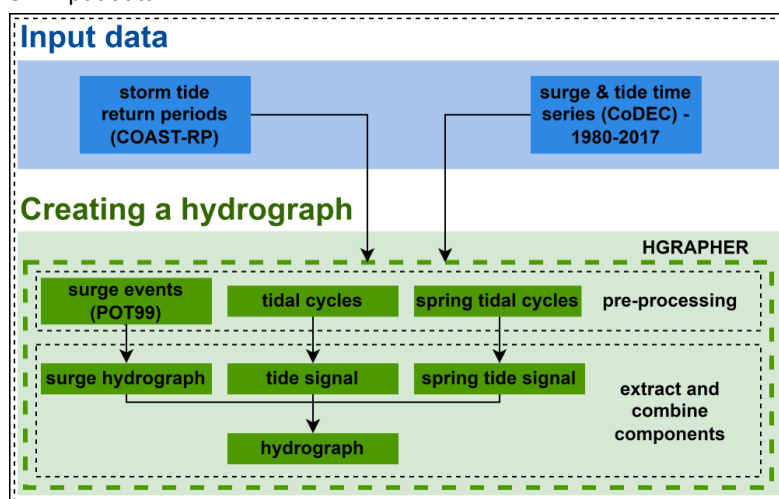

Figure 2: Modelling framework

178 Time series of storm tides (1980-2017) at a 10-minute interval from 23,226 output locations are taken
179 from the CoDEC-ERA5 dataset (Muis et al., 2020). The CoDEC-ERA5 dataset was generated by forcing
180 the 2D depth-averaged hydrodynamic Global Tide and Surge Model (GTSM) with wind and pressure
181 fields from the ERA5 climate reanalysis (Hersbach et al., 2019). GTSM forced with ERA5 has shown to
182 accurately simulate surge heights of historical TC and ETC events (Dullaart et al., 2020). In addition, a
183 comparison between modelled and observed annual maxima, showed a mean bias of -0.04 m (with a
184 standard deviation of 0.32 m) (Muis et al., 2020). Overall, the time series of surge and tidal levels from
185 the CoDEC-ERA5 dataset are of good quality and therefore valid input data to HGRAPHER. The surge
186 time series are computed as the difference between a storm tide simulation and a tide-only
187 simulation. As a result, the surge time series include non-linear tide-surge interaction effects
188 (Horsburgh and Wilson, 2007). The output locations are located at every 50 km along the coastline. In
189 addition, the locations of tide gauge stations are included. In order to scale the hydrograph to a storm
190 tide level that corresponds with a certain RP, we use storm tide RPs from the global COAST-RP dataset
191 (Dullaart et al., 2021b). In contrast to other global storm tide RP datasets, COAST-RP explicitly takes
192 into account low-probability high impact TCs (Dullaart et al., 2021a) by making use of 3,000 years of
193 synthetic TC tracks from the STORM dataset (Bloemendaal et al., 2019).

194 3.2 Creating a hydrograph

195 3.2.1 Surge hydrograph

196 The following procedure is used for each of the 23,226 output locations individually. To generate a
 197 hydrograph of the surge, we start with extracting independent extremes from the surge time series
 198 based on the Peaks-Over-Threshold (POT) method. Using the POT method for selecting extremes is
 199 preferred over annual maxima as the latter could result in excluding extreme events that happened in
 200 the same year. We use the 99th percentile over the complete time series as threshold and we select
 201 peaks that are at least 72 hours apart to ensure independent events (Wahl et al., 2017; Vousdoukas
 202 et al., 2016b; Haigh et al., 2016). The threshold results in the selection of on average 1 surge event per
 203 year and 40 events over the full time series. Setting the threshold is a trade-off between having an
 204 event set of sufficient size to compute a representative average shape without including too many
 205 relatively small surge events that would too strongly affect the resulting shape (see section 4.4). For
 206 each selected surge event, we first extract the time series from 36 hours before, until 36 hours after
 207 the peak (Fig. 3a). Second, each 72-hour surge event is normalized such that the maximum surge value
 208 is equal to 1 (unitless). Third, we combine the selected surge events to calculate the average surge
 209 hydrograph. This is done by determining the time (relative to the peak) at which a specific surge height
 210 (from 0 to 1 with increments of 0.01) is exceeded. As an example, in Fig. 3a we show that for one surge
 211 event the exceedance time at a normalized surge height of 0.25 is 14.0 hours before and 26.0 hours
 212 (16.0 + 10.0) after the surge maximum occurred as indicated by the black arrows. Then, for each
 213 normalized surge height the average exceedance time is computed, similar to Chbab (2015), resulting
 214 in an average curve. Because the shape of the rising and falling limb of the surge can differ, the
 215 exceedance time is calculated separately for each, and they are subsequently merged into the final
 216 average surge hydrograph.

217

218 3.2.2 Average and spring tide signal

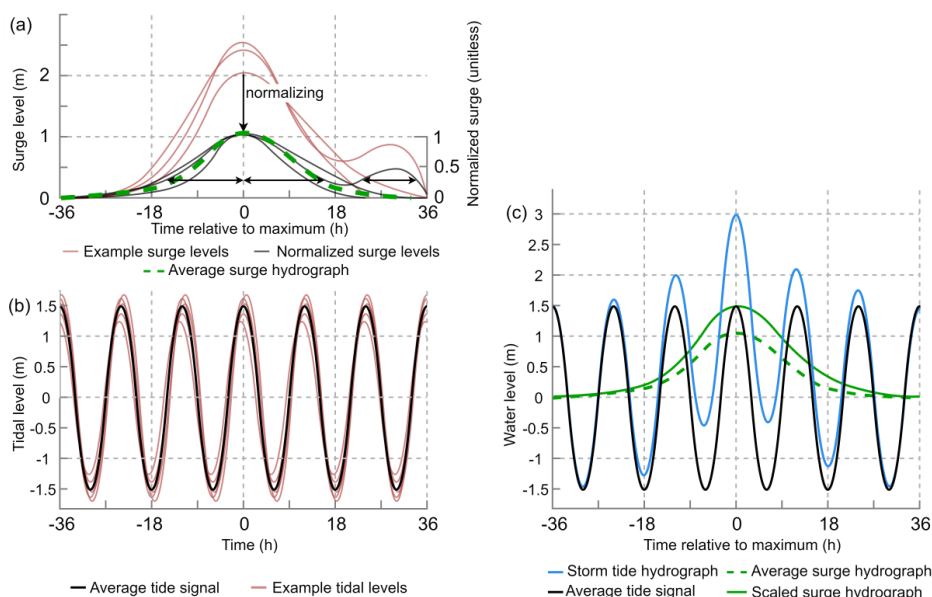

Figure 3: Visualization of the steps leading to the storm tide hydrograph of a hypothetical 1-in-100 year event of 3.0 m with the a) surge hydrograph, where the black arrows indicates the period over which a normalized surge height of 0.25 is exceeded. Note that for the falling limb we take the sum of the two time periods for which this is the case; b) average tide signal, and c) storm tide hydrograph. The average surge hydrograph is scaled to 1.5 m such that the combined water level equals the 1-in-100 year storm tide level of 3.0 m.

219 Next, we combine the surge hydrograph with the average tide signal (*Fig. 3b*). To create a curve
220 representing the average tide, we extract all tidal cycles of 24 hours and 50 minutes from the period
221 1980-2017. The start and end times of the tidal cycles are selected from the tide time series by
222 searching for a minimum around 24h and 50 minutes after the previous low tide. Last, we compute
223 the mean over all tidal cycles to extract the average tide signal.

224 In addition, we extract the spring tide signal because a storm surge event happening at spring tide can
225 result in a very different shape of the hydrograph. The spring-neap tide cycle takes two weeks. To
226 extract the average spring tide signal, we first search for the highest tide every two weeks. Second,
227 we select 72 hours of the tidal time series before and after the spring tide maximum. This procedure
228 is repeated for the available time series of the tide (1980-2017), after which we compute the mean
229 over all spring tides to extract the average spring tide signal.

230 3.2.3 Storm tide hydrograph

231 The surge hydrograph is combined with the average tide or spring tide to create a storm tide
232 hydrograph (*Fig. 3c*). In theory the surge maximum can coincide with any tide. However, in shallow
233 regions the timing will be influenced by interaction effects between the surge and the tide which
234 results in a phase difference. This is for example the case in the North Sea where the tidal wave will
235 start travelling faster under storm conditions due to the increased water level which reduces the
236 bottom friction (Horsburgh and Wilson, 2007; Resio and Westerink, 2008). To determine whether a
237 typical time offset between the surge and tide should be taken into account, we extract the
238 distribution of the timing offset between the surge and tidal maximum during the most extreme surge
239 events (POT99). For most locations around the globe, the distribution of the timing offset does not
240 show a clear signal (see section 4.4). Therefore, we assume that the surge and tidal maximum coincide.
241 With HGRAPHER a hydrograph can be generated for a total water level of interest. In this study we
242 use storm tide levels corresponding to a 100-year return period (RP100) because this is an often-used
243 coastal protection standard (Lamb et al., 2018; FEMA, 1968). If, for example, the RP100 storm tide
244 level is 3.0 meters and the average high tide is 1.5 meter this means the unitless average surge
245 hydrograph has to be scaled up to 1.5 meters, such that maximum surge plus the maximum tide is
246 equal to 3.0 meters (*Fig. 3c*).

247 4 Results

248 4.1 Storm surge hydrographs

249 For each output location from the CoDEC-ERA5 dataset, a surge hydrograph is generated. For
250 illustration, results are shown for La Rochelle in France and Marco Island in the United States (*Fig. 4a*
251 & *4b*). We find a storm surge duration (i.e. the time over which the normalized surge height is above
252 zero) of 54 hours in La Rochelle and 42 hours in Marco Island. Other studies find comparable storm
253 surge durations of 40 hours for Hoek van Holland and 45 hours for Den Helder in The Netherlands
254 (Chbab, 2015), and between 40 and 70 hours for the German Baltic Sea coast (MacPherson et al.,
255 2019). The difference in storm surge duration between La Rochelle and Marco Island is likely caused
256 by the different type of storm occurring in these regions. TCs can cause a fast shift from onshore to
257 offshore winds when making landfall, which results in the surge becoming negative in just a couple of
258 hours. Hurricane Irma is an example of a TC that made landfall near Marco Island and caused such a
259 fast shift in surge levels. The normalized surge level time series have a strong irregular behaviour. This
260 originates from the fact that the surge time series are obtained by subtracting tide-only simulations
261 from a total water level simulations (including tidal and meteorological forcing). Therefore, the surge
262 time series are the residual water level that include tide-surge interaction effects, and we believe this

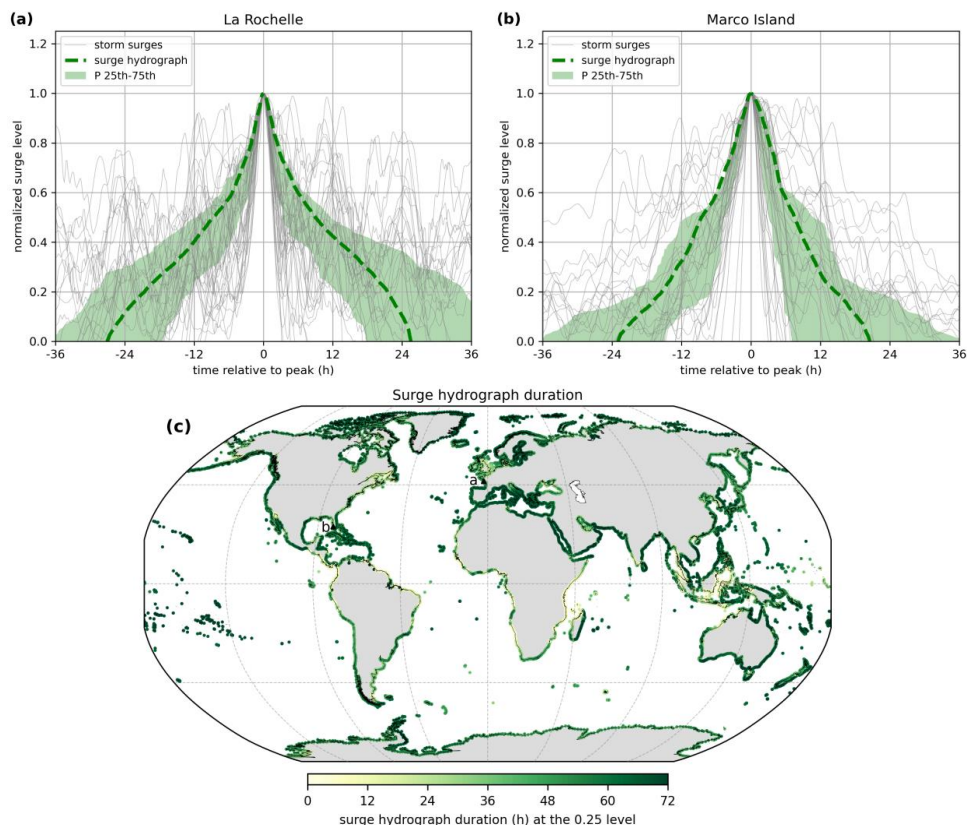

Figure 4: Surge hydrograph (dashed green line) for a) La Rochelle and b) Marco Island. Normalized surge levels are shown in grey and the green shaded area represents the 25th – 75th percentile. Panel c) shows the surge hydrograph duration at 0.25, with the locations of La Rochelle and Marco Island indicated by a and b, respectively.

263 partly explains the irregular behaviour. In addition, not all 40 events are extreme over their complete
 264 lifetime, which means that noise is affecting the lower ends of the hydrograph. Taking the mean over
 265 the normalized surge heights removes this irregular shape. At the global scale a distinct pattern shows
 266 up in certain regions (Fig. 4c). In Europe for example, the average storm surge duration is substantially
 267 lower in the North Sea compared to the Atlantic coastline and the Baltic Sea.

268 4.2 Average (spring) tide signal

269 For each output location the average and spring tide signal are computed. Although the tidal range at
 270 La Rochelle is substantially larger than at Marco Island, the general shape of the average tide signal is
 271 comparable (Fig. 5a & 5b). Both locations show a large variation in amplitude between tidal cycles.
 272 For spring tide, the variation in the tidal amplitude between the tidal cycles is smaller. Note that the
 273 grey shaded area exceeds the red shaded area at both locations during the first and third high tide
 274 because the average spring tide signal is computed by taking the average over a two week period,
 275 while the average tide signal is computed by taking the average over the daily tidal cycle of 24 hours
 276 and 50 minutes. Furthermore, the duration of the first and second high and low tide cycle of a tidal
 277 day differs at Marco Island. This is caused by the type of tide at this location which is a mixed

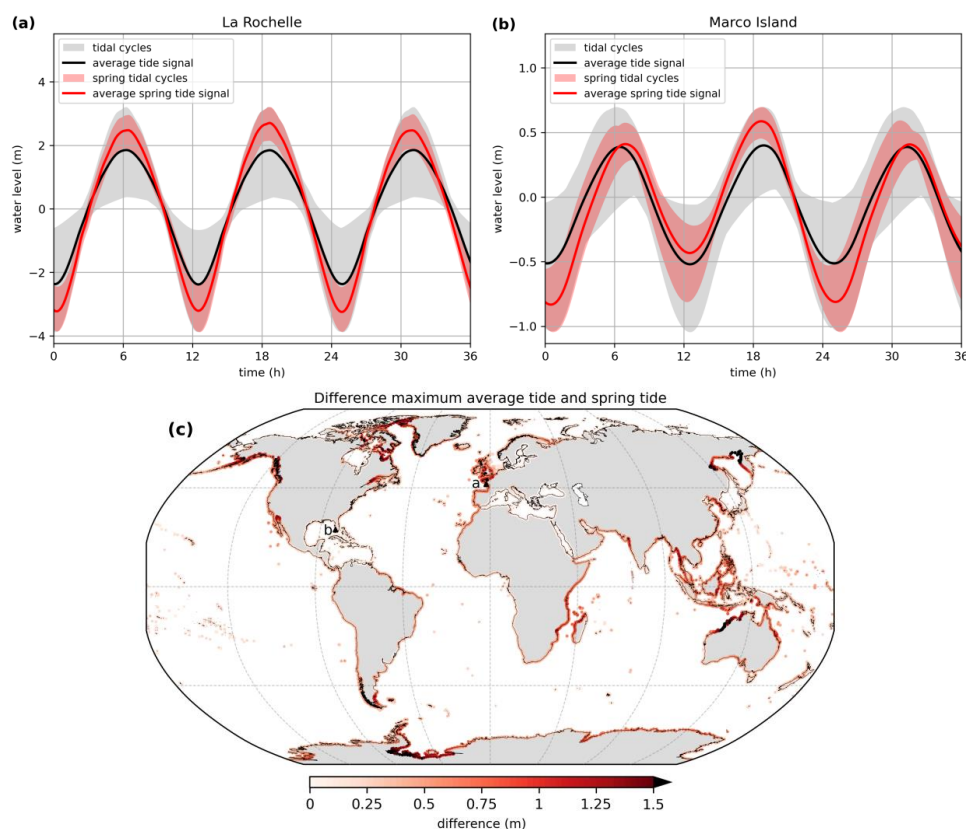

Figure 5: Average tide signal (black line) for a) La Rochelle and b) Marco Island. The grey shaded area shows the range of all tidal cycles. The average spring tide signal is shown in red and the red shaded area indicate all tidal cycles that are used to compute the average spring tide signal. Panel c) shows the absolute difference between the maximum average tide signal and average spring tide signal. The location of La Rochelle and Marco Island are indicated by the letters a and b, respectively.

278 semidiurnal tide (i.e. a tidal regime with two high and low tides per tidal day of different size) (Song
279 et al., 2011). Computing the average tide signal can be difficult at locations with a very small tidal
280 amplitude and mixed semidiurnal tide such a Montevideo (*Fig. A1*). Because of the large number of
281 shapes that the tidal cycles can have here, taking the average will not completely represent all possible
282 shapes. However, because the average high tide values are correctly represented by the average
283 (spring) tide signal, the findings are not affected to a large extent. For La Rochelle the maximum
284 average tide signal increases 46% from 1.85 m based on all tidal cycles to 2.70 m when taking the
285 average of the spring tidal cycles. In Marco Island the maximum average tide signal is 0.40 m and the
286 maximum average spring tide is 0.59 m (+48%). The larger absolute difference in La Rochelle means
287 that for an extreme storm tide to occur the timing of the surge maximum relative to the (spring) tide
288 maximum is more important compared to Marco Island. When applying HGRAPHER, it is important to
289 understand the typical characteristics of a storm tide in the area of interest, because this information
290 is needed to choose between the average and spring tide signal. For example, in northwest Australia
291 the difference between the maximum average and spring tide signal exceeds 1.5 m (*Fig. 5c*), indicating
292 that in this region an extreme storm tide is much more likely to occur during spring tide. Therefore,
293 using the average spring tide signal should be considered. At the global scale, the difference between
294 the average and spring tide signal maxima exceeds 0.5 m and 1.0 m, at 24% and 3% of all output
295 locations, respectively.

296 4.3 Storm tide hydrographs

297 The surge hydrograph is scaled up to a certain water level and combined with the average tide signal
 298 to obtain the storm tide hydrograph (Fig. 6a and 6b) that corresponds to the 1-in-100 year (RP100)
 299 storm tide level from the COAST-RP dataset (Dullaart et al., 2021b). In La Rochelle the RP100 storm
 300 tide level is 3.76 m and the average high tide is 1.85 m. Therefore, the unitless surge hydrograph is
 301 scaled up to 1.91 m, such that the combined water level equals the RP100 storm tide level. At Marco
 302 Island the RP100 storm tide level is 2.18 m to which the tide contributes 0.40 meter and the surge
 303 1.78 meter, respectively. From the RP100 storm tide hydrograph that we create globally it is possible
 304 to deduce the relative contribution of the surge (Fig. 6c). Especially in areas where the maximum
 305 spring tide signal substantially exceeds (>0.5 m) the maximum average tide signal the surge
 306 contribution might be too large compared to observed historical events. This effect is counteracted
 307 by the assumption that the surge and tide coincide in time. As a result, a smaller surge is sufficient to
 308 get to the desired RP100 storm tide level compared to the situation where a time offset is
 309 implemented to combine the average tide signal with the scaled surge hydrograph.

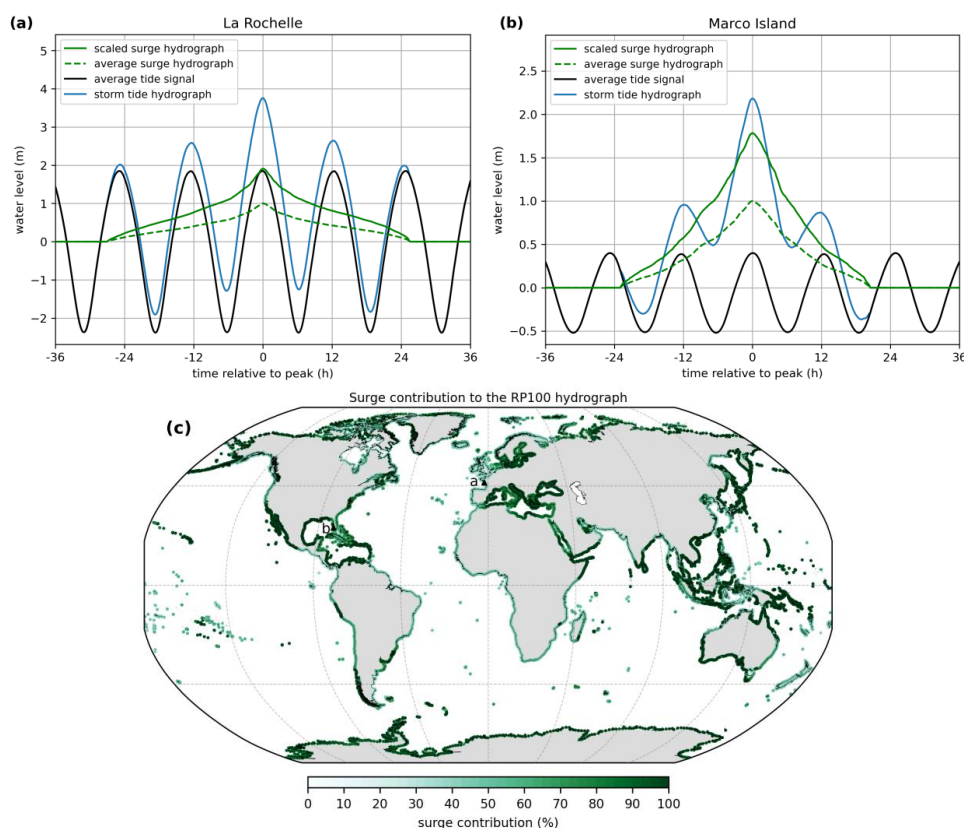

Figure 6: RP100 storm tide hydrograph (blue line) for a) La Rochelle and b) Marco Island. The average tide signal (black line), average surge hydrograph (green line), and scaled surge hydrograph (dashed green line) are also shown. Panel c) shows the relative contribution of the surge to the RP100 storm tide hydrograph maximum as a percentage. The locations of La Rochelle and Marco Island are indicated by the letters a and b, respectively.

310 4.4 Assumptions underlying the hydrograph

311 HGRAPHER is based on certain assumptions to create the storm tide hydrographs. Here, we aim to
 312 better understand how these assumptions influence the results. First, we assume that the POT99
 313 threshold results in the selection of a set of surge events from the residual time series that represents
 314 the typical evolution of a surge event at any location. However, using a higher or lower POT percentile
 315 to select surge events will give different results, depending on the typical characteristics of a location.
 316 We illustrate this using La Rochelle and Marco Island as an example. Using a higher (POT99.5) or lower
 317 (POT98) POT percentile does not result in a clearly deviating surge hydrograph at La Rochelle (Fig. 7).
 318 At Marco Island however, a clear difference can be observed between the surge hydrographs. Using
 319 the higher POT99.5 percentile (i.e. only using the ~20 most extreme surge events) results in a
 320 hydrograph that is more narrow and has a shorter duration. This is most likely caused by the different
 321 types of storms that occur at Marco Island. Using a higher POT percentile as threshold will result in an
 322 event set with a relatively larger share of TCs, compared to ETCs. This indicates that surge events
 323 caused by TCs are typically shorter compared to ETC-related surge events at Marco Island. Overall, to
 324 select the best POT percentile to generate the surge hydrograph, knowledge about the local
 325 conditions is required. For example, if surge events happen very infrequently (i.e. less than once per
 326 year) a percentile higher than POT99 should be used. Correspondingly, in areas where TCs occur such
 327 a higher POT percentile should be chosen if the research focusses on TCs. For this, knowledge about
 328 the number of historical TC storm surge events is required. Conversely, if the goal is to create a RP1
 329 storm tide hydrograph a lower POT percentile is warranted compared to when one is interested in the
 330 RP100 storm tide hydrograph.

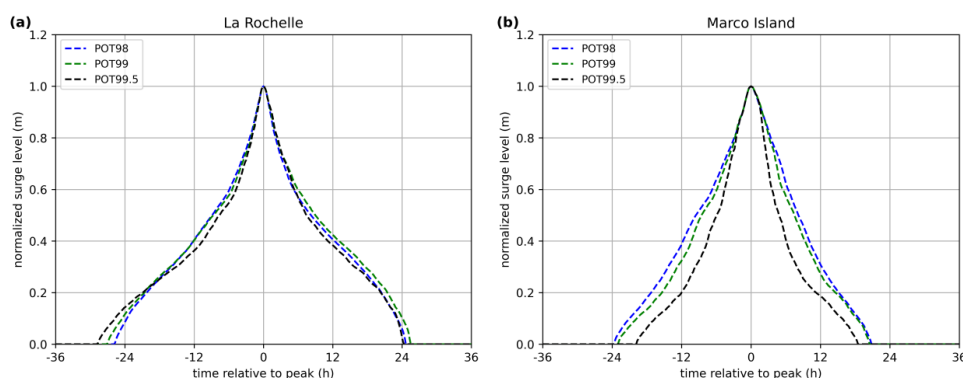

Figure 7: POT99 surge hydrograph (dashed green line) for a) La Rochelle and b) Marco Island. The blue and black dotted lines show the average surge hydrograph based on the surge events that exceed the POT98 and POT99.5 percentile.

331 Second, when combining the surge hydrograph with the average tide signal we assume that the
 332 maxima of the two coincide in time. Including a time offset will lead to a storm tide hydrograph of
 333 which the water level is elevated over a longer period of time, potentially increasing the severity of a
 334 flood event. To test this assumption we compute the time offset at La Rochelle and Marco Island (Fig.
 335 8a & 8b), which is defined as the timing of the maximum storm tide relative to astronomical high tide
 336 (Fig. 1). What can be observed at both output locations is that the distribution is centred around zero.
 337 However, at Marco Island the distribution is more spread out, indicated by a standard deviation of
 338 0.68 compared to 0.13 for La Rochelle. At the global scale, large mean absolute time offsets are
 339 observed in areas with either a very small tidal range, such as the Baltic Sea and the Mediterranean
 340 Sea, or a diurnal tide regime in combination with large TC induced storm surges, such as the Gulf of

341 Mexico (Fig. 8c). We show the absolute time offset instead of the actual values because this way all
342 areas where large time offsets occur are revealed, including areas with both positive and negative
343 time offsets. The globally averaged absolute mean offset is 33 minutes, and the median is 9 minutes.
344 To conclude, the assumption that the surge and tide maxima coincide is appropriate at most output
345 locations. However, at certain locations it should be considered to include a time offset when creating
346 a storm tide hydrograph.

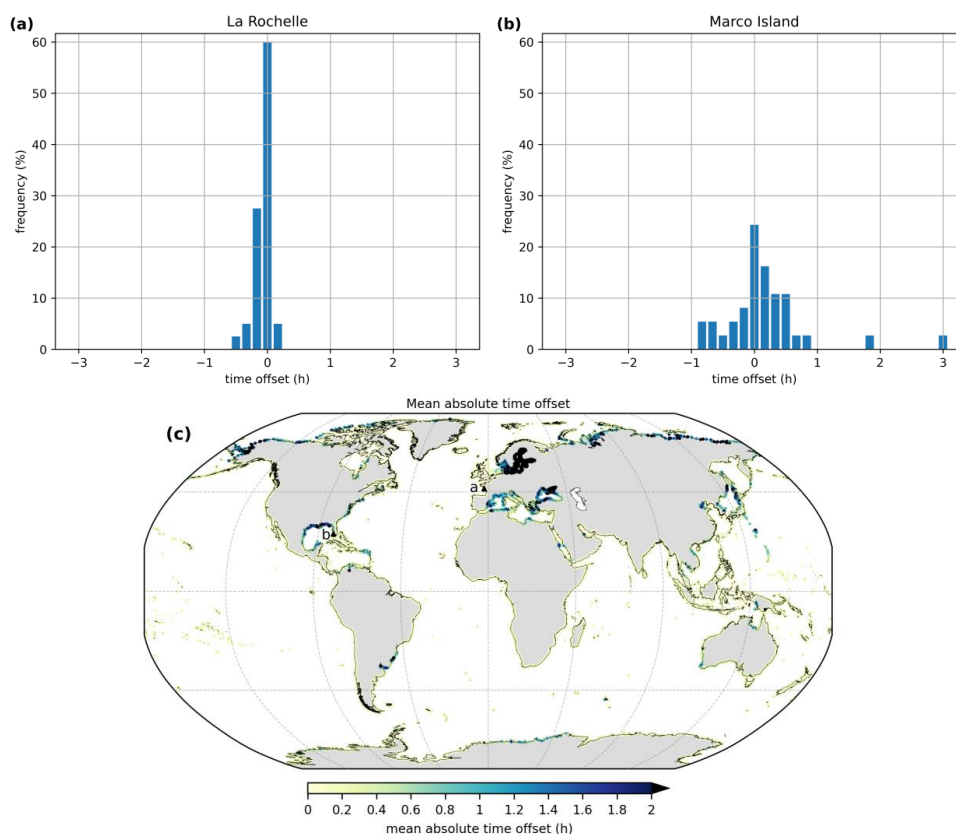

Figure 8: time offset distribution of the POT99 storm tide maxima relative to astronomical high tide at a) La Rochelle and b) Marco Island. Each blue bar represents a 10-minute period. Panel c) shows the mean absolute time offset in hours. The locations of La Rochelle and Marco Island are indicated by the letters a and b, respectively.

347 **5 Discussion and conclusion**

348 This study improves the global understanding of the duration and shape of extreme sea level events.
349 It provides a novel global dataset of storm tide hydrographs which is a first step in moving away from
350 the planar approach towards more dynamic inundation modelling at large scales. The open-source
351 model that we developed that can generate hydrographs is called HGRAPHER and allows users to
352 create storm tide hydrographs for a RP of interest. Here, we used time series of surge, tide and storm
353 tide levels from the CoDEC dataset (Muis et al., 2020) and generated storm tide hydrographs with a
354 1-in-100 year return period based on COAST-RP (Dullaart et al., 2021b). Users have multiple options
355 including, 1) use the average tide signal or spring tide signal; 2) define a POT percentile to select surge
356 events for generating the surge hydrograph; 3) include a time offset for combining the surge
357 hydrograph with the tide; 4) define for which RP a storm tide hydrograph should be generated; and 5)
358 use other time series as forcing data for HGRAPHER.

359 Several aspects of our methodology could be further improved. First, surge level time series are
360 obtained by subtracting tidal level time series from the storm tide level. As a result, the surge time
361 series do not only contain the meteorological contribution to the sea level, but also contain tide-surge
362 interaction effects, generally referred to as the residual water level (Horsburgh and Wilson, 2007).
363 This could be addressed by using a ‘surge-only’ simulation, which would not be affected by interaction
364 effects. Another aspect that could be improved is that our analysis is based on a 40 years timeseries.
365 This provides a limited number of events, specifically for regions that do not regularly experience
366 extremes such as the Caribbean. Potentially we could extend our analysis by using synthetic events,
367 such as those presented for TCs in (Dullaart et al., 2021a). For extra-tropical regions, seasonal forecasts
368 could be used to create a large ensemble of events. The advantage of a larger sample of events is that
369 it would allow to assess if hydrographs are different for different RPs.

370 Second, we do not account for different types of storms. TCs and ETCs have distinct meteorological
371 characteristics resulting in a different evolution of the water level over time. For example, TCs can
372 have stronger wind speeds and lower air pressure than ETCs, resulting in a higher storm surge (Keller
373 and DeVecchio, 2016). ETCs on the other hand generally affect a larger coastal area because they are
374 often larger in size than TCs (Irish et al., 2008). In addition, once TCs move inland the wind direction
375 can become offshore directly at the coast, resulting in a storm surge sign that quickly changes from
376 positive to negative. An example of this is during TC Irma, which made landfall in Florida in 2017 (Cheng
377 and Wang, 2019). A potential direction for future research would be to separate storm surges by type
378 of storm that caused them and develop a surge hydrograph individually for TCs and ETCs.

379 Third, the average tide signal is computed by taking the average over thousands of tidal cycles with a
380 duration of 1 lunar day, lasting 24 hours and 50 minutes. For the majority of the output locations
381 HGRAPHER correctly extracts the average (spring) tide signal. However, in areas with a mixed tidal
382 regime the daily uneven magnitude of the two high tides are averaged out. This is because over time
383 it alters whether the first or second high tide is the highest tide during that lunar day. Including the
384 mixed tidal regime characteristics at these locations, such as Montevideo (*App. A*), would result in a
385 more realistic storm tide hydrograph. However, for this multiple storm tide hydrographs have to be
386 generated that can be applied to different RPs. This makes the storm tide hydrographs dataset easy
387 to implement in large scale flood hazard assessments.

388 A final limitation is that our analysis does not include waves. Wave setup can increase storm tide levels
389 at the coast. Therefore, it is often an important component of extreme sea levels, and including a
390 dynamic wave setup component in HGRAPHER is a potential direction for future research. To

391 accomplish this, we could make use of a parametric approach that has been used in previous global
392 scale studies to obtain estimates of wave setup (Vousdoukas et al., 2018; Kirezci et al., 2020).

393 HGRAPHER and the global dataset of storm tide hydrographs improve our understanding of the
394 duration and shape of storm tide levels. As a next step, the hydrographs could be applied in inundation
395 modelling and thereby provide a basis to move towards more dynamic inundation modelling at large
396 scales. More specifically, the storm tide hydrographs can be used as boundary conditions for large
397 scale dynamic inundation modelling. This way, the time component is taken into account when
398 modelling inundation which will substantially improve the accuracy of large-scale coastal flood hazard
399 assessments.

400 **6 Appendices**

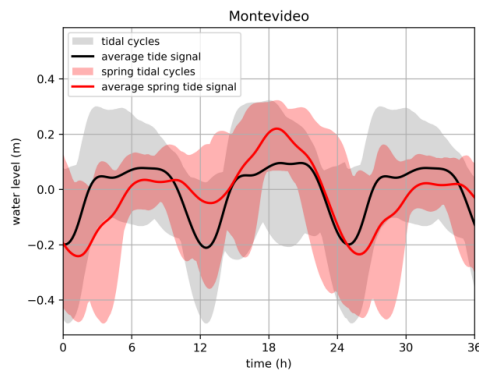

Figure A1: Average tide signal (black line) for Montevideo. The grey shaded area shows the range of all tidal cycles. The average spring tide signal is shown in red and the red shaded area indicate all tidal cycles that are used to compute the average spring tide signal.

401

17

402 **7 Code availability**

403 The HGRAPHER method developed in this study consists of several scripts that are available from
404 GitHub at github.com/jobdullaart/HGRAPHER

405

406 **8 Data availability**

407 Sea level time series used in this study (CoDEC dataset) are available from the Copernicus Climate Data
408 Store (CDS) at doi.org/10.24381/cds.8c59054f. In addition, the hydrographs generated in this study
409 are available from the 4TU data repository at doi.org/10.4121/21270948.

410

411 **9 Author contribution**

412 JD developed the HGRAPHER method and wrote the paper. SM, HM, DE, PW, and JA participated in
413 technical discussions and co-wrote the paper.

414

415 **10 Competing interests**

416 The authors declare that they have no conflict of interest.
