10 **Abstract.** Heating rates induced by optically significant water constituents (OSCs), e.g. phytoplankton and coloured
11 dissolved organic matter (CDOM), contribute to the seasonal modulation of thermal energy fluxes across the ocean-
12 atmosphere interface in coastal and regional shelf seas. This is investigated in the Western Baltic Sea, a marginal sea
13 characterised by considerable inputs of freshwater carrying nutrients and CDOM, and complex bio-optical and
14 hydrodynamic processes. Using a coupled bio-optical-ocean model (ROMS-Bio-Optic), the inherent optical properties
15 of different OSCs are modelled under varying environmental conditions and the underwater light field is spectrally-
16 resolved in a dynamic ocean. We estimate the relative contribution of these OSCs to the divergence of the heat flux and
17 heating rates and find that phytoplankton dominates the OSC contribution to heating in spring and summer, while
18 CDOM dominates in summer and autumn. The study shows that seasonal and spatial changes in OSCs in the Western
19 Baltic Sea have a small but noticeable impact on radiative heating in surface waters and consequences for the exchange
20 of energy fluxes across the air-sea interface and the distribution of heat within the water column. In the Pomeranian
21 Bight, where riverine influx of CDOM is strongest, water constituent-induced heating rates in surface waters in 2018
22 are estimated to be between 0.8 and 0.9 K m⁻¹ d⁻¹ in spring and summer, predominantly as a result of increased
23 absorption by phytoplankton and CDOM. Further offshore, OSC-induced heating rates during the same periods are
24 estimated to be between 0.4 and 0.8 K m⁻¹ d⁻¹. Warmer surface waters are balanced by cooler subsurface waters. Surface
25 heat fluxes (latent, sensible and longwave) respond to warmer sea surface temperatures with a small increase in heat
26 loss to the atmosphere of 5 Wm⁻² during the period April to September. We find relatively good agreement between our
27 modelled water constituent absorption, and in situ and satellite observations. More rigorous co-located heating rate
28 calculations using an atmosphere-ocean radiative transfer model provide evidence of the suitability of the ROMS-Bio-
29 Optic model for estimating heating rates.

30 **1 Introduction**

31 Radiant energy fluxes impact biological production in the ocean and are modulated in turn as a result of biological
32 production. This has fundamental consequences for upper ocean physics, surface nutrient supply, net primary and export
33 production and the exchange of soluble gases across the air-sea interface into the marine atmospheric boundary layer.

34 The contribution of optically significant water constituents (OSCs) to heating rates in the upper ocean is connected to
35 net primary and export production, through the direct effect of temperature on metabolic rates of marine plankton and
36 increased stratification and reduced vertical exchange of nutrients. This plays an important role in controlling the flow
37 of carbon and energy through pelagic systems (Wohlers et al., 2009; Taucher and Oschlies, 2011), in particular, the
38 partitioning between particulate and dissolved organic carbon, the transfer of primary produced organic matter to higher
39 trophic levels, the efficiency of the biological carbon pump and the exchange of CO₂ across the air-sea interface. Shelf
40 seas and coastal waters are characterised often by highly variable presence of inorganic suspended particulate matter
41 and coloured dissolved organic matter (CDOM). CDOM is the fraction of dissolved organic matter (DOM) that absorbs
42 light in natural waters in parts of the ultraviolet and visible spectral ranges (c. 200 - 550 nm). It is present throughout
43 the world oceans, both open and deep waters, and in coastal and shelf seas. It significantly contributes to the attenuation
44 of light in natural waters and thereby impacts ocean heat content, in particular in coastal and shelf seas (Soppa et al.,
45 2019; Gnanadesikan et al., 2019; Kim et al., 2015, 2016, 2018; Hill, 2008). In the Baltic Sea, CDOM is prevalent and
46 displays strong seasonal and spatial variability (Kowalczyk, 1999; Kowalczyk et al., 2006). Sources of CDOM and
47 changes to its composition through non-conservative processes are tightly coupled to the underwater light field. These
48 will vary with environmental conditions and phytoplankton community structure. Moreover, heterogeneity in
49 phytoplankton pigments and other water constituents will have implications for sub-mesoscale vertical mixing and
50 advective fluxes, and thus water temperature, density and the supply of nutrients to the surface. Understanding how the
51 variable presence of water constituents impacts energy fluxes in the upper ocean and across the air-sea interface, and the
52 accumulative effect on the upper ocean heat budget in shelf seas and coastal waters is of particular importance for our
53 capacity to adequately model regional ocean climate.

54 A number of feedback mechanisms determine the biogeochemical dynamics in the upper ocean layer. Solar
55 radiation penetrating the water column is scattered and absorbed by pure water, as well as by dissolved and particulate
56 water constituents. Absorbed radiation is mostly transformed into heat and thus directly controls heating rates and
57 subsequently impacts the vertical stratification of the euphotic layer. A portion of the light absorbed by autotrophic
58 protists is used for photosynthesis and consequently contributes to biomass production. The vertical distribution of
59 absorbing material may be altered significantly due to biogenic (and in coastal areas, non-biogenic) processes (e.g. by
60 the development of a subsurface algae bloom) which in turn leads to a significant change of the depth range at which
61 heating occurs (e.g. increased heating within the algae layer) and the availability of light (e.g. strongly reduced light
62 availability below the algae layer).

63 Biogeochemical dynamics are especially complex in shelf and coastal waters where organic and inorganic
64 particulate matter as well as CDOM may be present in individually highly varying concentration ranges, e.g. caused by
65 riverine inputs or sediment resuspension from the seafloor. For example, accounting for the highly variable light
66 attenuation in turbid river plumes is critical if nearshore physics are to be resolved correctly (Cahill et al., 2008; Kim et
67 al., 2020). Changes in surface temperature and buoyancy-driven circulation have important consequences for the

68 development, transport and fate of phytoplankton biomass. The resulting carbon fluxes across the air-sea interface,
69 exported to the benthos or advected off the shelf system are key to understanding the carbon budgets of shelf systems
70 and the open ocean.

71 **1.1 Ocean radiant heating and biological production**

72 For studies of heat transfer modulated by biological production in the upper ocean, it is important to accurately
73 prescribe the shortwave solar radiation in the upper water column. Downward solar radiation penetrating into the upper
74 ocean can be partitioned into three spectral domains: Visible (UV/VIS): $\sim 0.30 \mu\text{m} - \sim 0.75 \mu\text{m}$; Near Infrared (NIR):
75 $\sim 0.75 \mu\text{m} - \sim 1.3 \mu\text{m}$; Shortwave Infrared (SWIR): $\sim 1.3 \mu\text{m} - \sim 3.5 \mu\text{m}$. SWIR radiant energy plays an important role in
76 the surface thermal structure of the water column, however, its attenuation can be considered as invariable to changes of
77 water constituents (Morel and Antoine, 1994) as it is almost completely dominated by water absorption and is fully
78 attenuated very close to the sea surface. NIR radiant energy penetrates a bit deeper into the ocean but is still almost
79 entirely absorbed within the topmost one meter layer due to the still strong absorption of pure sea water at these
80 wavelengths. In contrast to that, the (spectral) attenuation of UV/VIS radiant energy within the water body is strongly
81 dependent on the presence of water constituents and may therefore vary considerably horizontally and vertically. More
82 specifically, the variability of UV/VIS in the water column is determined by absorption and scattering of three
83 substance classes: phytoplankton, CDOM and inorganic suspended sediment (Sathyendranath et al., 1989). Radiant
84 energy within the visible range is also harvested by autotrophic protists for photosynthesis purposes.

85 Biogeochemical dynamics in productive waters are characterized by the feedbacks between the absorption of
86 light by dissolved and particulate material and the corresponding ocean radiant heating in the upper water column. This
87 has been elegantly demonstrated for the open ocean where the upper ocean chlorophyll concentration regulates the
88 radiant transmission and heating rates in the mixed layer depth (Lewis et al., 1990; Morel and Antoine, 1994; Ohlmann
89 et al., 1996, 1998, 2000a, b; Murtugudde et al., 2002; Oschlies, 2004; Manizza et al., 2005, 2008). Enhanced near-
90 surface stratification has a positive feedback on phytoplankton growth by restricting phytoplankton within shallower
91 mixed layers with more available light, which in turn increases near surface local heating (Dickey and Falkowski, 2002).
92 Ohlmann et al. (2000) demonstrated that an increase in chlorophyll concentration from 0.03 mg m^{-3} to 3 mg m^{-3} in the
93 upper 10 m of the water column can decrease the solar flux in the waters below by as much as 35 Wm^{-2} . A 10 Wm^{-3}
94 change in the solar radiation absorbed within a 10 m layer can represent a temperature change within that layer of more
95 than $0.6^\circ\text{C month}^{-1}$ (Simpson and Dickey, 1981). Löptien and Meier (2011) show that increased water turbidity affects
96 the summer sea surface temperature trends in the Baltic Sea significantly.

97 **1.2 Biogeochemical ocean models**

98 Despite these findings, coupled ecosystem-circulation models rarely share the same parameterization or source of
99 radiative forcing to drive the hydrodynamics and fuel photosynthesis even though their requirements for information on

100 light and heat overlap. This is in part due to the fact that historically, circulation and ecosystem models have evolved
101 independently and it is only in the last 10 to 15 years that coupling between the two has made significant advances. It is
102 typical that the ecosystem model is “plugged” into a circulation model and communication between the two is in one
103 direction only: state variables (such as temperature) computed in the circulation model are communicated to the
104 biological model at each time step, however, any change to the radiative fluxes as a consequence of biological activity
105 is not necessarily accounted for or communicated back to the circulation model so that potentially available
106 “information” related to heat transfer in the upper ocean and across the ocean-atmosphere interface is not being used.
107 Many parameterizations of the subsurface vertical distribution of shortwave solar radiation have evolved over the last
108 years (e.g. Paulson and Simpson, 1977; Zaneveld and Spinrad, 1980; Simpson and Dickey, 1981; Morel, 1988; Morel
109 and Antoine, 1994; Ohlmann and Siegel, 2000). The most common formulation of radiative forcing in bio-physical
110 models is one directional (i.e. assuming horizontal homogeneity) where radiative transfer is approximated by vertically
111 attenuating the net surface shortwave radiation by an exponential function based on Beer-Lambert Law (Paulson and
112 Simpson, 1977):

113

$$114 \quad I_z = I_{IR} \cdot e^{-k_{IR}z} + I_{VIS} \cdot e^{-k_{VIS}z} \quad (1)$$

115

116 The total surface irradiance is split into two wavebands corresponding to infrared (IR) and visible (VIS), and
117 the attenuation coefficients, k , for both the IR and VIS parts of the spectrum are prescribed according to different Jerlov
118 (1976) water types. For photosynthesis purposes, one of the more simple parameterizations of light attenuation is based
119 on the surface photosynthetically available radiation (PAR) computed as a fraction of the net surface solar flux
120 (typically 43%) and then attenuated through the water column as a function of chlorophyll concentration (e.g. Fennel et
121 al., 2006, 2008; Fennel and Wilkin, 2009). A further level of complexity may be introduced by splitting the visible
122 portion of the light spectrum into two wavebands (red and blue/green) and computing the diffuse attenuation
123 coefficients, k , for the two wavebands as a function of modelled chlorophyll concentration after Morel (1988) as
124 described by Manizza et al. (2008):

125

$$126 \quad I_z = I_{IR} \cdot e^{-k_{IR}z} + I_{RED(z-1)} \cdot e^{-k_{RED}\Delta z} + I_{BLUE(z-1)} \cdot e^{-k_{BLUE}\Delta z} \quad (2)$$

127

128 This chlorophyll-based approach is reasonably accurate for the open ocean where phytoplankton dominates the
129 inherent optical properties of the water constituents (Morel and Prieur, 1977); however, it is inadequate in shelf and
130 coastal oceans as it neglects important contributions from CDOM and suspended sediments. More recently, Neumann et
131 al. (2015) show that, in the Baltic Sea, including more water constituents in the estimation of light attenuation in their
132 model yields a more realistic representation of the light climate, and improved estimates of primary productivity, Secchi
133 disk depth and oxygen concentrations. They estimate $K(\text{PAR})$ by explicitly accounting for modelled phytoplankton

134 biomass, detritus, dissolved organic matter due to metabolism and degradation processes, and parameterizing CDOM as
135 a function of salinity, as follows:

136

$$137 \quad K_{PAR} = k_w + k_c Chl + k_{det} DET + k_{don} DON + k_{CDOM}(S) \quad (3)$$

138

139 where k_w [m^{-1}] is the attenuation coefficient of water, k_c , k_{det} , and k_{don} [$(mg\ N)^{-1}m^2$] are the nitrogen-specific
140 attenuation coefficients of chlorophyllous particles, detritus, and dissolved organic matter, respectively and Chl, DET,
141 and DON [$mg\ N\ m^{-3}$] are the concentrations of phytoplankton biomass, detritus, and dissolved organic matter due to
142 metabolism and degradation processes, respectively. k_{CDOM} [m^{-1}] is the attenuation coefficient of dissolved organic
143 substance transported by rivers with fresh water into the estuary and S is salinity.

144 More recently, Neumann et al. (2021) explicitly consider light absorption due to terrestrial CDOM in their
145 ecosystem model of the Baltic Sea, using earth observation CDOM absorption data from Sentinel-2 MSI as a proxy for
146 terrestrial sources of CDOM. They show a significant improvement in CDOM estimates in particular in the northern
147 parts of the Baltic Sea where the impacts of terrestrial CDOM are large.

148 A few studies have tried to explore the full biophysical feedbacks using coupled physical-biological ocean
149 models (Oschlies, 2004; Manizza et al., 2005; 2008) and fully coupled atmosphere-bio-physical ocean model (Jolliff
150 and Smith, 2014; Wetzel et al., 2006). Notably, results from Oschlies (2004) include a net cooling of the North Atlantic
151 by biota of about $1\ Wm^{-2}$, with enhanced upper ocean stratification in summer and deeper winter mixed layer depths (>
152 100 m) in parts of the subpolar gyre. Coastal upwelling and associated nutrient supply is reduced, especially in coastal
153 upwelling regions of West Africa. Overall, there is a negative feedback of biotically induced radiative heating on
154 chlorophyll-a concentrations, except in parts of the subpolar North Atlantic where intensification of the spring bloom
155 results in increased annual mean chlorophyll-a concentrations. Wetzel et al. (2006) further highlighted the importance of
156 marine biology on the radiative budget of the upper ocean, and found positive feedbacks with the climate system cause
157 a global shift of the seasonal cycle, with the onset of spring occurring about two weeks earlier. Increased wind stress
158 and changes in the shortwave radiation led to significant warming in the mid latitudes in summer and to seasonal
159 modifications of the overall warming in the equatorial Pacific. Jolliff and Smith (2014) demonstrated a regional
160 example of biological modulation of upper ocean physics in Monterey Bay, California and show how the spatiotemporal
161 pattern of a phytoplankton bloom can persist because of enhanced thermal stratification promoting vertical stability
162 and more efficient use of macronutrients. Furthermore, biothermal warming of surface waters modifies the local surface
163 pressure gradient and modulates wind stress patterns.

164 More recent studies which investigate the role of OSCs and surface heating, highlight the role of CDOM in
165 Arctic amplification (e.g. Soppa et al., 2019; Pefanis et al., 2020) and the impact of CDOM on the annual cycle of sea
166 surface temperature in coastal and northern subpolar regions (Gnanadesikan et al., 2019; Kim et al., 2015; 2016; 2018).
167 Soppa et al. (2019) found that a CDOM absorption at 443 nm of $1.77\ m^{-1}$ contributed to an increased radiative heating

168 of $0.6^{\circ}\text{C d}^{-1}$ in the upper 2 m in the Laptev Sea shelf waters, implying increased sea ice melt rates and changes in the
169 surface heat fluxes to the atmosphere. Pefanis et al. (2020) confirm that increases in CDOM in the Arctic amplify
170 surface warming by increasing surface temperatures in summer and decreasing sea-ice concentrations. They also show
171 that summertime surface warming associated with increases in CDOM induces more heat loss to the atmosphere,
172 primarily through latent and sensible heat fluxes. Gnanadesikan et al. (2019) demonstrate that the presence of CDOM
173 leads to an increase in the amplitude of the seasonal cycle of SST over coastal and northern subpolar regions, with
174 potential implications for extreme ocean temperatures. Importantly, they find the size and sign of the change in
175 amplitude are controlled by the interplay between enhanced surface shortwave heating, shading and cooling of the
176 subsurface and the extent to which these are connected by vertical mixing. They show that the interplay between heat
177 term balances varies regionally. In the central Baltic Sea (58°N , 19.5°E), changes in the seasonal cycle of the heat
178 budget are explained by a 1D balance between the penetration of shortwave radiation and vertical mixing (see Figure 3a
179 in Gnanadesikan et al., 2019) with advective and diffusive terms being relatively small. In other regions around the
180 world, the heat term balance is represented by a more complicated interplay between the penetration of shortwave
181 radiation, vertical and horizontal mixing and advection (see Figure 3b, c, d in Gnanadesikan et al., 2019).

182 Lastly, Skákala et al. (2022) demonstrate a significant impact of biogeochemistry on physics in the North West
183 European Shelf, with the light attenuation by chlorophyll being responsible for a 1°C warming in the upper 20 m of the
184 ocean with comparable cooling taking place between 20 and 200 m. They also show that accounting for this water
185 constituent-induced heating improves the timing of the simulated phytoplankton bloom in the region.

186 In this work, we examine the relationship between OSCs, in particular, CDOM, phytoplankton and detritus,
187 and heating rates in the Western Baltic Sea. High concentrations of CDOM optically distinguish the Baltic Sea from
188 other coastal seas (Simis et al., 2017), making it an interesting study site for this application. CDOM also exhibits
189 strong seasonal and spatial variability in the region which is dependent on sources of CDOM and physics, e.g. periods
190 of intensive mixing and high riverine discharge versus periods of thermal stratification, reduced riverine discharge,
191 enhanced biological production and production of CDOM (Kowalczyk, 1999; Kowalczyk et al, 2005a). In this study,
192 we examine precisely this interplay between physics and OSCs using an integrated analysis framework. This consists of
193 a coupled bio-optical ocean model which incorporates the optical properties of key water constituents and explicitly
194 resolves sources of both terrestrial and autochthonous CDOM as a state variable in a 4D ocean state. We model the
195 inherent optical properties of different water constituents under varying environmental conditions and spectrally resolve
196 the underwater light field in a dynamic ocean. From this, we estimate the contribution of key water constituents to
197 surface heating rates and feedbacks with the marine atmospheric boundary layer heat fluxes. We evaluate our estimates
198 of surface heating rates using an ocean-atmosphere radiative transfer model and optical measurements from in situ and
199 remote sensing observations.

200 **2 Methods**

201 **2.1 Study site**

202 Kowalczyk et al. (2006) have shown that there are three pools of CDOM in the waters of the Southern Baltic Sea: a
203 riverine pool, an aged marine pool and a pool primarily produced in offshore waters. They explored the seasonal
204 dependence between the light absorption coefficient of CDOM at 375 nm, $a_{CDOM}(375)$, and salinity and chlorophyll-*a*
205 concentrations in the Southern Baltic Sea and found a seasonal dependence between physical processes and the source
206 of CDOM. In March, April and November, months of intensive mixing and high riverine discharge, most of the
207 variability in $a_{CDOM}(375)$ values could be explained by dilution of terrestrially derived CDOM alone. In February,
208 May and September, months of thermal stratification, reduced riverine discharge and enhanced biological activity,
209 autochthonous production of CDOM was found to be a significant source of CDOM in the Southern Baltic Sea.
210 Changes in the values of spectral slope coefficients are regarded as an indicator of compositional changes in CDOM.
211 These changes can be a result of either conservative mixing processes, i.e. mixing, or non-conservative processes, e.g.
212 production, degradation or flocculation (Kowalczyk et al., 2006).

213

214

215

216 Figure 1: Western Baltic Sea model domain bathymetry (m) with location of model output analysis stations, Darß Sill
217 (DS), Arkona Sea (AS), Oder Bank (OB) and Bornholm Basin (BB) (green dots) and in situ CDOM and NAP (non-
218 algal particle) absorption measurements from the Institute of Oceanology of the Polish Academy of Sciences, IOPAN
219 (red dots).

220

221 Our study site in the Western Baltic Sea (Figure 1) includes the Bornholm Basin, where we expect the seasonal cycle to
222 be explained by a 1D balance between the penetration of shortwave radiation and vertical mixing (Gnanadesikan et al.,
223 2019), and the Darß Sill, Arkona Sea and Oder Bank, where advection and diffusion will also contribute to the seasonal
224 heat balance, making for an interesting contrast between local regimes. At the Bornholm Basin, we expect to find
225 marine CDOM, at the Darß Sill and Arkona Sea, we expect to find a mixture of riverine and marine CDOM, depending
226 on the season, while at the Oder Bank, we expect the CDOM pool to be dominated by riverine sources from multiple
227 inlets and rivers connecting the Oder River outlet through Szczecin Lagoon with the Greifswalder Bodden and the
228 coastal Baltic Sea (Kowalczyk et al., 1999).

229 2.2 Theory

230 Light penetrating a water body can be described as consisting of three streams (Aas, 1987; Ackleson et al., 1994; Gregg,
231 2002 and Dutkiewicz et al., 2015). These are the downward direct irradiance, E_{dir} , the downward diffuse irradiance, E_{diff}
232 and the upward diffuse irradiance, E_u . $E_{dir} + E_{diff}$ is commonly referred to as downward irradiance, E_d . For studies of
233 heat transfer and photosynthesis, we need to know the scalar irradiance, E_0 which describes the light field integrated
234 over a sphere, and is thus independent of direction. All of these irradiance quantities (E_{dir} , E_{diff} , E_u and E_0) are a function
235 of wavelength and depth.

236 Following Morel (1988), the rate of radiant energy converted into heat can be estimated as follows:

237

$$238 \frac{dT}{dt} = -\frac{d(E_d - E_u)}{dz} \frac{1}{\rho C_p} \quad (4)$$

239

240 where the first term on the right hand side is the heat flux, E_d and E_u are the downward and upward irradiances,
241 respectively, ρ is the in situ density and C_p is the specific heat capacity of water. In a horizontally homogeneous water
242 body, the divergence of the radiative flux can be approximated as follows (Morel, 1988):

243

$$244 \frac{d(E_d - E_u)}{dz} \cong -aE_0 \approx K_d E_d \quad (5)$$

245

246 where a is the local absorption coefficient, E_0 is the scalar irradiance at the depth in question and K_d is the
247 downward diffuse attenuation coefficient for downwelling irradiance. These quantities are all dependent on depth,
248 concentrations of OSCs (e.g. phytoplankton pigments, CDOM, detritus) and wavelength. Thus,

249

$$250 \frac{dT}{dt} = -\frac{\int_{400}^{700} [E_d(\lambda, z) K_d(\lambda, z)] d\lambda}{\rho C_p} \quad (6)$$

251

252 K_d varies with both absorption, a , and scattering b , as well as with the angular distribution of the incoming
253 light field. It can be calculated from E_d , as follows (Gordon et al., 1980):

254

$$255 \quad K_d = \frac{-d \ln E_d(\lambda, z)}{dz} = \frac{-1}{E_d(\lambda, z)} \frac{dE_d(\lambda, z)}{dz} \quad (7)$$

256

257 Biogeochemical-optical relationships vary significantly over different regions and/or seasons, therefore,
258 regional and temporal relationships have been adopted to cope with such variations when information concerning the
259 directionality of the underwater light field is limited. For example, in open ocean waters, where attenuation of
260 underwater light is primarily a function of chlorophyll concentration, Sathyendranath and Platt (1988) parameterize K_d ,
261 as follows:

262

$$263 \quad K_d = \frac{a+b}{\mu_0} \quad (8)$$

264

265 where a is the absorption and b is the total scattering (forward and backscatter) of OSCs, while μ_0 is the
266 average cosine, which tells you how much the light field differs from isotropic conditions.

267 In more complex coastal waters, Lee et al. (2005) have derived an empirical algorithm to parameterize K_d , as
268 follows:

269

$$270 \quad K_d = (1 + 0.005\theta)a(\lambda, z) + 4.18(1 - 0.52e^{-10.8a(\lambda, z)})b_b(\lambda, z) \quad (9)$$

271

272 where θ is the solar zenith angle in degrees and b_b is the backscatter coefficient.

273 If the absorption and scattering properties of different water constituents are known, K_d can be estimated using
274 Eq. (8) or Eq. (9) and E_d can then be calculated using Eq. (10).

275

$$276 \quad E_d = E_d(0)e^{-K_d z} \quad (10)$$

277

278 Thus, the heat balance relationship described in Eq. (6), can be used to estimate heating rates.

279

280 2.3 Model system

281 2.3.1 Regional Ocean Modelling System, ROMS

282 The ocean model component, ROMS, is widely used for shelf circulation (e.g. Haidvogel et al., 2008, Wilkin et al.,
283 2011) and coupled physical-biological applications (e.g. Cahill et al., 2008; 2016, Fennel et al., 2006; 2008; 2013,
284 Fennel and Wilkin, 2009). The ROMS computational kernel (Shchepetkin and McWilliams, 2005) produces accurate
285 evolution of tracer fields, which is a particularly attractive feature for biogeochemical modelling because it facilitates
286 the correct interaction among tracers and accounting of total nutrient and carbon budgets. Within ROMS, we have
287 incorporated a novel spectrally-resolved bio-optical module, herein called Bio-Optic.

288 BioOptic is an adaptation of the carbon-based, ecological/optical modelling system Ecosim (Bissett et al.,
289 1999a, b) which was developed for simulations of carbon cycling and biological productivity. It simulates up to four
290 phytoplankton functional groups each with a characteristic pigment suite which varies with the group carbon-to-
291 chlorophyll-a ratio, C:Chla. The properties of each functional group evolve over time as a function of light and nutrient
292 conditions (i.e. NO_3 , NH_4 , PO_4 , SiO and FeO). Marine and riverine sources of dissolved organic carbon (DOC and
293 CDOC) are accounted for and explicitly resolved into labile (e.g. available for biological and photo-degradation) and
294 relict (e.g. available for photo-degradation) forms. Dissolved inorganic carbon is also accounted for. Riverine sources of
295 carbon and nutrients are introduced via point sources. The underwater light field is spectrally-resolved between 400 and
296 700 nm, which allows for differential growth of different phytoplankton groups that have unique pigment complements.
297 The interaction between Ecosim's components describe autotrophic growth of and competition between phytoplankton
298 groups, differential carbon and nitrogen cycling, nitrogen fixation and grazing.

299 BioOptic builds on Ecosim's functionality as follows. The inherent optical properties (absorption, scatter and
300 backscatter) of each of the OSCs (i.e. phytoplankton, detritus and CDOM) are explicitly resolved and their individual
301 contribution to the downward attenuation and downward and scalar irradiance fields is calculated. The surface solar
302 downwelling spectral irradiance, $E_d(\lambda, 0^-)$ and the average cosine zenith angle, $\mu_0(\lambda, 0^-)$, just beneath the sea surface, are
303 calculated according to Gregg and Carder (1990). This includes the impact of clouds, water vapour and aerosols in the
304 atmosphere and the surface roughness and reflectance at the ocean-atmosphere interface. Spectral irradiances between
305 400 and 700 nm are provided at 5 nm intervals. The downwelling irradiance attenuation coefficient, K_d , is calculated
306 following Eq. (9) after Lee et al. (2005). The spectrally-resolved downward light stream, $E_d(\lambda, z)$, which is calculated
307 according to Eq. (10), incorporates both direct and diffuse components of the light field and is attenuated by absorption,
308 a , and scattering, b (forward, b_f and backward, b_b) of phytoplankton, detritus and CDOM. The average cosine is
309 modified with depth as a function of absorption and backscattering, and the total scalar irradiance, $E_0(\lambda, z)$, which is the
310 light available to phytoplankton, is calculated following Eq. (5) after Morel (1988).

311 The explicit calculation of in-water spectrally-resolved absorption, scattering and backscattering coefficients,
312 average cosine, downwelling irradiance attenuation coefficient, K_d , in addition to the scalar, E_0 , and downward, E_d ,
313 irradiance fields, has important implications. The spectrally-resolved underwater light field drives the evolution of

314 OSCs in the ecosystem model, while the OSCs in turn determine the evolution of the light field in each layer by
315 absorption and scattering of the light. This means that the OSCs' contribution to the divergence of the heat flux (Morel,
316 1988) can be accounted for within the full hydrodynamic solution. Furthermore, water constituent-induced heating rates
317 can be assessed and their impact on the ocean sea surface temperature is communicated to the bulk flux formulation of
318 the atmosphere in the modelling system.

319 While this still represents a very simplified treatment of radiative transfer with the water column, it does
320 permit a direct evaluation of the optical terms and heating rates with those derived from a full solution of the radiative
321 transfer equations and provides a means to improving the parameterization of water constituent-based heat flux
322 algorithms in ocean models.

323 **2.3.2 Vector radiative transfer model, MOMO**

324 A more rigorous treatment of the vertical structure of the light field is provided by atmosphere-ocean radiative transfer
325 models, such as MOMO (Fell and Fischer, 2001), which simulate the light field in the stratified atmosphere-ocean
326 system for the VIS and NIR spectral ranges. MOMO uses the matrix operator method to calculate zenithally and
327 azimuthally resolved light fields for different types and concentrations of optically active components in the ocean and
328 atmosphere, thus, the full directionality of the light field is accounted for. The main advantage of the matrix-operator
329 method is its efficiency in simulating light propagation in optically dense media. It is therefore particularly suited for
330 the use in the development of remote sensing algorithms for the retrieval of water constituents. It is most recently
331 described in Hollstein and Fischer (2012) and is based on previous work by Fischer and Grassl (1984) and Fell and
332 Fischer (2001). It has been successfully applied to remote sensing of lakes (Heege and Fischer, 2004), analysis of hyper-
333 spectral, ocean colour data to derive surface fluorescence signals (Guanter et al., 2010), analysis of ocean color data
334 from MERIS measurements (Zhang et al., 2003) and a new retrieval of sun-induced chlorophyll fluorescence in water
335 from ocean colour measurements (Kritten et al., 2020). For our purposes, the most pertinent elements of MOMO
336 include the calculation of the spectrally-resolved downward surface irradiance for the VIS and NIR ranges, the direct
337 and diffuse downwelling and the diffuse upwelling components of the underwater light field.

338 **2.4 Experimental setup**

339 The ROMS Bio-Optic modelling system was configured for the Western Baltic Sea as described in Table 1. The model
340 domain has a horizontal resolution of ~ 1.8km with 285 x 169 grid points in the horizontal, 30 sigma levels in the
341 vertical, a bulk flux atmosphere forced with DWD-ICON output (Zängl et al., 2015) and river forcing including runoff
342 and biogeochemistry derived from HELCOM PLC (Pollution Load Compilation) data (Neumann, pers. comm). Open
343 boundaries to the north and east were forced with output from GETM physics (Gräwe et al., 2015a, b) using a
344 combination of Chapman / Flather conditions for u and v velocities and transports, and Radiation + Nudging for
345 temperature and salinity. This 3D setup is based on an existing GETM physics setup which has been previously

346 evaluated and published (Gräwe et al., 2015a,b). We focus our evaluation on the modelled inherent optical properties of
347 the water constituents using observations from Kowalczyk et al. (2005a,b) and Meler et al. (2016a,b).

348 We performed two experiments, as follows:

349 1. 3D Western Baltic Sea, feedback of constituent-induced heating into hydrodynamic solution (herein referred to
350 as “biofeed”)

351 2. 3D Western Baltic Sea, no feedback of constituent-induced heating into hydrodynamic solution (herein referred
352 to as “nobiofeed”)

353 The simulation period for both experiments was 2018.

354

355 **Table 1: Model configuration**

Model Configuration	
Components	3D Western Baltic Sea
Model Grid	285 x 169 (1nm), 30 sigma levels
Simulation Period	2018
Boundary Conditions	Chapman for zeta, Flather for ubar and vbar; Radiation + Nudging for temperature and salinity
Bulk Flux Atmosphere	DWD-ICON 3-hourly
River Forcing	HELCOM PLC (Pollution Load Compilation), Neumann (pers. comm.)
Initial Condition	GETM / ERGOM
Time Step	DT = 30s; NDTFAST = 20s
Evaluation	Water constituent absorption: <ul style="list-style-type: none">• Kolwaczuk et al, 2005; Meler et al., 2016; MERIS Climatology Water constituent-induced heating rates: <ul style="list-style-type: none">• Comparable MOMO full radiative transfer calculations at Bornholm Basin

356

357 MOMO simulations were performed over a range of solar zenith angles representative of seasons in the
358 Western Baltic Sea using phytoplankton, CDOM and detrital absorption and scattering coefficients modelled using
359 ROMS-Bio-Optic. Phase functions measured by Siegel et al. (2005) for various Baltic Sea coastal waters indicate that
360 the Baltic Sea in general has a relatively low backscatter. Seasonal heating rates were derived from ROMS-Bio-Optic at
361 the Bornholm Basin location and from comparable MOMO simulations in order to assess the suitability of the
362 simplified treatment of radiative transfer in ROMS-Bio-Optic and the implications of not resolving the full
363 directionality of the light field therein.

364 **2.5 In situ and remotely sensed data**

365 In situ observations and remotely sensed data from the MERIS ocean colour archive of CDOM absorption at 443 nm
366 were used to develop a climatology of CDOM absorption with which to evaluate our modelled estimates of seasonal
367 CDOM absorption. Below, the source and processing of the different data sets are briefly described.

368 **2.5.1 In situ data**

369 A time series (1994 - 2017) of in situ observations of CDOM absorption at 443 nm was reprocessed into seasonal means
370 for our study area (Figure 1). This data set was collected as a result of the implementation of numerous research projects
371 and statutory research programs conducted by the Remote Sensing Laboratory at the Institute of Oceanology, Polish
372 Academy of Sciences (IOPAN), Sopot Poland in the whole Baltic Sea. The main aim of the study on CDOM optical
373 properties was the assessment of its temporal and spatial variability (Kowalczyk and Kaczmarek, 1996, Kowalczyk,
374 1999) and its relation to hydrodynamic conditions and Baltic Sea productivity (Kowalczyk et al., 2006). As the primary
375 goal of this research was the development and validation of ocean colour remote sensing algorithms (Kowalczyk et al.,
376 2005a), the vast majority of samples for determination of CDOM absorption spectrum were collected in the surface
377 layer. However, since 2014, samples were also collected within the water column, depending on the thermohaline
378 stratification of water masses and depth distribution of autotrophic protists, in order to better resolve the impact of non-
379 linear processes (i.e. photo-degradation, autochthonous production by phytoplankton, diffusion from bottom sediments)
380 influencing CDOM optical properties (Kowalczyk et al., 2015). The sampling program is conducted in the whole Baltic
381 Sea and is designed to resolve the spatial variability of the CDOM absorption coefficient. We use a subset of this time
382 series located in our study area (Figure 1). Most of the samples were taken in spring and autumn, with a smaller number
383 of samples collected in winter and summer mostly due to adverse weather conditions or unavailability of research
384 vessels in summer months. Water samples were collected by Niskin bottle and were filtered first through acid-washed
385 Whatman glass fibre filters (GF/F, nominal pore size 0.7 µm). The water was then passed through acid washed
386 membrane filters with 0.2 µm pore to remove fine-sized particles. From 2014 until the present, water for CDOM
387 absorption spectra were gravity filtered directly from Niskin bottles through Millipore Opticap XL4 Durapore filter
388 cartridge with nominal pore size 0.2 µm. Filtered water was kept in acid washed amber glass 200 ml sample bottles
389 until spectrophotometric analysis, which was performed with use of various models of bench top research grade, double
390 beam spectrophotometers both in land base laboratory (Kowalczyk and Kaczmarek, 1996; Kowalczyk, 1999) and on the
391 ship (Kowalczyk et al., 2005a,b, 2006). The cuvette pathlength was 5 or 10 cm depending on the spectrophotometer
392 model. MilliQ water was used as the reference for all measurements. The absorption coefficient $a_{CDOM}(\lambda)$ was
393 calculated using Eq. (11) as follows:

394

395
$$a_{CDOM}(\lambda) = \frac{2.303A(\lambda)}{L} \quad (11)$$

396

397 where L is the optical path length, A is the absorbance (the flux that has been absorbed) and the factor 2.303 is the
398 natural logarithm of 10.

399 The whole CDOM absorption data base in the IOPAN repository, collected between 1994 and 2017, was
400 reprocessed to calculate the spectrum slope coefficient, S . A nonlinear least squares fitting method using a Trust-Region
401 algorithm implemented in Matlab was applied (Stedmon et al., 2000, Kowalczyk et al., 2006) in the spectral range 300-
402 600 nm, using Eq. (12) as follows:

403

$$404 \quad a_{CDOM}(\lambda) = a_{CDOM}(\lambda_0)e^{-S(\lambda_0-\lambda)} + K \quad (12)$$

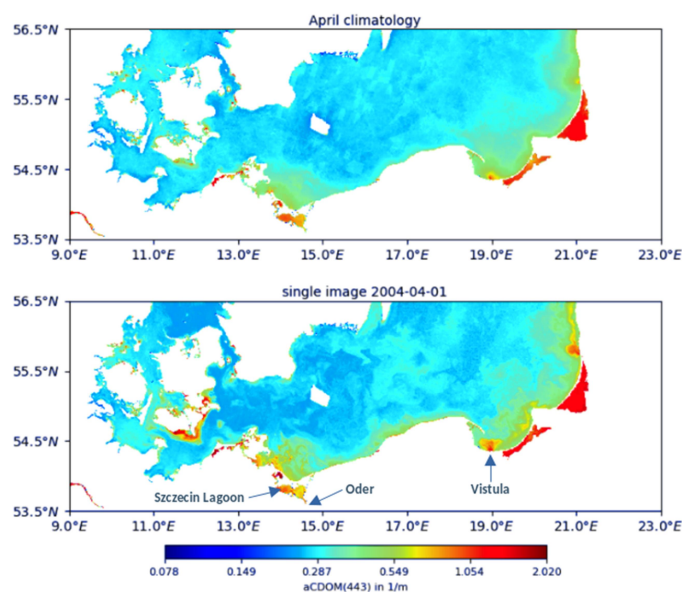

405

406 where λ_0 is 350 nm, and K is a background constant that allows for any baseline shift caused by residual
407 scattering by fine size particle fractions, micro-air bubbles or colloidal material present in the sample, refractive index
408 differences between sample and the reference, or attenuation not due to CDOM. The parameters $a_{CDOM}(350)$, S , and
409 K were estimated simultaneously via non-linear regression using Eq. (12).

410 **2.5.2 Remotely sensed data**

411 MERIS FRS L2 (full resolution level 2) product from 2003 to 2012 was used to create a monthly climatology of CDOM
412 absorption for the Western Baltic Sea region. The MERIS FRS L2 product was processed with the C2RCC algorithm
413 (Doerffer and Schiller, 2007) which has been trained with data-sets from European coastal waters. Full details of the
414 post processing of the MERIS data into a climatology can be found in Röhrenbach (2019). A monthly climatology for
415 the complete time frame of the MERIS archive was created and includes the mean value, standard deviation and number
416 of observations for each point.

417

418

419

420 Figure 2: April climatology (top) and snapshot (01.04.2004) (bottom) of CDOM absorption at 443 nm (adapted from

421

Röhrenbach, 2019).

422

423 Figure 2 shows the difference between a snapshot of the MERIS data product (01.04.2004) and the
424 corresponding April climatology. The snapshot has almost complete data coverage, which is quite rare compared to
425 other time periods where only a small part of the region of interest is in the frame or free of cloud coverage. The
426 climatology smooths the spatial variability, providing the average spatial distribution and gradients in CDOM
427 absorption. High values of aCDOM(443) can be seen around the river mouths of the Vistula river ($\approx 1.7 \text{ m}^{-1}$) and the
428 Oder river ($\approx 0.7 \text{ m}^{-1}$), whereas offshore areas show lower values ($\approx 0.2 \text{ m}^{-1}$) and spatial variability. The snapshot image
429 presents the typical situation at the beginning of the spring freshet. Both Vistula and Oder rivers have similar
430 hydrographic properties with maximum flow observed in April and May and minimum flow in June and February. The
431 land use in the catchment is also similar and consists of a mixture of agriculture, forestry and urbanised areas. The
432 difference in aCDOM(443) values and the spatial extent of fresh water plumes seen as areas with elevated CDOM
433 absorption results from the geomorphology of the outlets. The Vistula River has artificial outlets, built in 1895, and this
434 channel carries up to 90 % of the flow with only a small fraction feeding old deltaic branches, cut off by locks and dikes.
435 The Oder river outlet is less transformed by human activity, and the Oder River feeds the Szczecin Lagoon which is
436 connected to the coastal Baltic Sea via three inlets: two located in Poland (Swina and Dziwna) and one in Germany
437 (Peene). The shallow Szczecin Lagoon acts as a buffer and biogeochemical reactor, where photochemical, microbial and

438 physical (flocculation) transformation of CDOM may occur leading to effective decreased absorption values recorded
439 on the marine side of the estuary.

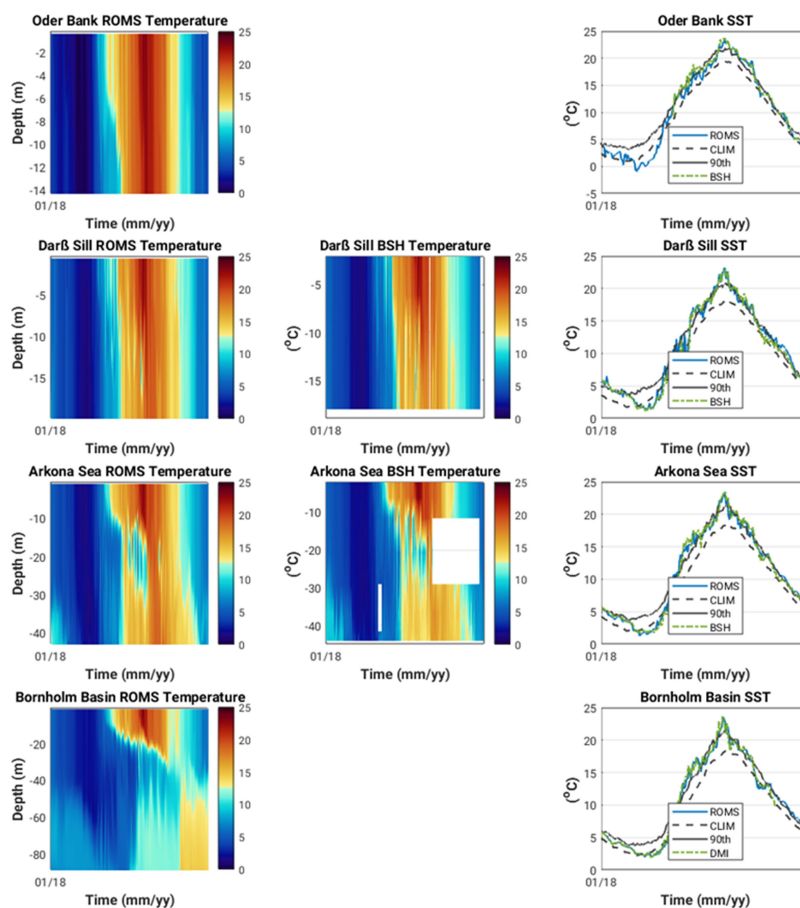

440 **3 Results**

441 In section 3.1, we show the results from the biofeed experiment which includes the feedback from OSC-induced heating
442 into the hydrodynamic solution. In section, 3.2 we show the difference between the biofeed experiment and the
443 nobiofeed experiment where no feedback from OSC-induced heating is included in the hydrodynamic solution.

444 **3.1 Seasonal cycle of temperature and the inherent and apparent optical properties of OSCs at Oder Bank, Darß 445 Sill, Arkona Sea and Bornholm Basin in Western Baltic Sea**

446 The modelled versus observed annual cycle of temperature at the different locations are shown in Figure 3. High
447 resolution temporal and vertically resolved observations for 2018 were only available at Darß Sill and Arkona Sea sites
448 (middle plots, Figure 3). Oder Bank and Darß Sill are shallow, well-mixed locations, where seasonal warming and
449 cooling of the whole water column takes place between May and October. At the deeper Arkona Sea and Bornholm
450 Basin locations, the onset of seasonal stratification sets in early May and starts to break down in late October. Intense
451 summertime warming late July, early August (SST ~ 25°C) leads to a deepening of the thermocline from c. 20 m to the
452 seafloor at Arkona Sea and to c. 38 m at Bornholm Basin. Overall, there is very good agreement between the modelled
453 biofeed results and observed temperature fields at all locations, especially the sea surface temperature (see Table 2 for r^2 ,
454 RMSE and BIAS statistics).

455

456

457

458 Figure 3: Modelled (left) versus observed (middle) annual cycle of temperature and sea surface temperature (right) in
459 Oder Bank, Darß Sill, Arkona Sea and Bornholm Basin. (see text for details).

460

461 This is especially important as 2018 was a year where two significant marine heat waves (defined as periods where the
462 surface temperature exceeds the 90th percentile of the 30 year local mean for longer than 5 days) took place in May -
463 June (38 days) and July – August (32 days). This result confirms the importance of accounting for the contribution of
464 OSCs to the transfer of light energy.

465

466

467 **Table 2: Model versus observations statistics**

	r^2	RMSE	BIAS
Oder Bank	0.98	0.025	0.0017
Darß Sill	0.98	0.020	-0.0010
Arkona Sea	0.99	0.016	-0.0010
Bornholm Basin	0.99	0.005	0.0003

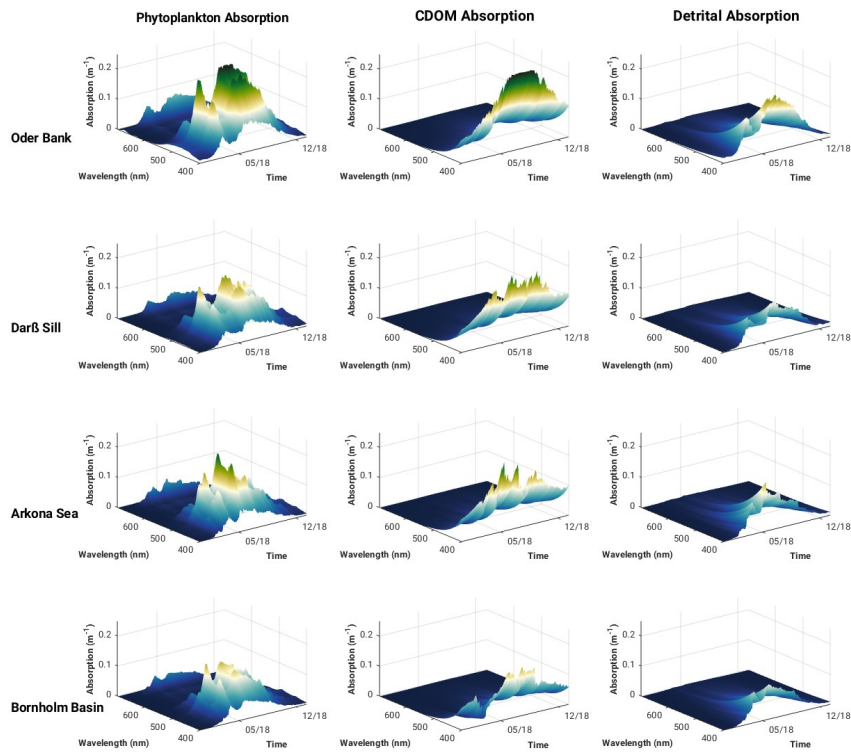

468

469 Modelled seasonal spectral surface absorption from the 3D Western Baltic Sea experiment for phytoplankton,
470 CDOM and detritus is shown for Oder Bank, Darß Sill, Arkona Sea and the Bornholm Basin (Figure 4) show typical
471 absorption characteristics for the individual constituents. CDOM and detritus have high absorption values at the blue
472 end of the spectrum, while phytoplankton shows two maxima, one between 440 nm and 490 nm and a smaller one
473 around 670 nm. There is a clear seasonal pattern for each of the constituents, with spring and summer being peak
474 seasons for phytoplankton blooms, and summer and autumn favouring increased CDOM and detrital absorption.
475 Considerable variability in absorption characteristics is evident between the locations. The highest absorption for all the
476 constituents is seen at the coastal Oder Bank location, which is strongly influenced by riverine inputs from the Oder
477 River. There is a decreasing gradient, especially in CDOM and detrital absorption, moving from the coastal zone to the
478 offshore regions. The summer phytoplankton bloom in the Arkona Sea has a higher peak than the Darß Sill.

479 CDOM, detritus and phytoplankton specific absorption curves intersect around 442 nm, making this an
480 interesting wavelength to explore further with respect to the impact of these constituents on the vertical distribution of
481 absorption and the downward attenuation and irradiance fields.

482 The vertical profiles of phytoplankton, CDOM and detrital absorption at 442 nm (Figure 5) show the vertical
483 extent of water constituent absorption to be the full water column at Oder Bank and Darß Sill and between 15 and 20 m
484 depth at Arkona Sea and Bornholm Basin. In spring and especially in summer, phytoplankton dominate sub-surface
485 absorption at all locations, followed by CDOM and then detrital absorption.

486 The spectrally-resolved surface downward attenuation (K_d) and downward irradiance (E_d) at each of the
487 locations shown in Figure 6 reflect the seasonal impact of the water constituent absorption and solar irradiance.
488 Irradiance at the surface peaks in summer and is at its lowest in winter, as expected. The slight modification of
489 downwelling irradiance intensity in the Baltic Sea depends on atmospheric conditions. Results of direct measurements
490 and local parameterizations of radiative transfer models summarised by Dera and Woźniak (2010) indicate that observed
491 monthly averaged solar irradiance intensities at the sea level in the Baltic Sea are always lower than model estimates
492 based on the clear sky assumption. Atmospheric conditions have a regional and seasonal impact on observed solar
493 irradiance entities e.g. in the southern Baltic Proper and western Baltic Sea, the long-term monthly average for E_d at the
494 surface in May is only 4.8 and 1.8 Wm^{-2} , respectively, lower from E_d intensity observed in June in both regions. This is
495 caused by much lower cloud cover over Baltic Sea observed in May than in June.

496

497

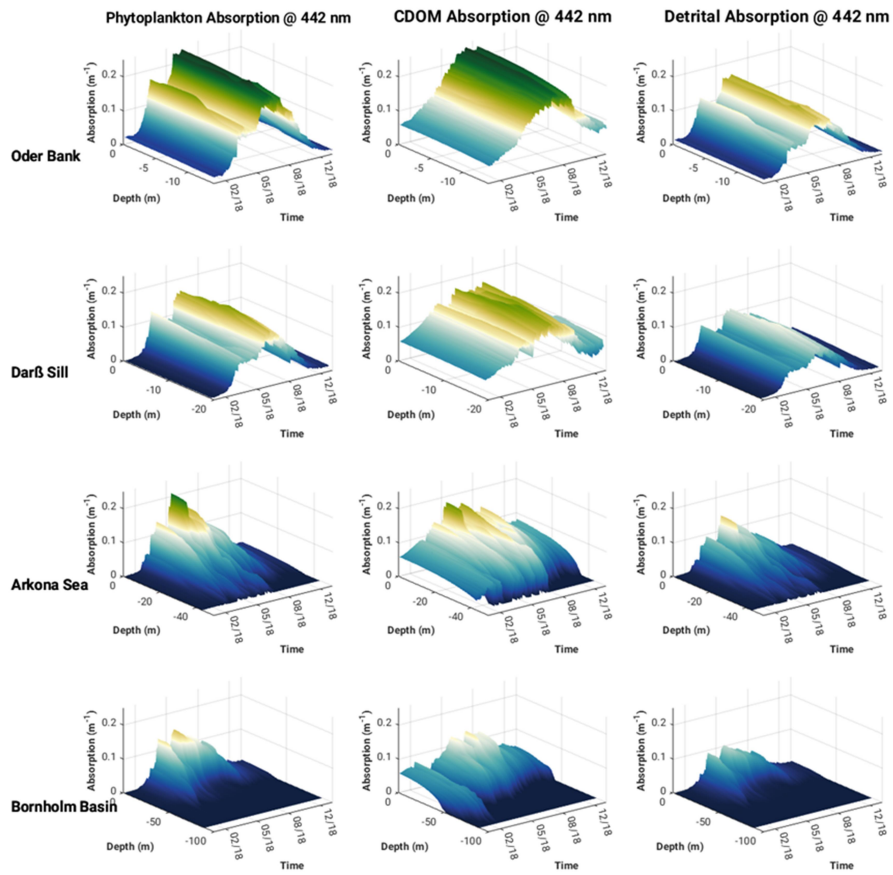

498

503

504 Figure 5: Vertical structure of phytoplankton, CDOM and detrital absorption at 442 nm at Darß Sill, Arkona Sea, Oder

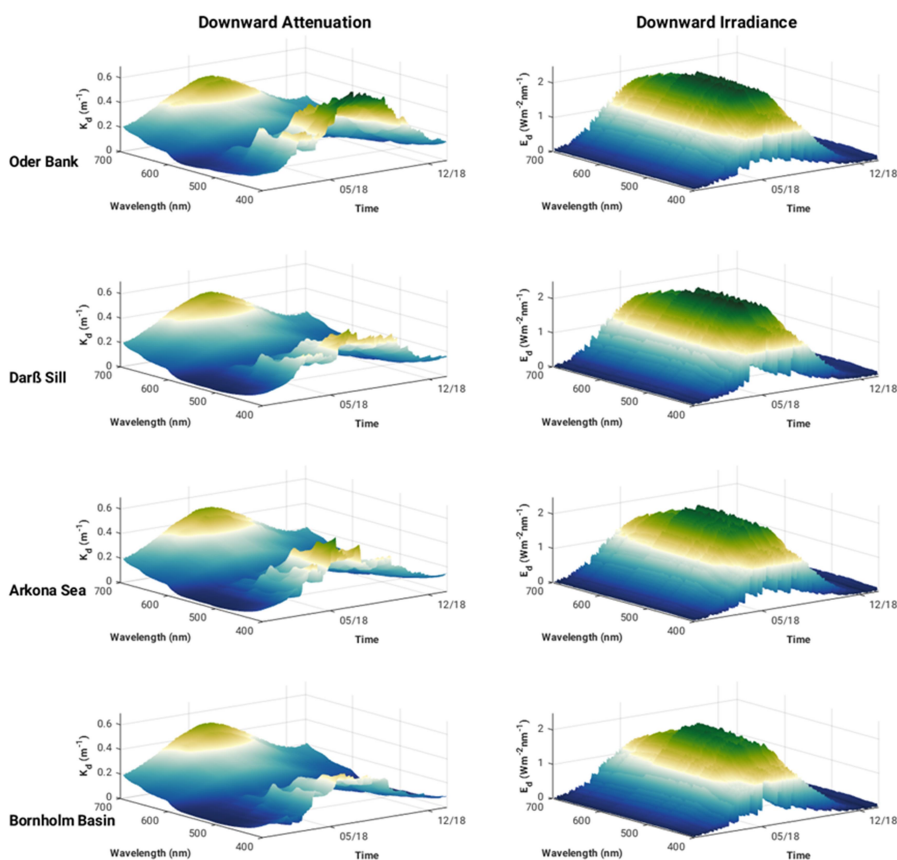

505

Bank and Bornholm Basin in 2018 from ROMS-Bio-Optic 3D Western Baltic Sea model experiment.

506

507

508

509

510

511 Figure 6: Surface spectral downward diffuse light attenuation and downward irradiance at Oder Bank, Darß

512 Sill, Arkona Sea and Bornholm Basin in 2018 from ROMS-Bio-Optic 3D Western Baltic Sea model experiment.

513

514 Variability in the surface layer attenuation is greatest between 400 and 550 nm, especially during the stratified

515 spring, summer and autumn seasons reflecting the seasonal dynamics of phytoplankton, CDOM and detritus. Vertical

516 profiles of K_d and E_d at 442 nm (Figure 7) show light penetrating deeper in winter, indicating relatively well-mixed

517 (clear) waters, contrasted by seasonally stratified waters in spring, summer and autumn. Variability between the

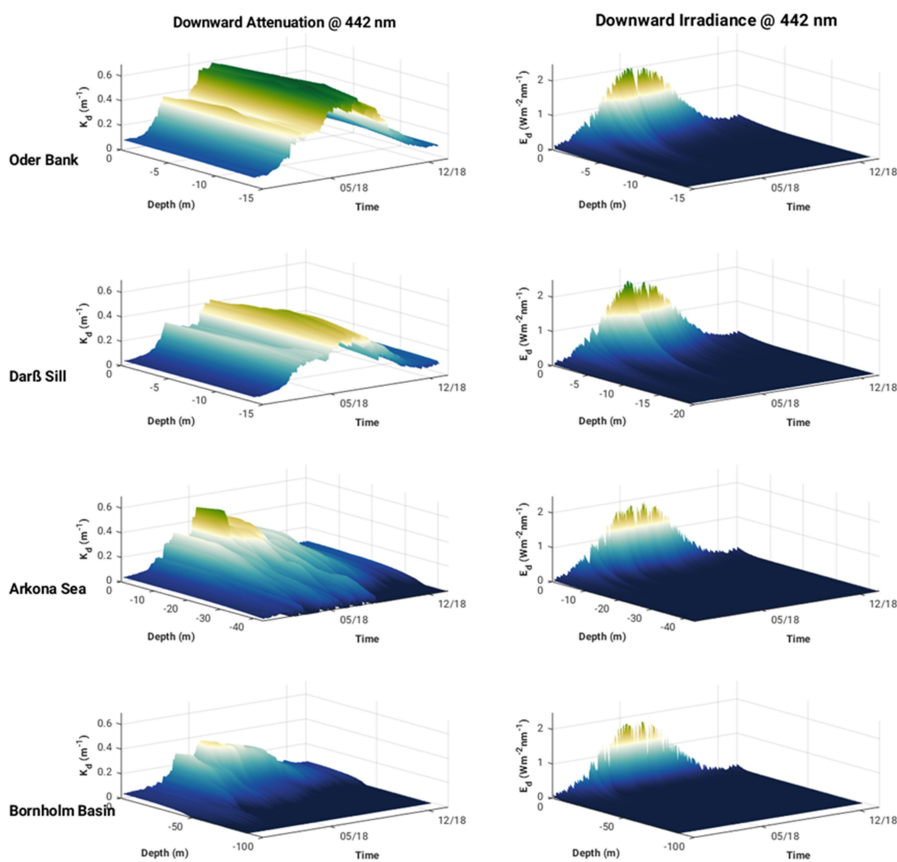

518 locations is also much higher during these seasons revealing the different influence of constituents at these locations, for

519 example, the impact of the spring and summer phytoplankton blooms at Oder Bank and Arkona Sea on attenuation.

520 (High attenuation values at the red end of the spectrum are mostly related to the absorption of pure water itself).

521

522

523

524 Figure 7: Vertical structure of downward diffuse light attenuation and downward irradiance at 442 nm at Oder
525 Bank, Darß Sill, Arkona Sea and Bornholm Basin in 2018 from ROMS-Bio-Optic 3D Western Baltic Sea model
526 experiment.

527

528 It should be noted that seasonal and spatial variability in the concentration of optically significant water
529 constituents impacts not only the penetration of solar energy into the water column, but also influences the spectral
530 properties of the underwater light field. Elevated absorption by CDOM and phytoplankton pigments in the spring and
531 summer at the Oder Bank, Darß Sill and Arkona Sea causes a red shift in the solar irradiance maximum transmission
532 waveband to 570 nm from 500 nm estimated for the Bornholm Basin (Figure 6). This is consistent with observations

533 reported by Kowalczyk et al. (2005a) who reported a shift in solar irradiance maximum transmission waveband from
534 550 nm in the Baltic Proper to 575 nm in Pomeranian Bay and Gulf in Gdansk. An even bigger shift in the solar
535 irradiance maximum transmission waveband was observed between Atlantic Ocean coastal water off the west coast of
536 Ireland (maximum solar irradiance transmission at 490 nm) and Baltic Sea in Gulf of Gdansk (maximum solar
537 irradiance transmission at 570 nm). This shift was attributed to elevated CDOM absorption, which was c. two times
538 higher in the Baltic Sea compared to coastal Atlantic Ocean, while the chlorophyll-a concentration was at a similar level
539 in both regions (Darecki et al., 2003).

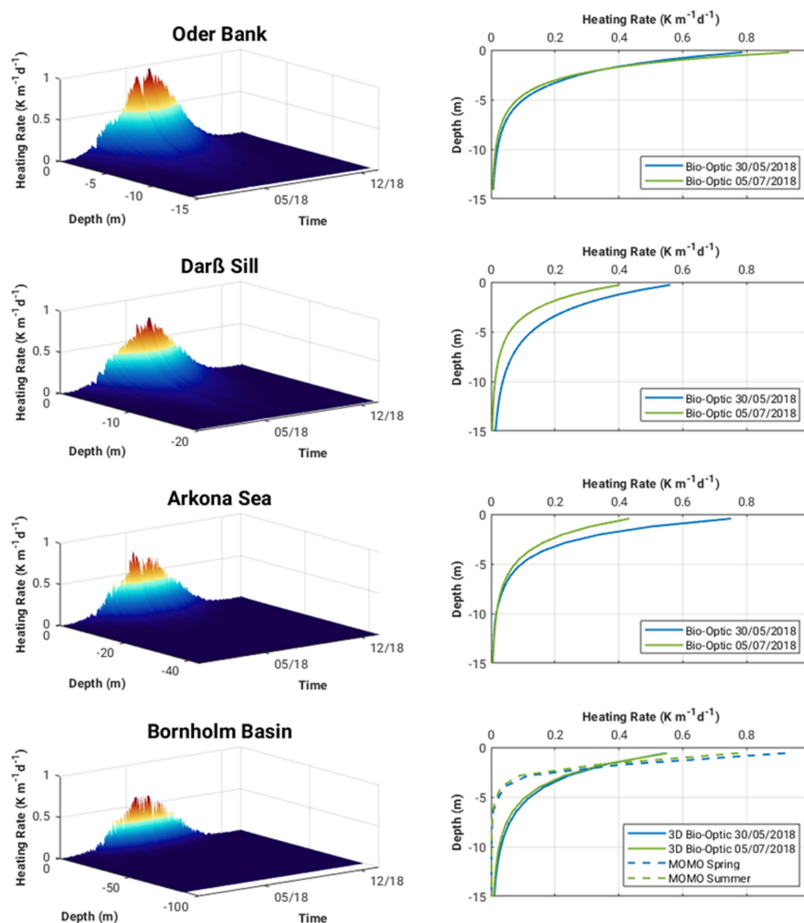

540 **3.3 Heating rates and surface heat fluxes**

541 The vertical and temporal evolution of water constituent-induced heating rates at each of the locations is shown in
542 Figure 8. Maximum heating rates occur late spring and mid-summer and are between 0.8 and 0.9 $\text{K m}^{-1}\text{d}^{-1}$ at Oder Bank
543 and between 0.4 and 0.8 $\text{K m}^{-1}\text{d}^{-1}$ at the other locations. Vertical profiles of two heating rate maxima in May and July
544 indicate approximately 70% of the water constituent-induced heating is contained within the top 5 m, and decreases
545 exponentially to zero by 10 to 15 m depth.

546 We compared the Bio-Optic heating rate estimates at Bornholm Basin with a comparable full radiative transfer
547 calculation by MOMO for the two heating rate maxima events in May and June (Figure 8, bottom right). Bornholm
548 Basin is chosen as the evaluation site for the heating rate calculations because the seasonal cycle of the heat balance
549 there can be approximated as a 1-dimensional balance between the penetration of solar radiation and vertical mixing
550 (Gnanadesikan et al., 2019) and advective and diffusive terms will be relatively small. The main difference between the
551 two calculations, Bio-Optic and MOMO, is that the MOMO takes into account the full directionality of the light field
552 while Bio-Optic does not. There are differences in the seasonal heating rate results between the two approaches but they
553 are not so large. At the surface, the Bio-Optic estimates are 0.3 $\text{K m}^{-1}\text{d}^{-1}$ smaller in spring and 0.25 $\text{K m}^{-1}\text{d}^{-1}$ smaller in
554 summer than the MOMO estimates. In the MOMO calculations, most of the water constituent-induced heating (c. 80 %)
555 is contained within the top 2 m, and this decreases exponentially more rapidly than Bio-Optic to zero by 5 m depth.

556 We find that by accounting for the full directionality of the light field, as shown by the case investigated by
557 MOMO, the impact water constituents have on the heating rates is contained within the top 2 to 3 m, consistent with the
558 findings of Soppa et al. (2019). However, MOMO may be overestimating the actual magnitude of water constituent-
559 induced surface heating rates as none of the other physics (i.e. advection, diffusion) and environmental forcing
560 represented in the Bio-Optic experiments, are taken into account in MOMO. It could also be that the algorithm used to
561 calculate K_d in Bio-Optic (Lee et al., 2005) is not optimal for the conditions in the Baltic Sea (we elaborate this point
562 further in the discussion).

563
564

565

566

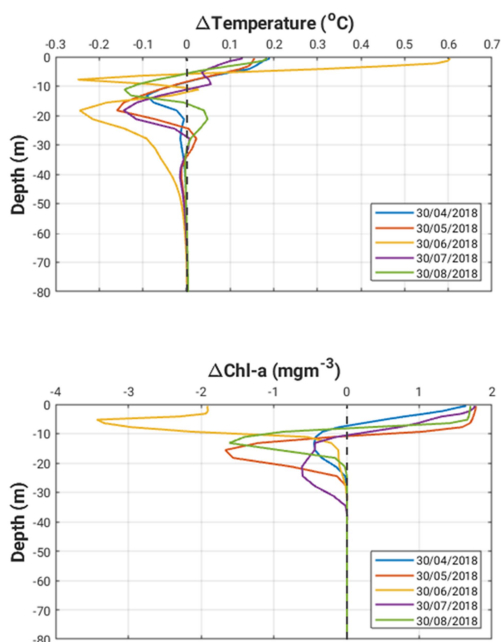

567 Figure 8: Surface heating rates (left panel) and vertical profiles of two heating rate maxima in May and July 2018 (right
568 panel) for at Oder Bank, Darß Sill, Arkona Sea and Bornholm Basin.

569

570 Figure 9 shows the temperature and chlorophyll-a anomalies (biofeed minus nobiofeed experiments) for
571 selected days during the productive period at Bornholm Basin. Accounting for the feedback of OSC-induced heating in
572 the hydrodynamic solution has the effect of increasing the surface layer (c. top 10m) water temperature by between 0.1
573 and 0.2°C in spring and late summer, and as much as 0.6°C mid-summer. Below the thermocline, the water temperature
574 is cooler by 0.1 to 0.2°C. Differences in the thermal structure when the feedback is accounted for impacts the
575 development, transport and fate of phytoplankton biomass. This consequence is seen in differences in the chlorophyll-a

576 structure at different times during the productive period. In spring, when the upper water column is stratifying, the
577 increase in temperature in the surface layer will stimulate production and increase the absorption of light by
578 phytoplankton, thus, strongly reducing the availability of light below the algae layer. Phytoplankton is restricted within
579 the shallow mixed layer with more availability of light, which will in turn increase surface heating. As nutrients become
580 depleted in the surface layer and the supply of nutrients from deeper waters is inhibited by the stronger thermocline
581 mid-summer, the net effect is less biomass production in the surface layer mid-summer in biofeed compared to
582 nobiofeed. As the water column becomes less stable late August, and nutrients are mixed back into the surface, biomass
583 production is larger again in biofeed compared to nobiofeed.
584

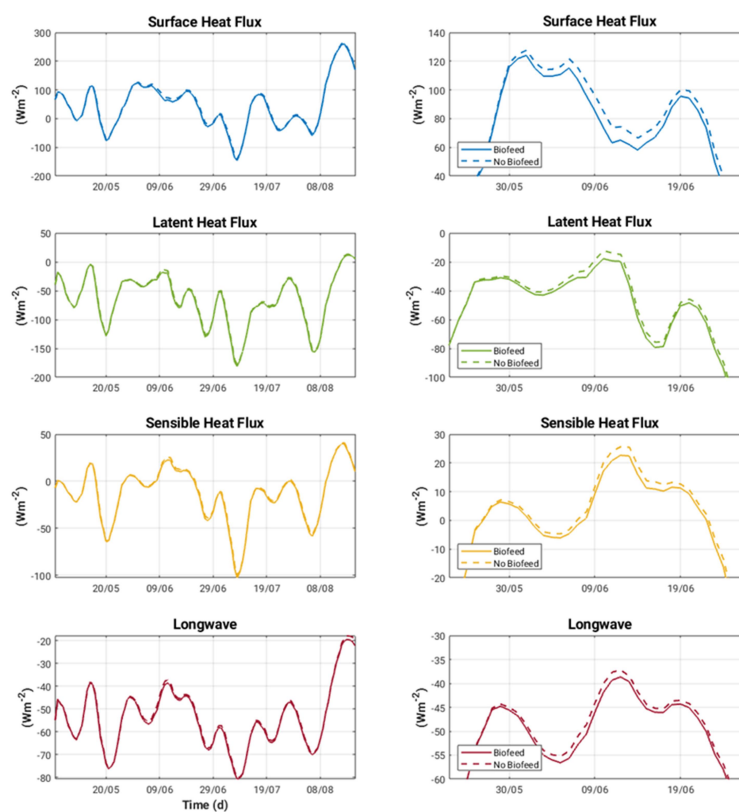

585
586
587 Figure 9: Vertical profiles of temperature and chlorophyll-a anomalies (biofeed minus nobiofeed experiments) during
588 productive period at Bornholm Basin.

590 The impact this has on surface heat fluxes during the productive period at Bornholm Basin is shown in Figure
591 10. The increase in OSC-induced surface temperature captured in spring and summer lead to an increase in heat loss to
592 the atmosphere, with the average difference for the period April to September being on the order of 5.2 Wm^{-2} . This is
593 primarily a result of latent (2.6 Wm^{-2}) and sensible (1.7 Wm^{-2}) heat fluxes. Putting this into context with modelled

594 estimates by Omstedt and Nohr (2004) of between 5 and 18 Wm^{-2} for the net annual heat losses in the Baltic Sea,
595 indicates it may be important to consider OSC-induced heating rates in regional heat balance budgets.
596

599 Figure 10: Surface heat fluxes for both biofeed and nobiofeed experiments during productive period at Bornholm Basin.

600

601 4 Discussion

602 Modelled seasonal and spatial changes in OSCs in the Western Baltic Sea have a small but noticeable impact on
603 radiative heating in surface waters, especially in spring and summer as a consequence of increased absorption of light
604 by phytoplankton and CDOM. Our modelled estimates for 2018 show phytoplankton dominating absorption in spring
605 and summer, as a result of a succession of phytoplankton blooms, and CDOM dominating absorption in summer and

606 autumn. Simis et al. (2017), found that phytoplankton pigment visibly influences $K_d(675)$ in spring and summer, while
607 absorption by CDOM at 412 nm can account for 38–70 % of the total OSC absorption in the area influenced by the
608 Oder River in autumn. First order variability in CDOM absorption in the Baltic Sea is driven by terrestrial sources.
609 Second order variability is driven by autochthonous DOM production during phytoplankton blooms and
610 photodegradation. The spatial and temporal variability in our modelled OSC absorption at the different locations,
611 especially in spring, summer and autumn, are in good agreement with seasonal observations for different water types in
612 the Southern Baltic Sea reported by Meler et al. (2016a) (See appendix, Figure A1). This is encouraging for future
613 modelling studies of this nature, as more consistent, long term time series of the optical properties of the Baltic Sea are
614 realised e.g. using automated measurement systems such as Bio-Argo floats equipped with a simple spectral radiometer.
615 Such a strategy has been applied with significant success in the Mediterranean Sea (Terzić et al., 2019; Terzić et al.,
616 2021a; Terzić et al., 2021b). We also find it encouraging that the (simplified) Bio-Optic and (full) MOMO radiative
617 transfer heating rate estimates were somewhat comparable and informative. The directionality of the light field appears
618 to be important to understand the depth of influence of water constituent-induced heating rates, while accounting for the
619 spatial and temporal variability in the physics of the environment is important in determining the magnitude of the
620 heating rates. However, we think further work is needed to optimise the Bio-Optic diffuse attenuation coefficient (K_d)
621 algorithm for the Baltic Sea.

622 K_d which describes the transfer of light energy through the water column, also reflects the seasonal variability
623 of water types, i.e. winter (well-mixed) versus spring, summer and autumn (seasonally stratified) and the influence of
624 constituents in different water types during stratified seasons (i.e. spatial variability). Our results show a gradient in K_d
625 and in heating rates which decreases as you move offshore. In late spring, at the Oder Bank, water constituent
626 contribution to surface heating can be as much as $0.9 \text{ K m}^{-1}\text{d}^{-1}$, while at Darß Sill, Arkona Sea and Bornholm Basin,
627 water constituent contribution to surface heating in spring and summer is less, between 0.4 and $0.8 \text{ K m}^{-1}\text{d}^{-1}$. Reports on
628 the spectral properties, temporal and spatial variability of the diffuse attenuation coefficient in the Baltic Sea based on
629 field observations are limited and date back to the early 2000s (Kratzer et al. 2003, Lund-Hansen, 2004, Darecki and
630 Stramski 2004, Kowalczyk et al., 2005a, Lee et al., 2005). Darecki and Stramski (2004) have assessed that locally
631 optimised satellite remote sensing algorithms for estimating $K_d(490)$ based on MODIS data yield the least uncertainty
632 compared to other variables e.g. chlorophyll-a. However, information on the full K_d spectrum is needed to assess the
633 individual impact of the most significant optical seawater constituents on surface heating rates. Until recently, the only
634 solution was empirical or semi-analytical modelling based on either remote sensing data (Lee et al. 2005; Löptien and
635 Meier, 2011; Alikas et al., 2015) or in situ measurements of apparent or inherent optical measurements (Gonçalves-
636 Araujo and Markager, 2020). The most accurate estimation of K_d could be achieved by using the semi-analytical model,
637 however, uncertainty in those estimates heavily depends on the local parametrization of the specific inherent optical
638 properties which, in the Baltic Sea regions, have contrasting and highly variable seasonal cycles (Simis et al., 2017).
639 Kratzer and Moore (2018) concluded that the correct choice of the volume scattering phase function in the Baltic Sea

640 determines the accuracy of the prediction of inherent and apparent optical properties in the Baltic Sea region. CDOM
641 and suspended particles are the most significant optical constituents controlling water transparency. CDOM absorption
642 is regulated mostly by riverine discharge especially in coastal waters, however, under certain condition, CDOM
643 absorption in the Baltic Sea is statistically correlated with phytoplankton biomass (Kowalczuk et al., 2006, Meler et al.,
644 2016a). Particulate absorption and scattering is significantly correlated with phytoplankton biomass, which has a well-
645 defined seasonal and spatial pattern in the Baltic Sea (Meler et al., 2016b, Meler et al., 2017). By including a spectrally
646 resolved underwater light field in our model and diagnosing inherent and apparent optical properties, we are able to
647 resolve the full K_d spectrum and better understand the role different OSCs play in determining the temporal and spatial
648 variability in K_d and the impact on heating rates. Further optimisation of the Bio-Optic K_d algorithm for the Baltic Sea
649 is currently in progress.

650 Climate change scenarios for central Europe predict significant change in the precipitation regime, which will
651 be manifested in a shift in the seasonal distribution of precipitation: increased rainfall and decline in snowfall in winter,
652 persistent droughts in summer with episodic intensive thunderstorms (IPCC, 2022). Changes in the precipitation regime
653 coupled with an increase of mean temperatures will significantly impact the outflow of freshwater from the Baltic Sea
654 catchment into the marine basin itself (Meier et al., 2022). We could anticipate that the flux of terrestrial CDOM would
655 be affected most, because currently observed climatic changes in the southern part of Baltic Sea catchment have caused
656 mild winters with reduced numbers of frost days and almost a total reduction in snow fall. As a result, CDOM that was
657 previously immobilised in the frosted ground, streams and rivers, is now being transported to the sea in late winter and
658 spring. In the summer, a deepening minima of flows in rivers reduces CDOM input to Baltic Sea. Recent results by
659 Zabłocka (2017) indicate that the monthly averaged Vistula river flow maximum during the period 1993 to 1998
660 occurred in April, while from 2008 to 2010, this maximum shifted to March. As the Baltic Sea is warming at a rate up to
661 four times the global mean warming rate (Belkin, 2009), we can expect this trend in earlier river flow maxima to
662 continue and a higher contribution of CDOM to the absorption budget in winter and spring, as the chlorophyll-a
663 concentration (phototrophic protists biomass proxy) maximum still occurs in April (Stoń-Egiert and Ostrowska, 2022).

664 Changes in the hydrological regime and a reduction in mineral nutrient input (Łysiak-Pastuszek et al., 2004)
665 have noticeably impacted both phototrophic protists biomass and functional structure. Stoń-Egiert and Ostrowska (2022)
666 have reported a statistically significant decreasing trend of $2.11 \% \text{ yr}^{-1}$ of the total chlorophyll-a concentrations over last
667 two decades (1999 to 2018), with decreasing pigment markers for such protists groups as diatoms, dinoflagellates,
668 cryptophytes and green algae and an increase of cyanobacteria. As a consequence, primary production in the southern
669 Baltic Sea also declined in the period from 1993 to 2018, compared to its maximum in the late 1980s (Zdun et al., 2021).
670 Kahru et al. (2016) have also reported on changes in the seasonality in the Baltic Sea environment: the cumulative sum
671 of $30,000 \text{ Wm}^{-2}\text{d}^{-1}$ of surface incoming shortwave irradiance (SIS) was reached 23 days earlier in 2014 compared to 3
672 decades earlier; the period of the year when the sea surface temperature was at least 17°C has almost doubled (from 29
673 days in 1982 to 56 days in 2014); the period when $K_d(490)$ was over 0.4 m^{-1} increased from about 60 days in 1998 to

674 240 days in 2013 (quadrupled); the period when satellite-estimated chlorophyll of at least 3 mgm^{-3} has doubled from
675 110 days in 1998 to 220 days in 2013 and the timing of both the phytoplankton spring and summer blooms has
676 advanced, with the annual chlorophyll maximum that in the 1980s corresponded to the spring diatom bloom in May has
677 now shifted to the summer cyanobacteria bloom in July. It is interesting to note that we found two OSC-induced heating
678 rate maxima in May and July in our model results which coincide with two observed marine heatwave events. At Darß
679 Sill and Arkona Sea, these heating rate maxima were larger in May, by 0.18 and $0.35 \text{ K m}^{-1}\text{d}^{-1}$, respectively compared to
680 July, while at Oder bank the heating rate maxima was larger in July by $0.1 \text{ K m}^{-1}\text{d}^{-1}$.

681 **5 Conclusions**

682 Heating rates due to absorption of short wave radiation (UV-VIS) in the Western Baltic Sea are controlled by the
683 combined effects of the seasonal solar cycle and the concentration and distribution of OSCs. The intensity of radiative
684 energy reaching the sea surface is locally modified by radiative transfer through the atmosphere, which is mostly
685 controlled by cloudiness whose long term climatology minimum is observed in May (Dera and Woźniak, 2010). Further
686 modulation of heating rates in the Western Baltic Sea in UV and VIS spectral domains is dependent on water
687 transparency which is a complex function of the magnitude and seasonal cycles of inherent optical properties and the
688 directionality of the light field. Our study found that in 2018 the combined effect of CDOM and particulate absorption
689 on surface heating rates in the Western Baltic Sea could reach up to 0.4 to 0.8 K d^{-1} , during the productive period April
690 to September, and is relevant from the surface down to 2-5 m depth. Moreover, this modelled OSC-induced surface
691 warming results in a mean loss of heat (c. 5 Wm^{-2}) from the sea to the atmosphere, primarily in the form of latent and
692 sensible heat fluxes, which may be significant for regional heat balance budgets. Two way coupling with the
693 atmosphere is not included in our experiment, but we expect this would modulate (decrease) the magnitude of the net
694 loss of heat to the atmosphere.

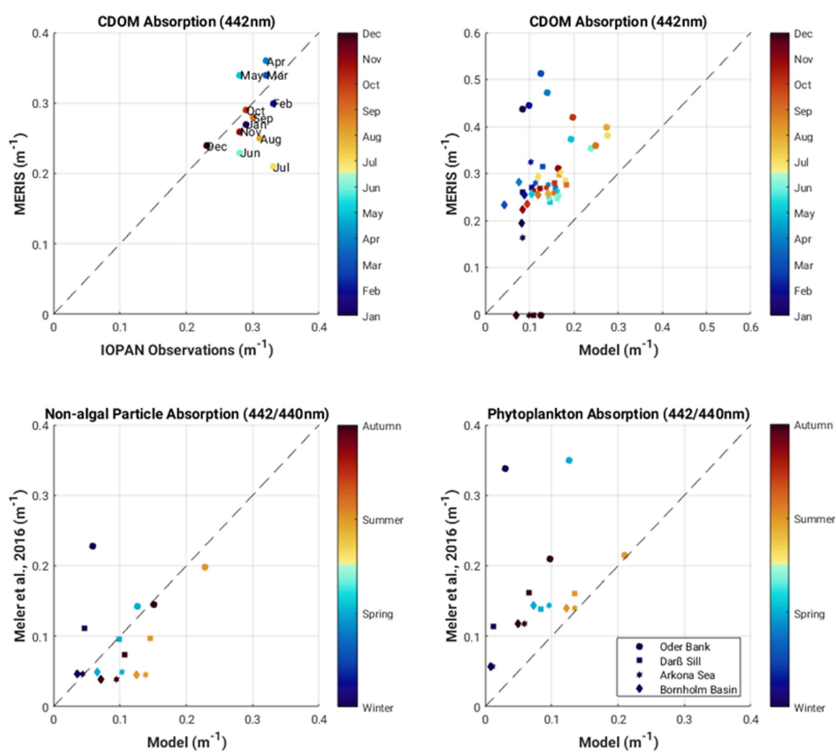

695 Anticipated and recently observed changes in phytoplankton functional types and their seasonal pattern and
696 CDOM terrestrial input patterns due to global warming will further modulate the spatial and temporal pattern of heating
697 rates in the Baltic Sea. Observed changes in the quantity and quality of CDOM, the composition and concentration of
698 phytoplankton functional types and photosynthetic pigments and thus changes to the optical properties of the Baltic Sea,
699 need to be communicated to coupled hydrodynamic-biogeochemical models such that the consequences of radiative
700 feedbacks can be better understood and better predictions of the future Baltic Sea environment can be made. Further
701 improvements to coupled hydrodynamic and ecological models are heavily dependent on the correct parameterization
702 of the downwelling irradiance diffuse attenuation coefficient K_d , which requires a proper understanding of the seasonal

703 and spatial variability of the optical properties in different water types. This work highlights the importance of K_d as a
704 bio-optical driver: K_d provides a pathway to estimating heating rates and connects biological activity with energy fluxes.

708

709 Figure A1: (a) MERIS and in situ monthly climatology of surface CDOM absorption (mean value calculated over
710 Western Baltic Sea region shown in Figure 1); (b) mean monthly surface CDOM absorption at model stations and
711 matching MERIS locations; seasonal mean surface non-algal particle absorption (CDOM+detritus) (c) and
712 phytoplankton absorption (d) at model stations compared with similar water type values found in Meler et al. (2016).

713

714

715

716 **Code Availability:**

717 The ROMS-BioOptic model code used in this study can be accessed at [https:// www.myroms.org](https://www.myroms.org). The MOMO model
718 code is available upon request from Jürgen Fischer, juergen.fischer@fu-berlin.de

719 **Data availability:**

720 The version of the Bio-Optic model code used to produce the results in this study, including initial conditions, river and
721 boundary forcing as well as selected model output used for analysis and producing figures are archived on Zenodo
722 (10.5281/zenodo.7215110 – reserved).

723 The atmospheric forcing data can be acquired for scientific research purposes upon request from Ulf Gräwe
724 (ulf.graewe@io-warnemuende.de).

725 The MERIS FRS L2 CDOM absorption monthly climatology for the Western Baltic Sea used in this study is archived
726 on Zenodo (10.5281/zenodo.7224656 - reserved).

727 The in situ CDOM absorption data can be acquired for scientific research purposes upon request from Piotr Kowalczyk
728 (piotr@iopan.pl).

729 **Author contributions:**

730 BC conceived the study, extended the ECOSIM model code and set up the regional deployment of ROMS-BioOptic in
731 the Western Baltic Sea. BC also performed all simulations and analysis, and wrote the manuscript with input from all
732 co-authors. PK provided the in situ CDOM absorption data used in the study and made significant contributions to the
733 manuscript. LK and JF provided support setting up the MOMO model code and expertise on radiative transfer theory in
734 the ocean. UG provided model grid bathymetry, atmospheric forcing, as well as initial and boundary conditions. UG and
735 JW provided support setting up and troubleshooting the regional deployment of ROMS in the Western Baltic Sea.

736 **Competing interests:**

737 The authors declare that they have no conflict of interest.

738 **Acknowledgements:**

739 BC was supported by funding from the German Research Foundation (Grant No. CA 1347/2-1, 2018 to 2021,
740 Temporary Position for Principal Investigator). PK was supported by the Statutory Research Program at the Institute of
741 Oceanology Polish Academy of Sciences no. II.5 and partially by project "Oceanographic Data and Information
742 System", eCUDO.pl (contract no. POPC.02.03.01-IP.01-00-0062/18) co-financed from European Regional
743 Development Fund, Digital Poland Operational Program, 2.2 Priority Axis. The authors gratefully acknowledge the
744 computing time granted by the Resource Allocation Board and provided on the supercomputer Lise and Emmy at
745 NHR@ZIB and NHR@Göttingen as part of the NHR infrastructure. The calculations for this research were conducted
746 with computing resources under the project ID bek00027. BC would like to thank the Free University of Berlin (FUB)
747 for hosting her during the project. The following individuals are also gratefully acknowledged: Jakob Röhrenbach for
748 compiling the MERIS CDOM absorption data archive, Rene Preusker for providing additional expertise on radiative
749 transfer theory, Jan El Kassar for providing data management support, Hernan Arango and David Robertson at Rutgers
750 University for providing support with ROMS code development and troubleshooting, Thomas Neumann from the
751 Leibniz Institute for Baltic Sea Research for providing the biogeochemical river forcing data used in the study and
752 Frank Fell for making some very helpful comments on an earlier version of the manuscript.
