15 **Abstract** Earth's biogeochemical cycles are intimately tied to the biotic and abiotic processing of organic matter
16 (OM). Spatial and temporal variation in OM chemistry is often studied using direct infusion, high resolution Fourier
17 transform mass spectrometry (FTMS). An increasingly common approach is to use ecological metrics (e.g., within-
18 sample diversity) to summarize high-dimensional FTMS data, notably Fourier transform ion cyclotron resonance
19 MS (FTICR MS). However, problems can arise when FTMS peak intensity data are used in a way that is analogous
20 to abundances in ecological analyses (e.g., species abundance distributions). Using peak intensity data in this way
21 requires the assumption that intensities act as direct proxies for concentrations. Here we show that comparisons of
22 the same peak across samples (within-peak) may carry information regarding variation in relative concentration, but
23 comparing different peaks (between-peak) within or between samples does not. We further developed a simulation
24 model to study the quantitative implications of using peak intensities to compute ecological metrics (e.g., intensity-
25 weighted mean properties and diversity) that rely on information about both within-peak and between-peak shifts in
26 relative abundance. We found that despite analytical limitations of linking concentration to intensity, ecological
27 metrics often perform well in terms of providing robust qualitative inferences and sometimes quantitatively-accurate
28 estimates of diversity and mean molecular characteristics. We conclude with recommendations for robust use of
29 peak intensities for natural organic matter studies. A primary recommendation is the use and extension of the
30 simulation model to provide objective guidance on the degree to which conceptual and quantitative inferences can
31 be made for a given analysis of a given dataset. Broad use of this approach can help ensure rigorous scientific
32 outcomes from the use of FTMS peak intensities in environmental applications.

33 **1 Introduction**

34 Organic matter (OM) plays a central role in Earth's biogeochemical cycles, and is both a resource for and product of
35 metabolism. The detailed chemistry of OM (e.g., nominal oxidation state) can modulate and reflect biogeochemical
36 rates and fluxes within and across ecosystems (Boye et al., 2017; Garayburu-Caruso et al., 2020; e.g., LaRowe and
37 Van Cappellen, 2011), yet our understanding of this complexity is limited by our analytical abilities to view it
38 (Hawkes and Kew, 2020a; Hedges et al., 2000; Steen et al., 2020). Given the importance of OM chemistry to
39 biogeochemical cycling, there is a need to understand how and why that chemistry varies through space and time.
40 To help meet this need, there has been growing interest in using concepts and methods from ecology to study the
41 chemogeography and chemodiversity of OM in a variety of ecosystems (Danczak et al., 2021; Kellerman et al.,
42 2014; e.g., Kujawinski et al., 2009; Tanentzap et al., 2019). This is a promising approach as there are many

43 conceptual parallels between the chemical species that comprise OM and the biological species that comprise
44 ecological communities (Danczak et al., 2020).

45
46 The most fundamental ecological data type is the species-by-site matrix. This matrix indicates how many individuals
47 of each species occur in each sampled community. Ecologists use species-by-site matrices to ask myriad questions
48 related to biological diversity, and often complement these data with information on the properties or ‘functional
49 traits’ of species (e.g., body size) (McGill et al., 2006; Villéger et al., 2017; Violle et al., 2007). Two common
50 analyses are known as α -diversity and β -diversity, each with numerous metrics (Anderson et al., 2011; Whittaker,
51 1972), including versions that include functional trait information (Laliberté and Legendre, 2010). α -diversity
52 measures the diversity within a given community. β -diversity has been variously defined, but essentially measures
53 variation in composition across communities. Both α -diversity and β -diversity can be quantified using presence-
54 absence data or they can include estimates of each species’ relative abundance within and between communities
55 (Fig. 1). In addition to being incorporated into these diversity metrics, functional trait data can be used to estimate
56 community-level mean trait values (Lavorel et al., 2008). As with diversity, mean trait values can be estimated using
57 presence-absence or relative abundance data. Estimates of diversity and mean trait values are examples of ecological
58 metrics often applied to OM chemistry (Bahureksa et al., 2021; Cooper et al., 2022; Sakas et al., 2024; Tanentzap et
59 al., 2019).

60
61 The chemistry of OM is commonly studied using high resolution Fourier transform mass spectrometry (FTMS)
62 techniques (e.g., Hawkes and Kew, 2020b), such as Orbitrap or Ion Cyclotron Resonance (ICR) MS, via direct
63 infusion of samples. At present, the highest resolution approach for untargeted analysis of OM is via a 21 Tesla
64 FTICR MS (Bahureksa et al., 2021; Marshall et al., 1998; Shaw et al., 2016; Smith et al., 2018). The output data
65 produced is a spectrum containing peaks represented by a signal intensity (Fig. 2 y-axis) and a mass-to-charge ratio
66 (m/z) (Fig. 2 x-axis), which is equivalent to the mass for singly charged ions as routinely detected in natural organic
67 matter (NOM) measurements. In turn, regardless of the type of MS instrument used, the MS data inherently lead to
68 an OM peak-by-sample data matrix, akin to an ecological species-by-site data matrix. The high resolution data from
69 MS often results in a large matrix, wherein a single sample may contain thousands to tens of thousands of peaks. It
70 is often possible to assign molecular formulas to a large fraction of observed peaks, which enables calculation of
71 several properties such as stoichiometric ratios (Bahureksa et al., 2021; Cooper et al., 2022) that are akin to
72 organismal functional traits. To take advantage of these rich data, FTMS data have been analyzed using the same α -
73 diversity, β -diversity, and mean trait metrics that are commonly used by ecologists to study biological communities
74 (e.g., Kellerman et al., 2014). Such analyses are exciting, as they enable the same conceptual questions and
75 quantitative frameworks to be applied to biological (e.g., microbial communities) and chemical (i.e., NOM)
76 components that directly interact with each other within ecosystems (Danczak et al., 2020, 2021; Li et al., 2018;
77 Lucas et al., 2016; Osterholz et al., 2016; Tanentzap et al., 2019).

78
79 The use of ecological metrics with MS data is particularly common with FTMS datasets and there is great potential
80 to continue leveraging concepts from ecology in high-resolution NOM analyses. Care is required, however, in using
81 FTMS peak intensity data to estimate α -diversity, β -diversity, mean trait values, and related ecological analyses
82 (e.g., ‘species’ abundance distributions). Key to these ecological analyses is the assumption that within complex
83 NOM samples, differences in peak intensity are proportional to differences in concentrations of the associated
84 molecules. Studies using FTMS often avoid using peak intensities due to uncertainties in whether it is valid to
85 assume proportionality between peak intensities and concentrations within and across NOM samples (Bhatia et al.,
86 2010; Danczak et al., 2020; Kujawinski, 2002). These studies may be discarding useful information, though it is
87 unclear what biases and uncertainties are introduced into ecological metrics when using FTMS peak intensities. To
88 help advance robust use of FTMS datasets for NOM studies, we review the theoretical reasons why peak intensities
89 may not reflect true concentrations, provide empirical evaluation of this theory, and invoke *in silico* simulation to
90 quantify the associated impacts on ecology-inspired analyses. While theory and empirical analyses demonstrate
91 disconnects between peak intensities and concentrations in FTMS data, the simulations show that intensity-weighted

92 ecological metrics often provide robust estimates of NOM diversity and mean trait values. We end with practical
93 recommendations and propose a path forward for increasing robust use of FTMS peak intensities for NOM studies.

94 **2 Theoretical Foundations**

95 Here we provide a review of the theoretical foundations behind why assuming proportionality between peak
96 intensities and concentrations in FTMS can be challenging. This section will be of most value to FTMS data users
97 that are not formally trained in mass spectrometry, and serves as a review of mass spectrometry principles
98 (Bahureksa et al., 2021; see also Kujawinski, 2002; Urban, 2016). We focus on FTMS (i.e., FTICR and Orbitrap),
99 but many of the principles are applicable across all MS platforms. We highlight three considerations: ionization, ion
100 transfer, and ion signal detection in the context of commercial FTMS instruments. These considerations have
101 practical implications tied to within-peak and between-peak comparisons (Fig. 2). Here, we define ‘within-peak’ as
102 comparing peak intensities of the same feature (i.e., m/z or molecular formula) across different sample spectra and
103 ‘between-peak’ as comparing peak intensities across different features. Both within-peak and between-peak
104 comparisons are fundamentally based on the m/z observed within a mass spectrum and neither address comparisons
105 across isomers. Further, we suggest consistent use of the term ‘intensity’ in FTMS NOM studies to describe how
106 much signal is observed for a given peak, as opposed to ‘height’, ‘magnitude’, or other alternatives. While
107 terminology is not our central focus, it is useful to pursue consistency across studies. As discussed below, within-
108 peak comparisons can be robust under certain situations, but there are limitations with between-peak comparisons
109 that may be unavoidable. The following discussion is not an exhaustive treatment of all decisions associated with a
110 complete FTMS experiment, and we do not deeply address factors such as sample preparation, choice of ionization
111 mode, and instrument specific parameter optimization. These topics have been discussed in a recent review
112 (Bahureksa et al., 2021).

113 **2.1 Ionization Efficiency and Isomers**

114 Electrospray ionization (ESI) is the most common technique for generating ions from NOM samples. When using
115 ESI, the peak intensity for any given molecular mass (or molecular formula) will depend on both concentration and
116 ionization efficiency, the latter of which is dependent on structure, pKa, and the other molecules in the sample
117 (Kruve et al., 2014). In NOM samples, one detected mass or peak combines signals from multiple isomers which all
118 have the same molecular formula but different structures. The different structures impact ionization efficiency, but
119 FTMS data contains no information about this structural variation. Unfortunately, to date, no liquid chromatography
120 (Han et al., 2021; Kim et al., 2019) or ion mobility separation (Leyva et al., 2020; Tose et al., 2018) technique has
121 yet demonstrated sufficient resolution to completely infer structural variation among isomers within complex NOM
122 samples. Unknown variation in structure can, therefore, lead to unknown variation in peak intensities. This challenge
123 can be compounded by ionization suppression that occurs when the ionization efficiency of one type of molecule
124 (i.e., peak) is altered by the presence of other types of molecules (Ruddy et al., 2018). Ionization suppression can be
125 mitigated by online separation whereby non-targeted LC-MS approaches may yield more quantitative data (Kruve,
126 2020), but matrix effects remain a significant issue even for LC-MS (Trufelli et al., 2011). In NOM samples with
127 thousands of types of organic molecules, the molecular interactions likely have complex influences over realized
128 ionization efficiencies. While it is possible to control for some of these challenges (e.g., using consistent sample
129 concentrations and preparations), many additional factors (e.g. molecular structures, pKas, and interactions among
130 molecules in NOM samples) cannot yet be accounted for. Interpretation of peak intensities as proxies for
131 concentrations in FTMS datastreams may, therefore, be prone to uncertainty.

132 **2.2 Ion transmission and collection**

133 In FTMS, packets of ions are accumulated in a trap prior to their transmission to the analyzer cell (Makarov et al.,
134 2006; Fig. 3 Panel A section d; Senko et al., 1997). The duration of time in which ions are accumulated is often
135 varied to yield an optimal ion population for the analyzer cell. The duration of this event can change the relative

136 abundance, and thus observed peak intensities of different ions (Cao et al., 2016). Increases in the true abundance of
137 other ions can decrease the measured peak intensity of a given ion due to a dilution effect resulting from a finite
138 number of ions that can fit within the ion trap. Additional challenges arise due to variation in the speed at which
139 different ions move from the accumulation trap and into the analysis cell. Smaller ions move more quickly and
140 therefore reach the analysis cell sooner than larger ions. Variation in the accumulation time across samples and
141 FTMS instruments, combined with among-ion variation in transmission speed, can introduce additional uncertainty
142 in the relationship between peak intensities and true concentrations.

143 **2.3 Ion signal detection**

144 The final step in data collection via FTMS is signal detection. The intensity of the signal is proportional to the
145 abundance of a given ion in the analysis cell, the proximity of ions to the detector (Kaiser et al., 2013), and the ion
146 charge state (Wörner et al., 2020). Similar to molecular interactions impacting ionization efficiencies, different types
147 of ions can interact to affect each other's signal intensity. The Fourier transform applied to the data also complicates
148 extremely accurate relative quantification of ion abundance between peaks (Makarov et al., 2019). These challenges
149 at the detection stage can add more uncertainty to the relationship between peak intensity and concentrations,
150 particularly for complex NOM samples.

151

152 **3 Empirical Evaluations**

153

154 In this section, we move beyond theoretical considerations to empirical evaluations of the real-world relationships
155 between peak intensities and concentrations. Similar to above, this section will be of primary value to those without
156 formal training as mass spectrometrists, but who use FTMS data to study NOM. The experimental methods used are
157 described in detail in the Supplementary Information.

158 **3.1 Direct comparison of peak intensities in idealized samples**

159 As discussed above, different organic compounds ionize with different efficiencies. In theory, this may lead to
160 variation in observed peak intensities even when all organic compounds have the same true concentration. To
161 evaluate this theoretical expectation, we analyzed several different types of organic compounds in different
162 conditions via FTICR-MS. We selected chemical standards (see Supplementary Information for details) which are
163 natural products with molecular formula and chemistries typical of compounds commonly observed in organic
164 matter, and were amenable to negative mode ESI analysis. First, we analyzed three separate dilution ladders of
165 individual pure compounds dissolved in pure methanol. These standards were analyzed at higher concentrations than
166 typically observed for NOM because they were single compounds rather than formula-summed features (with
167 multiple isomers) within a NOM spectrum; higher concentrations were required to compensate for lower isomeric
168 diversity. These three compounds gave rise to different peak intensities under otherwise identical conditions (Fig.
169 4A). Trehalose, for example, had much lower peak intensity than sinapic acid at the same actual concentration. The
170 difference in signal intensity was also apparent amongst compounds that ionize well under negative mode ESI; for
171 example, two different structures containing the same number of carboxylic acid units exhibited differences in signal
172 intensity. We also observed differences in peak intensities amongst structural isomers (i.e., same molecular formula
173 and mass) (Fig. 4B). Each peak observed via direct infusion FTICR-MS may be several isomers. These isomers may
174 be observable through chromatographic separation (Kim et al., 2019), ion mobility separations (Leyva et al., 2019),
175 or by statistical inference of tandem mass spectrometry (Zark et al., 2017), but not via direct infusion FTICR-MS.
176 We note that absolute differences in signal intensity may be smaller between molecules at lower concentrations, but
177 this does not necessarily mean that low intensity signals consistently indicate low concentrations and this does not
178 aid in quantitatively interpreting higher intensity signals. In summary, differences in peak intensities across organic
179 compounds do not necessarily equate to differences in concentration, unless assessed via a calibration curve for each
180 compound.

181 **3.2 Comparison of peak intensities in in real world samples**

182 Routine NOM samples contain a diverse range of thousands of molecules of unknown structures and relative
183 concentrations and often contain inorganic interferences, such as salts. Sample clean up that focuses on pre-
184 concentration and desalting is imperfect (Li et al., 2017; Raeke et al., 2016), but is commonly used to minimize
185 inorganic interferences. Interactions among molecules remains a challenge, however, as discussed above. The
186 collection of molecules in a sample is referred to here as the ‘matrix.’ To explore matrix effects on peak intensities,
187 we prepared solutions of six different pure compounds at a fixed concentration (100 ppb) in three different solvent
188 systems - pure methanol, methanol eluted from a BondElut SPE cartridge, and methanol from elution off of a
189 BondElut SPE cartridge which had been loaded with artificial river water (ARW). Additionally, we added a
190 complex mixture that is often used as a NOM standard, Suwannee River Fulvic Acid (SRFA), at six different
191 concentrations, to each sample. Samples were analyzed independently but contemporaneously on the same
192 instrument to mirror a real study.

193
194 In methanol-only solvent, with no added SRFA, the six compounds yielded different peak intensities (Fig. 4C),
195 which is consistent with results from the previous subsection. As the concentration of SRFA was increased to 2
196 ppm, the relative signal intensity increased for some of the six compounds, but decreased for others. Above 2 ppm
197 of SRFA, peak intensities for all six compounds were substantially decreased. Use of an ‘impure’ methanol solvent,
198 i.e., the eluent from a SPE blank (Fig. 4D) or from an SPE of artificial river water (Fig. 4E), resulted in further
199 decreases in peak intensities. In both cases, the maximum peak intensity was ~20% of what was seen in pure
200 methanol (Fig. 4C), and some of the six compounds were no longer observed. Addition of SRFA to these samples
201 with ‘impure’ solvents, again, generally, decreased peak intensities. A ‘real-world’ sample set would have even
202 greater diversity and heterogeneity than presented here, and thus the issues with use of peak intensities for
203 quantitative interpretation would likely be exacerbated.

204
205 Combining the empirical results from this subsection and the previous subsection with instrument theory discussed
206 above suggests significant uncertainty in relationships between true concentrations and peak intensities from direct
207 infusion FTICR-MS. Calibration curves can be used in the simplest of situations, but will be challenging when there
208 are unknown variations in structural isomer and matrix compositions. Modeling of constrained systems may,
209 however, allow for data-driven and mechanistic data normalization strategies for enhanced use of peak intensity
210 data.

211 **3.3 Data Normalization Strategies**

212 In the previous section, we use the peak intensities for each analyte without any normalization, only scaling to the
213 base peak or between spectra to make comparison easier. However, more sophisticated or comprehensive
214 normalization strategies may be useful when trying to make quantitative inferences of the data. Considerations may
215 include whether to use the total intensity within a spectrum (including noise, isotopologues, and unannotated
216 features), or to use just the peak intensity apportioned to annotated features. Additionally, non-linear or more
217 sophisticated functions may have benefits. Such post-hoc statistical approaches have utility for some applications
218 but do not resolve the fundamental, underlying physical origins of the weak connection between peak intensities and
219 true concentrations. We refer readers to the work of Thompson et al. (2021) for more insights into the theory and
220 application of normalization of FTMS for complex mixtures.

222 **4 Conceptual implications for use of ecological metrics**

223
224 The preceding sections indicate challenges when using FTMS peak intensities as proxies for relative changes in
225 concentrations of organic molecules. The implication is that some ecologically-inspired analyses (e.g., Fig. 1) may
226 be challenging to use with FTMS peak intensity data. To understand which analyses could be impacted, we
227 differentiate analyses into two classes: those based on within-peak intensity comparisons and those based on

228 between-peak intensity comparisons (Fig. 2). As noted above, within-peak is based on comparing the same feature
229 (m/z or molecular formula) across spectra/samples, whereas between-peak compares different features (m/z or
230 molecular formulas) across and within spectra/samples.

231
232 We posit that analyses using FTMS between-peak intensity comparisons could have the greatest uncertainty.
233 Consider an ecological setting in which a researcher aims to quantify within-sample diversity (α -diversity) and
234 among-sample diversity (β -diversity) (Fig. 1) of tree communities (Fig. 5, left side). The researcher will likely set up
235 a plot of a given size and then directly count the number of each tree species in each plot, thus generating the
236 species-by-site matrix filled with directly observed abundance counts for each species. The ability of the researcher
237 to observe individuals of each species does not vary appreciably across species because each tree is not moving and
238 our ability to see a static object is not influenced by environmental factors. Thus, the number of individuals observed
239 for a given tree species is quantitatively comparable to the number of individuals observed for all other tree species
240 in the plot. The assumption that differences in observed abundances carry robust information about differences in
241 actual abundances is thus supported, in this example. In turn, it is valid to use relative abundances to compute α -
242 diversity such as via Shannon evenness (Elliott et al., 1997; Mouillot and Leprêtre, 1999; Redowan, 2015).
243 Furthermore, because the ability to observe each tree species is the same across communities, it is valid to use
244 relative abundances to compute β -diversity (e.g., via Bray-Curtis; Anderson et al., 2011) or conduct other ecological
245 analyses that use abundance data (e.g., species abundance distributions McGill et al., 2007).

246
247 We contrast this tree community example with another ecological setting. Consider a researcher studying bird
248 communities (Fig. 5, right side) that estimated species abundances solely based on the number of times an observer
249 hears the call of a given species. In this case, those species that call more frequently and/or more loudly will be more
250 likely to be heard, and thus an observer will infer a higher abundance even if all species in the community have the
251 same abundance. That is, such a method generates data that may indicate which species are present, but the ‘call
252 counts’ do not carry reliable information regarding absolute or between-species relative abundances. Follow-on
253 analyses of α -diversity and β -diversity should, therefore, be limited to approaches that use presence/absence data,
254 and species abundance distributions cannot be quantified.

255
256 If we continue with the bird community example and assume that the detectability of a given bird species is
257 consistent across sampled locations or times, then it would be appropriate to examine variation in within-species call
258 counts. This within-species analysis is directly analogous to the FTMS within-peak time series analysis in Merder et
259 al. (2021), discussed below. However, if call counts of a given species are suppressed by the presence or abundance
260 of other species, then call counts of a given species may not indicate changes in its abundance. The call count
261 example is directly analogous to influences of the NOM matrix: if the presence/abundance of a given organic
262 molecule modifies the ionization of other molecules, then within-peak changes in intensity may not indicate changes
263 in concentration. In turn, analyses based on within-peak intensity comparisons could lead to error and uncertainty in
264 values of computed ecological metrics, especially if there are significant cross-sample changes in the NOM matrix.

265
266 As described in the previous sections, the unique chemistry of every molecule in a NOM sample can influence
267 ionization properties for other molecules in the sample. Thus, FTMS data align with the bird community example
268 rather than the tree community example, with the differing physics of each molecule influencing between-peak
269 differences in peak intensity. Molecules that more readily ionize will produce higher peak intensities, which is akin
270 to bird species with noisier or more numerous calls producing a larger number of call counts that do not accurately
271 represent the underlying population distribution. Similarly, between-peak differences in intensity as observed via
272 FTMS cannot be directly used as a proxy to indicate between-peak differences in concentration.

273
274 In contrast to between-peak comparisons, within-peak comparisons examine changes in the relative intensity of a
275 single peak across samples. Such within-peak comparisons may be repeated independently for each peak of interest
276 in a given dataset. For example, Merder et al. (2021) quantified temporal dynamics of individual FTMS peaks and

277 then binned peaks into different groups with characteristic temporal fluctuations. In those analyses, peak intensities
278 were not compared between peaks. Instead, the temporal dynamics of each peak was compared to temporal
279 dynamics of other peaks. The underlying assumption of this type of analysis is that a between-sample increase in the
280 intensity of a given peak can be used as a robust proxy of a between-sample increase in concentration of that peak.
281 Materials presented in the previous sections indicate that this assumption can be met in some instances when using
282 FTMS data. However, great care is required with strong attention paid to assumptions of analysis methods. For
283 example, using Pearson correlation makes the assumption that concentration of a given peak is a *linear* function of
284 changes in its peak intensity. We showed above (Fig. 4) that this assumption is not always valid, even in ideal
285 conditions. Using a Spearman correlation avoids this assumption because it is based on ranks. That is, Spearman
286 correlations (e.g., Kellerman et al., 2014) make the more realistic assumption (for FTMS data) that an increase in
287 concentration of a given peak is reflected as an increase in its peak intensity without assuming any statistical or
288 mathematical form of that relationship.

289

290 **5 Ecological metrics using peak intensities are often robust**

291

292 The previous sections highlight challenges in connecting between-peak changes in observed intensity to between-
293 peak changes in true abundance (Fig. 4). These challenges violate an assumption of abundance-based ecological
294 analyses: proxies for abundance (e.g., peak intensity) should be proportional to true abundances. However, the
295 quantitative impacts of this situation likely vary across ecological metrics and with study details. There may be
296 certain metrics or conditions in which robust inferences can be made despite poor linkages between peak intensities
297 and true abundances. These cases are important to understand for robust use of abundance-based ecological metrics
298 in FTMS NOM studies.

299

300 To provide initial guidance on best practices for using FTMS peak intensities with ecological metrics, we developed
301 an *in silico* simulation model (full details are in Supplementary Material). This model generates synthetic data and
302 introduces errors that degrade the linkage between peak intensity and true abundance. Simulated values that are
303 influenced by introduced errors are conceptually analogous to intensities from real-world FTMS NOM studies. This
304 allows us to probe how errors inherent to FTMS may impact the relationship between true and observed values of
305 ecological metrics. To generate synthetic data, the simulation model produced samples with either 100 or 1000
306 peaks. This was done to study how the influences of errors change with the number of peaks; going above 1000
307 peaks did not change the outcomes and going below 100 peaks is unlikely to be relevant to many FTMS studies. For
308 each run of the model, the true abundances of each peak within each of two independent samples were randomly
309 assigned from Gaussian distributions that differed across samples and simulation iterations. We simulated two types
310 of error that modified the true abundances; within-sample error reflects variation in ionization efficiency across
311 molecules (but not across samples) and between-sample error reflects variation in ionization efficiency across
312 molecules and samples.

313

314 To examine how both types of error influence ecological metrics, we used the initial true abundances and the error-
315 modified abundances (analogous to observed peak intensities) to calculate within-sample α -diversity via the
316 Shannon diversity metric, between-sample β -diversity via the Bray-Curtis dissimilarity metric, and a generic
317 intensity-weighted sample-level mean trait value based on assigning an arbitrary trait value to each peak (Fig. 6).
318 The mean trait analysis is analogous to the approach commonly used in ecological studies for computing
319 community-level abundance-weighted trait values, such as plant leaf area index or animal body size (Muscarella and
320 Uriarte, 2016). This mean trait approach is also commonly used with FTMS data, such as for sample-level peak-
321 intensity-weighted values of stoichiometric ratios (e.g., H:C) and several other metrics derived from molecular
322 formulae (Roth et al., 2019; Wen et al., 2021).

323

324 Relating error-influenced ‘observed’ values of each ecological metric to their true values revealed that peak-
325 intensity-based ecological metrics are likely to be qualitatively robust despite quantitative biases (Figs. 7-9). All
326 three ecological metrics showed monotonic relationships between observed and true values for both types of error;
327 in Figures 7-9 all A/C and B/D panels have within-sample and between-sample error, respectively. Uncertainty was
328 lower when samples had 1000 peaks, relative to samples with 100 peaks; in Figures 7-9 all A/B and C/D panels have
329 100 and 1000 peaks, respectively. For Shannon diversity, observed values were consistently lower than true values,
330 but all observed vs. true relationships were linear (Fig. 7). For Bray-Curtis, inclusion of between-sample error
331 resulted in an overestimation of values and non-linear monotonic relationships between observed and true values
332 (Fig. 8). For mean trait values, we found no systematic quantitative biases, and the relationships between observed
333 and true values were consistently linear (Fig. 9).

334
335 The variation in observed values explained by true values (via a linear model) increases rapidly with the number of
336 peaks and asymptotes beyond ~500-1000 peaks per sample (Fig. S1). The number of peaks needed to reach the
337 asymptote and minimize uncertainty is likely dataset dependent and 500-1000 peaks should not be taken as a general
338 rule for real-world datasets. Nonetheless, we propose that qualitative gradients based on sample-to-sample changes
339 in the value of ecological metrics can generally be interpreted with increasing confidence as the number of peaks
340 increases. Quantitative comparisons from one dataset to another may, however, require further simulation-based
341 evaluation as the absolute magnitude of some ecological metrics are shifted away from their true magnitudes even
342 when there are large numbers of peaks (e.g., Fig. 8D). We encourage researchers to use the simulation model with
343 the numbers of peaks present in their real-world datasets to better understand their ability to make statistical and
344 conceptual inferences.

345 **6 Conclusions and Recommendations**

346 There is significant value in using FTMS data to study NOM chemistry (Bahureksa et al., 2021; Cooper et al., 2022;
347 Spencer et al., 2015; Stubbins et al., 2010), and it is vital that this be done based on rigorous use of the data. When
348 using ecological metrics with FTMS NOM data it is important to understand how the assumptions and limitations of
349 the metrics relate to limitations of the data. We suggest that studies using FTMS peak intensities need to include
350 material that directly discusses the data limitations, what peak intensities do and do not represent (e.g., tree-like vs.
351 bird-like data; Fig. 5), and how knowledge of those limitations was used to select specific metrics.

352
353 We have provided both theoretical reasoning and empirical observations showing that peak intensities do not
354 necessarily map to concentrations of the associated organic molecules within NOM-like complex mixtures of
355 organic molecules. This is particularly true for between-peak comparisons, and statistical post-hoc normalizations of
356 peak intensity data do not solve this challenge. We caution against using between-peak differences in intensity from
357 FTMS data to make direct inferences related to between-peak differences in abundance or concentration. This has
358 implications for some ecological analyses based directly on variation in species abundances, such as. For example,
359 estimation of ‘species abundance distributions’ are likely to be problematic. Analyses that bin peaks into high and
360 low abundance groups based on between-peak differences in concentration are also likely to be problematic. We did
361 not directly evaluate these types of analyses, and we suggest that future work should expand upon the ecological
362 metrics examined here via simulation.

363
364 While there are challenges and limitations in the use of ecological metrics with FTMS data, we show that there is a
365 tangible path forward. In particular, our simulation model revealed good performance of some common ecological
366 metrics of α -diversity, β -diversity, and mean trait values. We infer that conceptual and mechanistic inferences are
367 likely to be valid when based on analyses such as comparing peak-intensity-based ecological metrics across
368 experimental treatments or variation along environmental gradients. The performance of intensity-weighted mean
369 trait values was particularly good, both qualitatively and quantitatively. This indicates that using peak intensities to
370 estimate sample-level mean traits/properties likely provides quantitatively robust estimates, such as for

371 stoichiometric ratios (e.g., H/C, O/C) and many other commonly calculated quantitative properties related to
372 molecular formulas (e.g., nominal oxidation state of carbon, aromaticity index, double bond equivalent, etc.).
373

374 As general guidance we suggest avoiding analyses that make direct use of between-peak comparisons of peak
375 intensity and rely instead on derived metrics that use intensities from large numbers of peaks. For example, while
376 peak-intensity-weighted mean trait values appear to be robust, our physical experiments indicate caution against
377 direct comparison of peak intensities to infer between-peak differences in concentration. This is relevant to analyses
378 such as comparing peak intensities within a Van-Krevelen analysis or across classes of elemental composition (e.g.,
379 CHO, CHON, etc.). Such analyses could be problematic as quantitative variation in peak intensities across the Van-
380 Krevelen space or across classes of elemental composition is likely influenced by variation in ionization efficiencies
381 with unclear connections to true concentrations. It is, therefore, not recommended to use peak intensities to identify
382 parts of Van-Krevelen space (e.g., protein-like compounds) or compositional classes that have the highest
383 concentrations in a given sample. It is preferable to report the fractions of peaks contained within different parts of
384 Van-Krevelen space or within different compositional classes and avoid quantitative estimates based on peak
385 intensities (e.g., percent of total sample-level intensity found within a given class). An alternative approach for
386 robust and direct use of peak intensities, based on our physical experiments, is the use of Spearman-based
387 correlations for within-peak comparisons across samples. Such correlations could be done across spatial
388 environmental gradients, through time, and/or with respect to other sample-level quantitative measurements (e.g.,
389 organic carbon concentration). This implies that other types of correlation-based analyses are likely robust, such as
390 peak intensity-based network analyses. We further suggest that parametric statistics can often be used to relate the
391 ecological metrics studied here to other quantitative variables, both directly (e.g., via Pearson-based correlation) and
392 indirectly (e.g., via Bray-Curtis based non-metric multidimensional scaling).
393

394 There are many other kinds of analyses currently done with FTMS data and more will be imagined in the future. To
395 develop further guidance on how to best use peak intensities for a broader range of analyses we recommend use and
396 further development of the simulation model developed here. Fortunately, it is straightforward to extend the
397 simulation model to additional metrics (e.g., Hill numbers; Hill, 1973) and analyses (e.g., species abundance
398 distributions; McGill et al., 2007). We suggest that users of FTMS data do this before applying abundance-based
399 ecological metrics to real-world datasets. This will provide objective guidance on how to use (and whether to avoid)
400 specific metrics for specific FTMS datasets. The simulation model is the only tool we are aware of that can provide
401 objective evaluations of uncertainty and potential biases associated with using FTMS peak intensities to compute
402 ecological metrics. The model should not be taken as a static or mature tool, however. We encourage future work to
403 expand it to include additional ecological metrics/analyses, situations with more than two samples, sample-to-
404 sample variation in peak richness, links between peak richness and peak intensity, explicit molecular
405 properties/traits, non-random errors, and measured levels of error between concentrations and peak intensities. It can
406 be further extended to directly add error into peak intensities from real-world FTMS data and re-calculate ecological
407 metrics of interest across a range of introduced error. This would help gauge the robustness of conceptual inferences
408 derived from peak intensity-based analyses.
409

410 Further evaluations are outside of the scope of this work, but will be straightforward to include in future versions of
411 the simulation model. We envision each study customizing the model for their specific application. For any real-
412 world study, the model can be modified to include the actual number of samples, the number of peaks in each
413 sample, the peak intensity distributions, number of replicates, and the specific ecological analyses that will be
414 applied. In turn, simulation model outcomes can provide objective guidance tailored to each study. One may think of
415 the resulting guidance as akin to a power analysis whereby the simulation can indicate what can and cannot be
416 inferred from a given dataset. For example, the model indicates that observed Bray-Curtis values have little to no
417 correspondence to true values when Bray-Curtis is below ~0.2 (Fig. 8B, D). Bray-Curtis near and below ~0.2 are
418 commonly observed in FTMS studies (Bao et al., 2018; Derrien et al., 2018; e.g., Hawkes et al., 2016), and this
419 disconnect between observations and truth is maintained even with 1000 peaks per sample (Fig. 8D). In turn, FTMS

420 studies that observe Bray-Curtis below ~ 0.2 may not be able to use those observations to make valid conceptual
421 inferences. However, quantitative guidance must be developed for each study and we recommend that a version of
422 the simulation model should be used by future studies using peak intensities to conduct ecological analyses of FTMS
423 data. It may be that in time we understand the general rules well enough to leave the simulation behind, but for now,
424 we suggest its use is warranted to ensure robust inferences.

425
426 In addition to further use and development of the simulation model, we recommend translation of other modeling
427 approaches for use with FTMS data. Two potential approaches are based in machine learning and hierarchical
428 modeling. Machine learning could be used to model the instrument response for a diverse chemical space in typical
429 environmental samples to learn how measured signal intensities may relate to true concentrations. Even if such a
430 model does not yield high-accuracy results, it may nonetheless help understand error/biases and provide additional
431 guidance for robust use of peak intensity data. Potentially in concert with machine learning, hierarchical modeling
432 could be translated from its application in ecological analyses (Iknayan et al., 2014) for use with FTMS. This
433 approach has been used to model sources of error that lead to variation in detectability across biological species,
434 such as variation in species visibility (e.g., Dorazio and Royle, 2005). In turn, data can essentially be corrected by
435 accounting for the modeled sources of error (Roth et al., 2018), even revealing ‘hidden diversity’ (Richter et al.,
436 2021). There are likely direct analogs to FTMS data in terms of variation among molecules in detectability due to
437 variation in ionization and molecular interactions discussed in previous sections. Machine learning could be used to
438 understand sources of error and, in turn, inform hierarchical models aimed at improving the mapping between peak
439 intensity and concentration. If successful, this would increase the quality of information provided by peak intensities
440 in both existing and future datasets.

441
442 In summary, FTMS has many strengths and weaknesses just like any analytical platform. Other types of
443 compositional data also contain biases and uncertainties, such as the lack of true quantitation in sequence-based
444 microbiome data (Gloor et al., 2017). Careful use of FTMS peak intensity data informed by objective, model-based
445 guidance can overcome some of its weaknesses. We encourage further development of the model presented here and
446 inclusion of additional methods developed to address issues that arise in similar data types (e.g., Gloor et al., 2017;
447 Hardwick et al., 2018; Vieira-Silva et al., 2019). While these are important directions, we emphasize that despite
448 peak intensities not necessarily reflecting concentrations, ecological metrics overall appear to perform well. This is
449 likely due to the law of large numbers as FTMS, especially FTICR MS, datasets often contain 1000 or more peaks
450 per sample. Our simulation results indicate that large numbers of identified peaks allow ecological metrics to
451 essentially track towards their true values. We are encouraged by this outcome and look forward to further
452 applications of ecological metrics, concepts, and theory to NOM chemistry. Such advances could be greatly
453 facilitated by a public database of standardized FTICR MS datasets paired with push-button execution of the
454 simulation model for user-defined metrics and subsets of the database.

455
456 **7 Code Availability:** R code for running the simulation models is available on GitHub:
457 https://github.com/stegen/Peak_Intensity_Sims. Python code used to process the empirical data and to generate the
458 associated figures will be available upon publication.

459
460 **8 Data Availability:** Raw and processed data will be made publicly available upon manuscript acceptance.

461
462 **9 Author Contributions:** WK contributed to conceptualization, experimental data curation, formal analysis,
463 methodology, software, visualization, writing-original draft, writing-review/editing; AMP contributed to
464 conceptualization, methodology, visualization, writing-original draft, writing-review/editing; CHC and SMC
465 contributed to investigation and writing-review/editing; JE contributed to sample preparation and writing-
466 review/editing; MMT contributed to conceptualization, methodology, writing-review/editing; JH contributed to
467 conceptualization and writing-review/editing; RKC contributed to project administration, conceptualization,

468 experimental data curation, methodology, funding acquisition, writing-review/editing; JCS contributed to
469 conceptualization, simulation data curation, formal analysis, funding acquisition, investigation, methodology,
470 software, visualization, writing-original draft, writing-review/editing.

471 **10 Competing interests:** The authors declare that they have no conflict of interest.

472
473 **11 Acknowledgements:** A portion of this research was performed on a project award
474 (doi:10.46936/intm.proj.2020.51667/60000248) from the Environmental Molecular Sciences Laboratory, a DOE
475 Office of Science User Facility sponsored by the Biological and Environmental Research program under Contract
476 No. DE-AC05-76RL01830. JCS was also supported by an Early Career Award (grant 74193) to JCS at Pacific
477 Northwest National Laboratory (PNNL), a multiprogram national laboratory operated by Battelle for the United
478 States Department of Energy under contract DE-AC05-76RL01830. We thank Alan Roebuck for useful feedback on
479 the manuscript, Nathan Johnson for graphics development, Charles T. Resch for supplying the artificial river water,
480 Patricia Miller and Jason Toyoda for lab support.

Figure 1. Ecological concepts of α -diversity and β -diversity. Each gray box represents a sample of an ecological community or collection of organic molecules (i.e., a NOM assemblage). Symbols represent individual organisms or molecules. Different biological or molecular species are represented by a combination of shape and color. (Top) Each sample has one biological species (red circles) or one chemical species (red bar), and the species are the same within and between the samples. This reflects minimal α -diversity because there is a single species. This also reflects minimal β -diversity because there is no difference in which species are present in each sample. (Bottom) Each sample has five species (biological or chemical) represented by different colors and symbols. There are no shared species between samples. This reflects maximum α -diversity because every individual is a different species within each sample, and maximum β -diversity because there are no species shared between samples. In real ecological and NOM samples, α -diversity and β -diversity fall between these extremes.

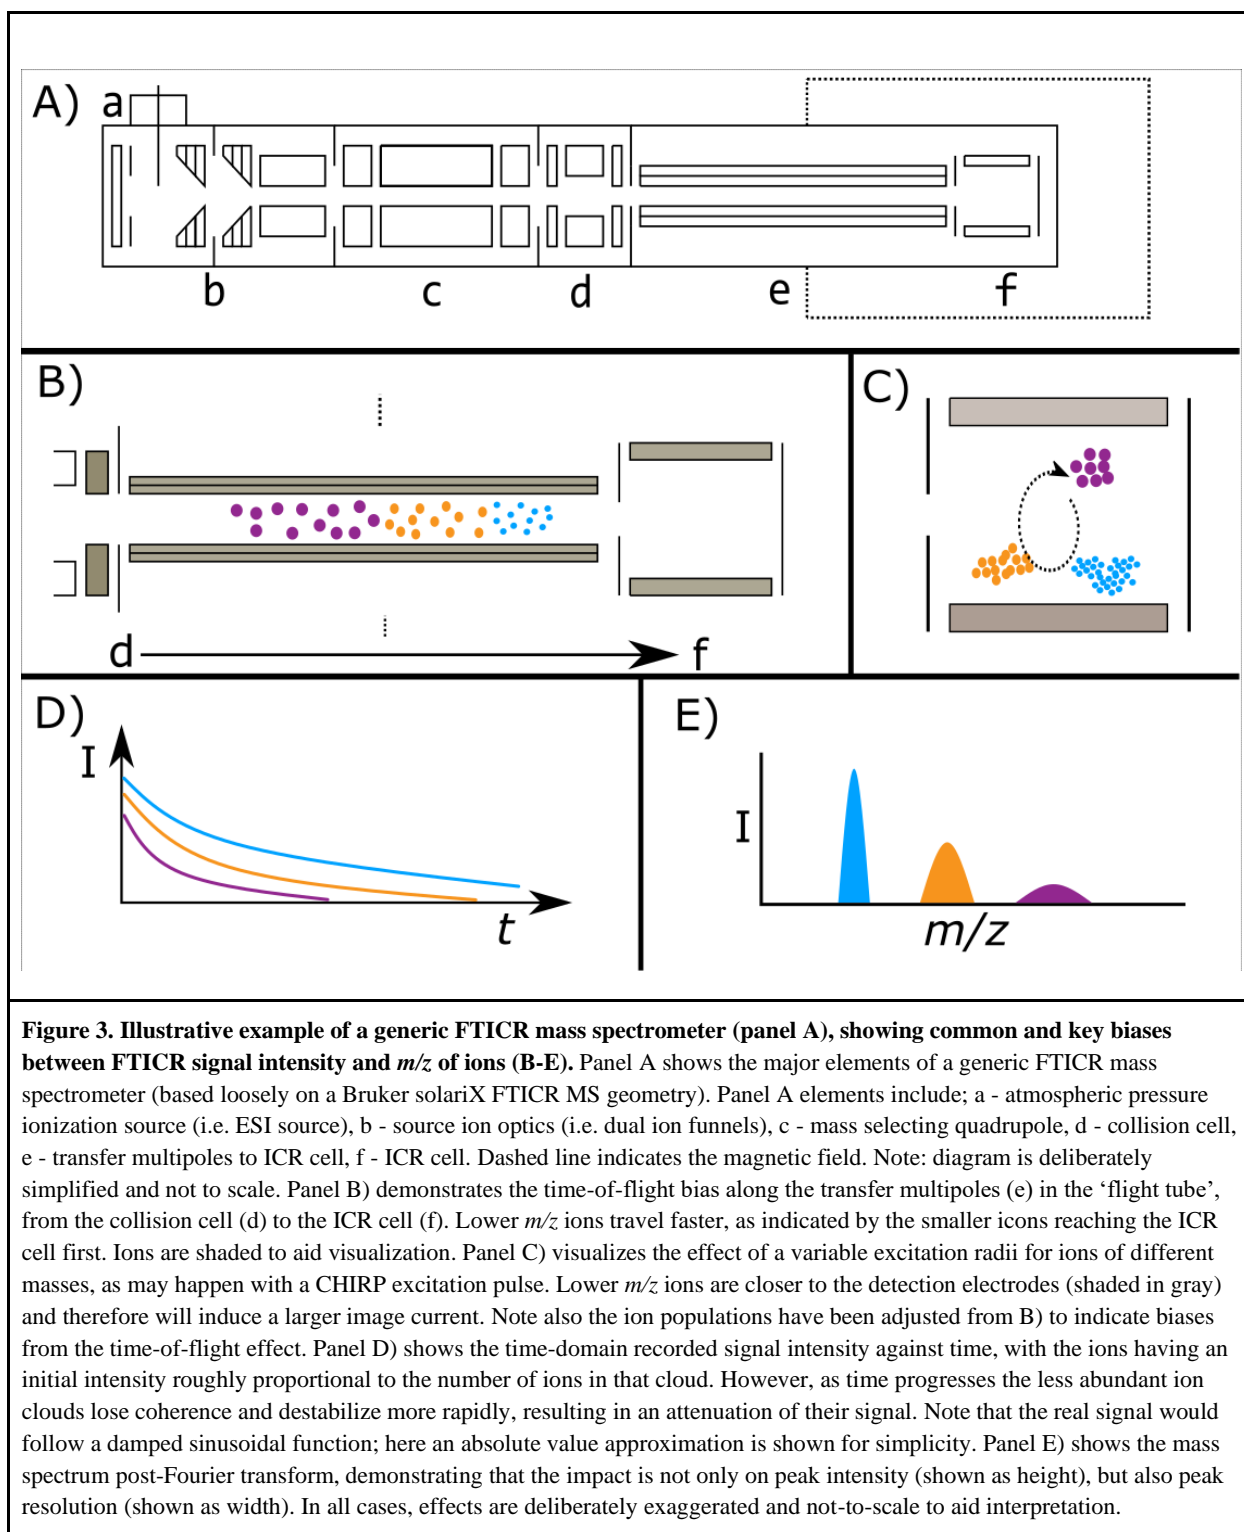

Figure 2. Summary of within-peak and between-peak comparisons of peak intensity. Two idealized mass spectra (i.e., from two samples) are shown with each peak defined by a mass-to-charge ratio (m/z) and represented by a different color. The intensity of each peak in each sample is represented by the height of each colored bar. Within-peak comparisons of intensity are based on comparing intensities at the same m/z across two or more samples. Between-peak comparisons of intensity are based on comparing intensities at two or more m/z values. Between-peak comparisons can be done within a sample (as shown) or between samples (not shown).

Figure 4 - A) Scatterplot visualization of the relationship between signal intensity (relative intensity) and concentration of analyte for three chemically distinct molecules analyzed contemporaneously but independently in pure methanol solvent. Relative intensity indicates data were scaled to the largest signal in any replicate from the associated series of spectra. Linear regression and confidence intervals calculated by the Seaborn plotting library with default settings. X-axis jitter was added to aid visualization of overlapping points. **B)** As with A), but for three structural isomers of chlorogenic acid. X-axis jitter was added to aid visualization of overlapping points. **C-E)** Compounds spiked into three different solvent matrices (methanol, BondElut methanol, and BondElut artificial river water (ARW)) at a fixed concentration (100 ppb), but with addition of SRFA at varying concentrations from 0 to 40 ppm. In all cases, $[M-H]^-$ ion only is shown, but other ions (i.e. $[M+Cl]^-$) were detected. Relative intensities have been scaled per plot for A and B, and are on the same scale for C-E). Pearson R correlation coefficients and p-values are reported in Table S1.

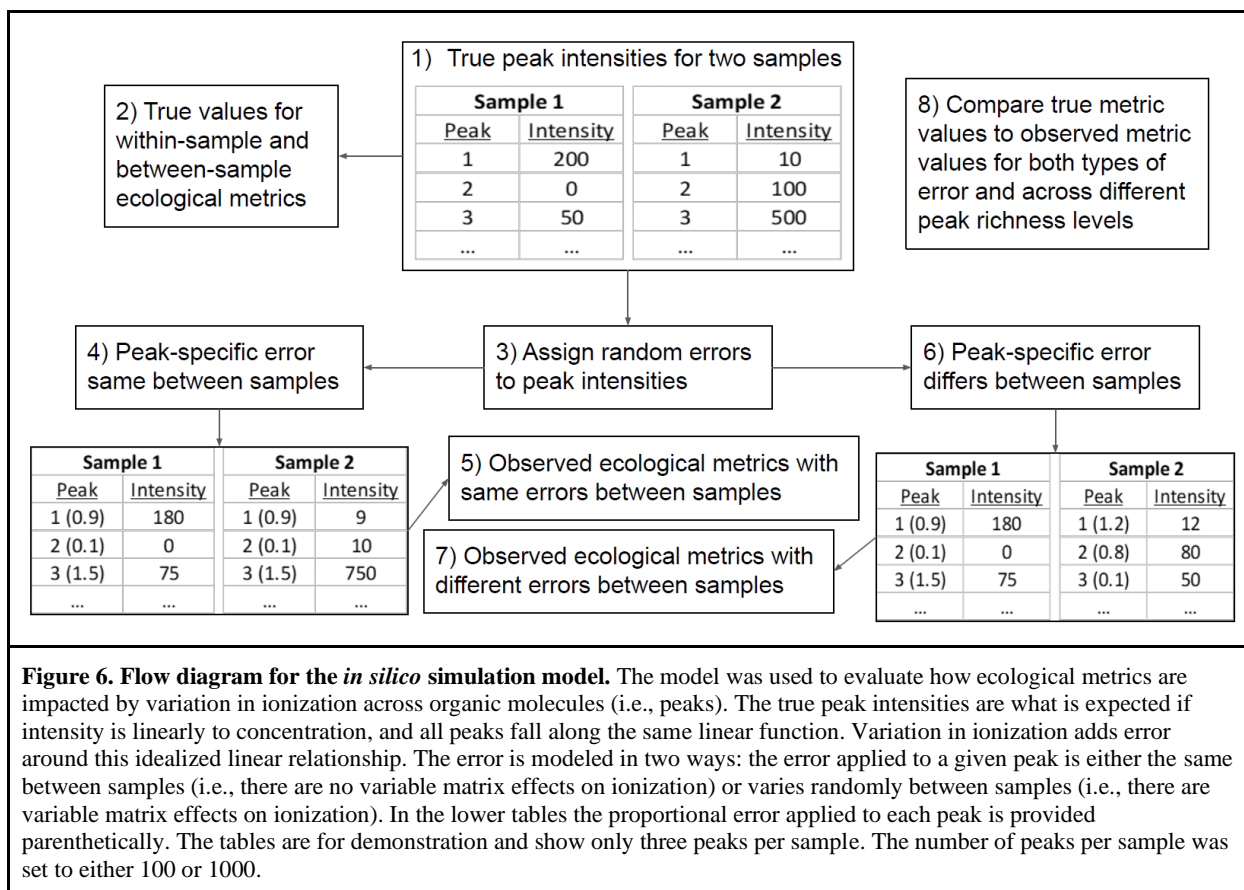

Figure 5. Graphical summary of how FTMS peak intensity data are often treated (left), which is distinct from the reality of those data (right). When surveying the number of individuals of each species within a tree community, there is good confidence that the measured abundances are close to real abundances. This is because there is relatively little variation across species in the ability to detect individuals. FTMS peak intensity data are often used as though they are like tree-community data. However, FTMS data are more like bird-community data. That is, the ability to detect different species varies due to intrinsic factors (e.g., activity patterns, how loud and often birds call, etc.) and extrinsic factors (e.g., habitat structural complexity, predator-induced behavioral changes, etc.). Similarly, the intrinsic physics of a given molecule will impact its ability to ionize and thus its observed peak intensity, and in environmental samples there are thousands of molecular species that impact the ionization ‘behavior’ of each other. FTMS data being more bird-like than tree-like needs to be accounted for when performing ecological analyses using FTMS data.

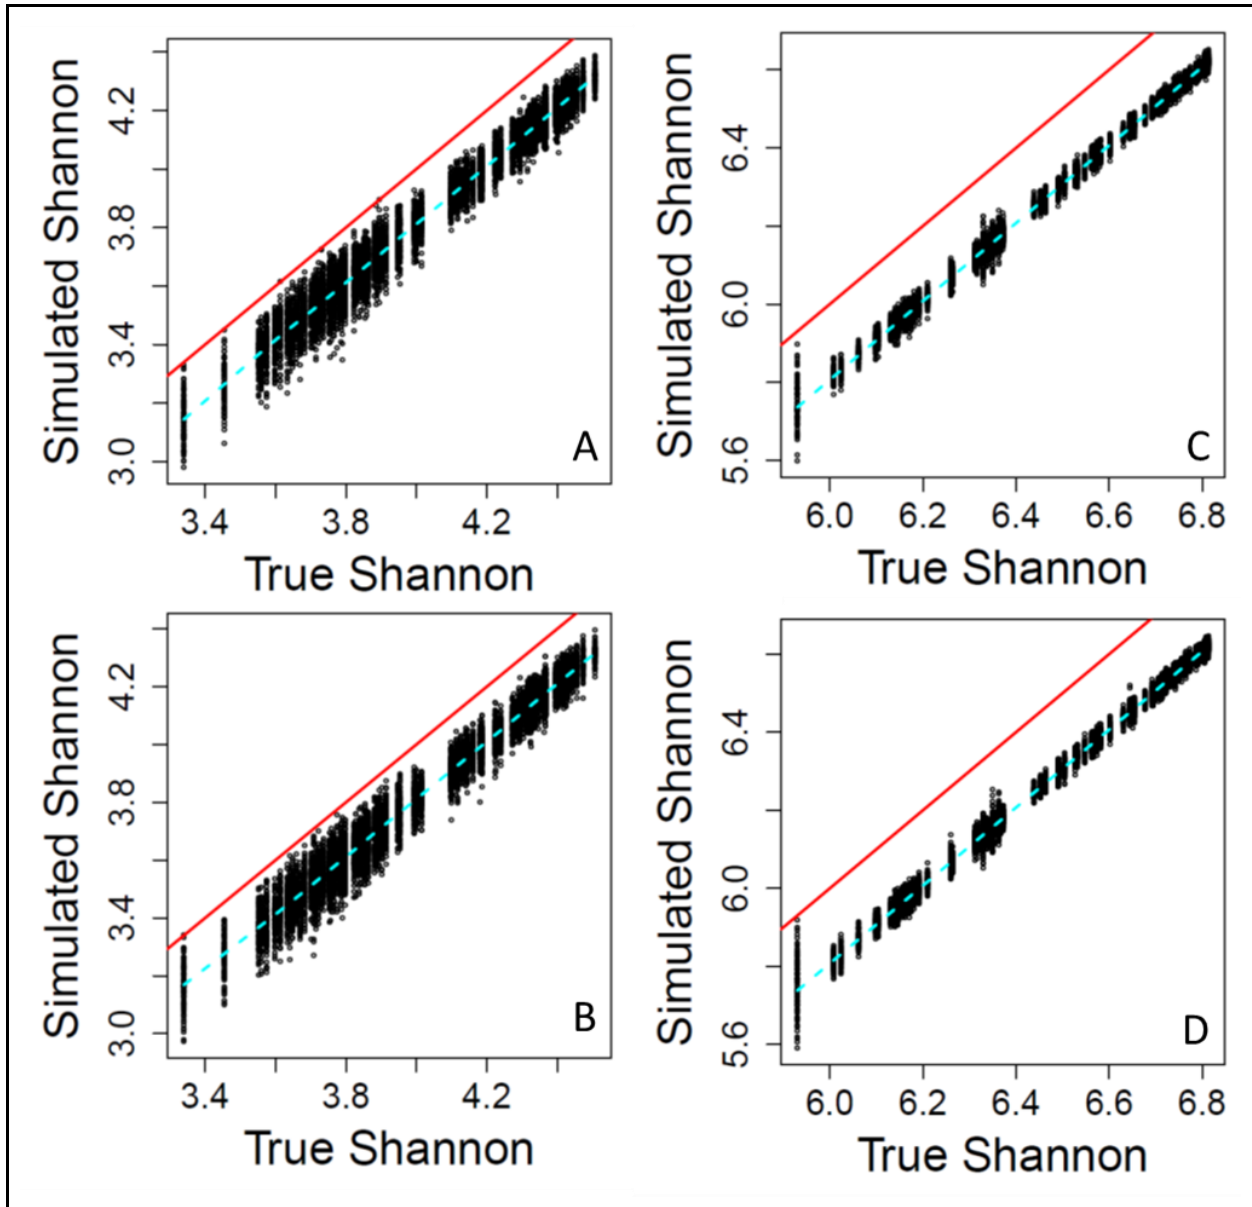

Figure 7. Shannon α -diversity that includes simulated error regressed against true Shannon, across different scenarios. (A) The same error applied to a given peak between samples, and 100 peaks per sample. (B) Different errors applied to a given peak between samples, and 100 peaks per sample. (C) The same error applied to a given peak between samples, and 1000 peaks per sample. (D) Different errors applied to a given peak between samples, and 1000 peaks per sample. On all panels the red line represents the one-to-one line and the dashed line is a spline fit to the data. All data are from the simulation model.

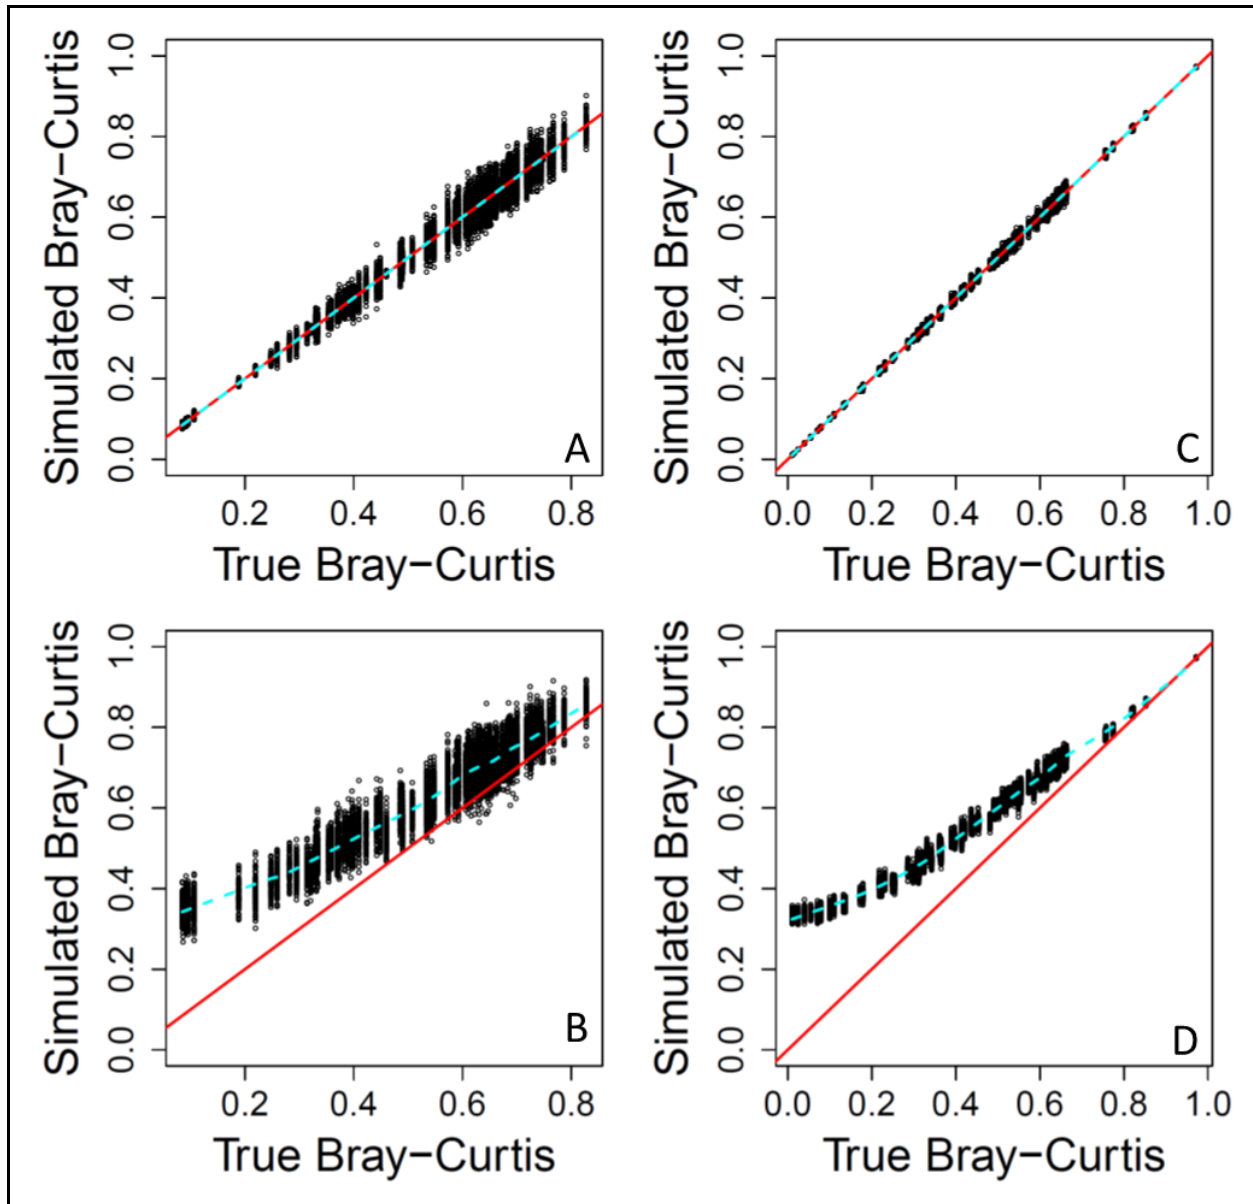

Figure 8. Bray-Curtis dissimilarity as a measure of β -diversity that includes simulated error regressed against true Bray-Curtis, across different scenarios. (A) The same error applied to a given peak between samples, and 100 peaks per sample. (B) Different errors applied to a given peak between samples, and 100 peaks per sample. (C) The same error applied to a given peak between samples, and 1000 peaks per sample. (D) Different errors applied to a given peak between samples, and 1000 peaks per sample. On all panels the red line represents the one-to-one line and the dashed line is a spline fit to the data. All data are from the simulation model.

Figure 9. Mean peak-intensity-weighted trait values that include simulated error regressed against true mean peak-intensity-weighted trait values, across different scenarios. (A) The same error applied to a given peak between samples, and 100 peaks per sample. (B) Different errors applied to a given peak between samples, and 100 peaks per sample. (C) The same error applied to a given peak between samples, and 1000 peaks per sample. (D) Different errors applied to a given peak between samples, and 1000 peaks per sample. On all panels the red line represents the one-to-one line and the dashed line is a spline fit to the data. All data are from the simulation model.
