Keywords: Ambient seismic noise, sedimentary basin geometry, Eastern Pyrenees

Abstract

Ambient seismic noise acquired in the Cerdanya Basin (Eastern Pyrenees) is used to assess the capability of different methodologies to map the geometry of a small-scale sedimentary basin. We present results based on a 1-year long broad-band deployment covering a large part of the Eastern Pyrenees and a 2-months long high-density deployment covering the basin with interstation distances around 1.5 km. The explored techniques include autocorrelations, ambient noise Rayleigh wave tomography, horizontal to vertical spectra ratio, and band-pass filtered ambient noise amplitude mapping. The basement depth estimations retrieved from each of these approaches, based on independent datasets and different implicit assumptions, are consistent, showing that the deeper part of the basin is located in its central part, reaching depths of 600-700 m close to the Têt Fault trace bounding the Cerdanya Basin to the NE. The overall consistency between the results from all the methodologies provides constraints to our basement depth estimation, although significant differences arise in some areas. The results show also that when high-density seismic data are available, HVSR and ambient noise amplitude in a selected frequency band analysis are useful tools to quickly map the sedimentary 3D geometry. Beside this methodological aspect, our results help to improve the geological characterization of the Cerdanya Basin and will provide further constraints to refine the seismic risk maps of an area of relevant touristic and economic activity.

1 Introduction

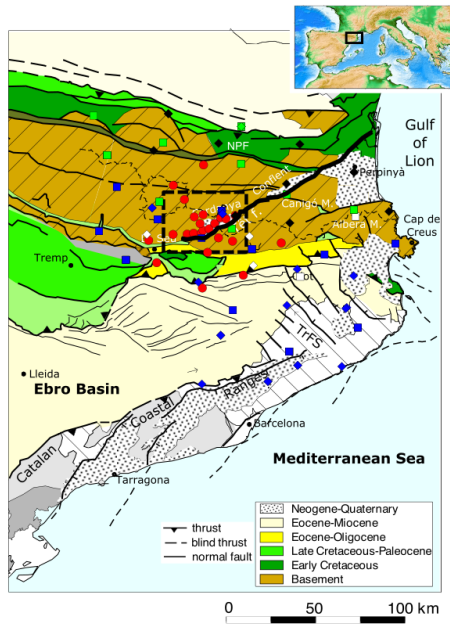
The objective of this contribution is to evaluate the potential of several methodologies based on the analysis of the seismic signals recorded in the absence of earthquake-generated waves, such as autocorrelations, Horizontal to Vertical Spectral Ratio (HVSR), Ambient Noise Tomography (ANT) or noise amplitude maps to define the geometry of the Cerdanya Basin (CB), a relatively small Neogene sedimentary basin located in the eastern part of the Pyrenees Axial Zone (Figure 1). The basin extends 35 km along its longer axis, has a maximum width of 5-7 km and is crossed by the Segre River, one of the main tributaries of the Ebro River. The mean altitude of the CB is 1100 m, with surrounding mountain ranges reaching 2500-2900 m.


Figure 1: Simplified tectonic map of the Eastern Pyrenees, adapted from Vergés et al. (2019) including the main Pyrenean thrusts and Neogene extensional faults. TrFS stands for Transverse Fault System, NPF for North Pyrenean Fault. Thick black line shows the location of the Têt Fault. Red dots show the deployment of the SANIMS broad-band stations. Permanent broad-band (squares) and accelerometric (diamonds) are included for reference. Blue: CA network; White: ES network; Green: FR network; Black: RA network. Dashed square shows the location of the map in Figure 2.

1.1 Geological setting

The Pyrenees, extending from the Mediterranean Sea to the Cantabrian Mountains, were built by the inversion of Mesozoic sedimentary basins and the stacking of northern Iberian crust thrust sheets to build the Axial Zone, the central part of the chain (e.g. Muñoz, 1992; Teixell, 1998). The northward underthrusting of the Iberian plate under a thinner European plate resulted in crustal thicknesses reaching 40-45 km beneath the central part of the chain. However, different geophysical results have evidenced that the Pyrenean range has not cylindrical symmetry (Chevrot et al., 2018). In particular, the eastern termination of the Pyrenees is marked by the abrupt thinning of the crust, decreasing from more than 40 km beneath the Cerdanya Basin to values close to 25 km beneath the Mediterranean shore (Gallart et al., 1980; Diaz et al., 2018). This thinning has been associated to the presence of widely distributed faults (e.g. Calvet et al., 2021; Taillefer et al., 2021), whose origin has been related to the initiation of the European Cenozoic Rifting System (e.g. Angrand and Mouthereau, 2021) or the back-arc extension leading to the opening of the Gulf of Lion (e.g. Séranne et al., 2021). The most prominent of the normal faults in the eastern Pyrenees is the Têt Fault, extending from the coastline to the Segre valley, south of Andorra, along approximately 100 km. The present-day activity of the fault is still under debate, as current displacements are low or nonexistent (e.g. Lacan and Ortuño, 2012), but some authors relate triangular facets of the Têt fault escarpment to its recent activity (e.g. Briais et al., 1990; Calvet, 1999). The fault is divided in two main segments; to the east, the Conflent segment, extending from the coastline to the village of MontLluís, and to the west, the Cerdanya segment, extending from this point to the town of Seu D'Urgell (Fig. 1). The present day seismic activity around the fault is minor to moderate, with most of the recorded events having magnitudes below 4. However, the Têt Fault could be on the origin of large, destructive earthquakes in the XV century (e.g. Briais et al., 1990). From thermochronological studies along the Têt Fault (Milesi et al., 2022), it has been observed that the most pronounced cooling of the Canigó and Carançà massifs, in the southern footwall of the Têt Fault, occurred during the Oligocene-lower Miocene between 26 and 19 Ma, while the South Mérens Massif in its hangingwall of the fault was not exhumed. Later on, during the Serravallian-Tortonian between 12 and 9 Ma, the Carançà Massif shows a new cooling event, while the Canigó Massif remained unaltered. Therefore, this segment of the Têt Fault has played a major role in the extensional evolution of the area, that, accordingly to Milesi et al. (2022), started during the late Priabonian, in the same time than the European Cenozoic Rifting System affecting western Europe. Since this episode, the Têt fault activity appear mainly controlled by the opening of the Gulf of Lion.

Deleted: 3

113

The Cerdanya Basin is a half-graben about 30 km long developed in the NW side of the southern segment of the Têt Fault and can be divided in two main sections located to the east and to the west of 1.85°, near the town of Riu de Cerdanya (Figure 2). This geometry is clearly related to the position of the Têt Fault, which has a general NE-SW trending, but changes abruptly its trend to E-W direction at its SW termination (Calvet et al., 2022).

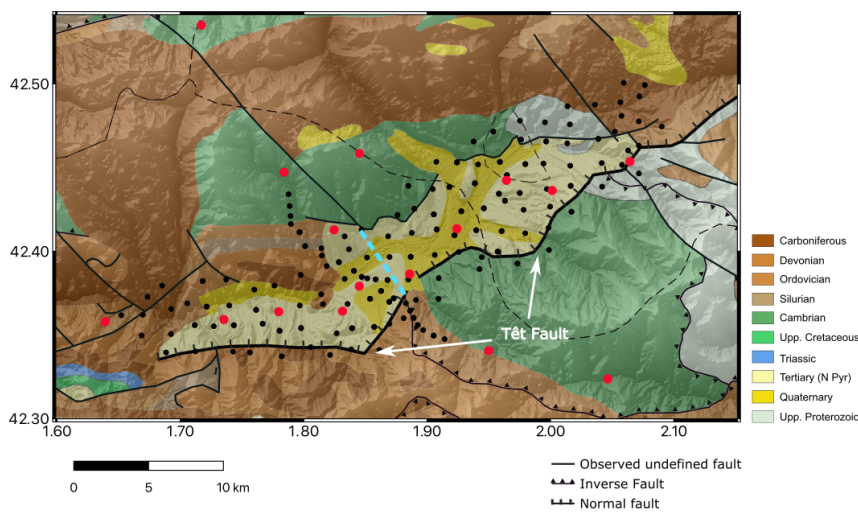
119


Figure 2: *High density deployment of seismic nodes (black dots) between April and June 2021. Red dots show the location of the previous broad-band deployment. Light blue dashed line shows the location of the profile presented by Gabàs et al (2016). The background shows the geological map around the Cerdanya Basin* (Instituto Geológico y Minero de España and Bureau de Recherches Géologiques et Minières, 2009).

125

The Cerdanya basin Neogene infill deposited directly on the Hercynian basement, formed by Cambro-Ordovician schists and Hercynian granitoids and including the Carançà and Canigó massifs to the SE and the Mérens massif to the NW. This Neogene infill is composed of alluvial and fluvial deposits (muds, sandstones and conglomerates) and lacustrine deposits (diatomites and thin lignite beds) with variable thickness between 400 and 1000 m, sourced from the two sides of the basin (Roca, 1996; Cabrera et al., 1988). Two stratigraphic units, separated by a slight discordance, form the filling of the basin (Roca and Santanach, 1996; Agustí et al., 2006). The lower unit is dated as Vallesian and Turolian, between 11 and 5.5 Ma, while the upper one

is of latest Miocene-Pliocene age between 6.5 and 6 Ma. The Neogene strata thicken and dip towards the Têt Fault and thus showing their growth pattern (Chapter 13 in Calvet el al., 2022). The Quaternary deposits (last 2.58 million years) cover a large area of the Cerdanya Basin and are mainly alluvial and fluvial terraces with thicknesses between a few meters and a few tens of meters (Turu et al., 2023). Thin remnants of moraines and associated fluvioglacial terraces are found at the confluence of the Segre and its tributary Querol River near Puigcerdà city. These Quaternary deposits mostly extend in the NE-SW segment of the Cerdanya Basin, while they are reduced in the E-W trending southern sector of the basin. In this sector, these deposits seem to be entrenched near the basin-basement contact, possibly triggered by uplift and high dissection of the Neogene basin infilling that crops out to the south near the E-W trending fault zone.

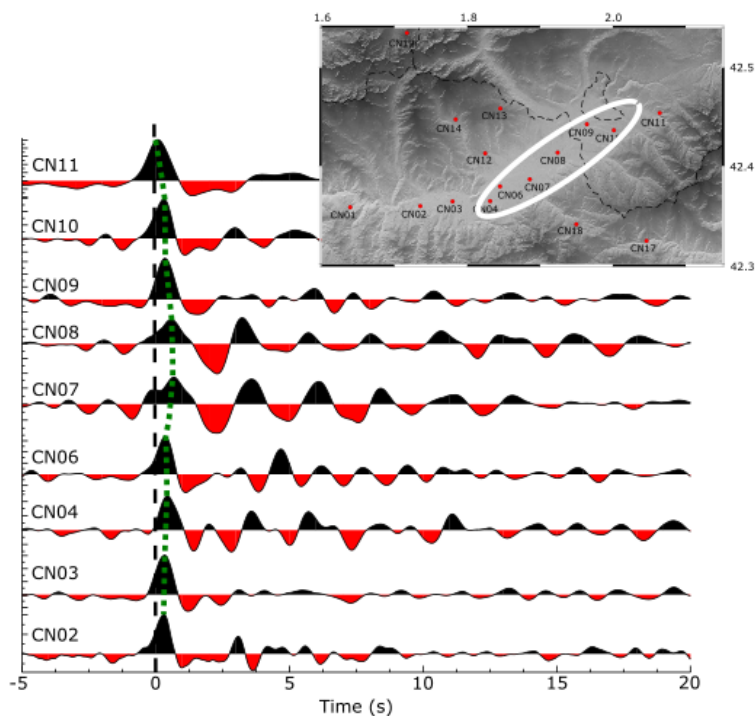
1.2 Previous knowledge on the Cerdanya Basin geometry

Previous geological and geophysical studies have provided information on the structure of the subsoil in the first hundred meters depth in the CB, using vertical electric sounding (Pous et al., 1986), seismic (Macau et al., 2006), or gravimetric (Rivero et al., 2002) methods and geological data including structural mapping, relative chronology of the fault slickensides and depositional analysis (Cabrera et al., 1988). The most relevant contribution to the knowledge of the basin geometry was published by Gabàs et al. (2016) and included the joint use of magnetotelluric and passive seismic data along a high-density 2D profile across the basin, between the villages of Ger and Alp (Figure 2). The obtained models show an average value of the electrical resistivity overburden close to 40 Ohm·m and can be correlated with Quaternary and Neogene deposits. The derived bedrock profile has a maximum sediment thickness of 500 m near its SE termination and an asymmetric geometry, with a smooth increase in depth to the NW and a more abrupt change in the SE termination. This layer is a resistive zone with electrical resistivity values between 1000 Ohm·m and 3000 Ohm·m and could be correlated with the top of the Palaeozoic rocks constituting the basement (limestones and slates) (Roca, 1996; IGME and BRGM 2009).

1.3 Data used

We use the seismic data acquired in the framework of the SANIMS project (Spanish M. of Science, Innovation and Universities, Ref.: RTI2018-095594-B-I00), which includes two different deployments. Firstly, we deployed 24 broad-band stations covering the CB and the surrounding areas with a twofold objective; investigating the basin and providing data for

181 regional-scale tomographic studies (Fig. 1). Ten of the stations were deployed along an EW
182 profile crossing the CB with an interstation spacing of 4-6 km. The rest of the instruments were
183 deployed forming an outer circle located about 35 km from the basin. These instruments were
184 active between September 2019 and November 2020. Secondly, we deployed a high-resolution
185 network covering the basin using 140 Rau-Sercel nodes equipped with 3-component 10 Hz
186 geophones and acquiring data at 250 samples per second (Fig. 2). The network had an
187 interstation spacing of 1.5 km, covering an area of about 300 km^2 and was active for two
188 months, between April and June 2021. Additionally, a high-density node profile, crossing the
189 basin along a NW-SE line, was designed with an interstation spacing of 700 m. Although the
190 two deployments were planned to be operative during the same time period, the logistical
191 constrains related to the COVID19 mitigation measures delayed the high-density station
192 deployment by one year.
193
194 *1.4 Receiver Functions results*
195 Before discussing the results provided by noise-based methodologies, we want to point out that
196 a first piece of information on which is the area with thicker sediments can be obtained from
197 the inspection of the Receiver Functions (RF) calculated with the main objective of mapping
198 the bottom of the crust. The RF method uses the P-to-S wave conversion at large velocity
199 discontinuities to map subsurface structures, typically the Moho, and is widely used to explore
200 crustal structure. As the objective of this paper is not to analyze in detail the results from this
201 technique, the steps followed to calculate the RFs are described in the Supplementary Material
202 S1.
203
204 Zelt and Ellis (1999) have described the effect of sedimentary basins on RFs, which include
205 an apparent time lag of the first peak, resulting from the delayed arrival of the P-to-S converted
206 phase at the base of the sedimentary layer and the presence of large reverberating phases that
207 can overprint the arrival of the phase converted at the Moho. Figure 3 shows the RF stack at
208 the broad-band stations installed along the CB. It is easy to observe that stacks corresponding
209 to stations CN02 to CN10 show late arrivals of the direct P wave, with maximum time lags for
210 stations CN07 and CN08. These two sites show also large reverberations between 2 and 6 s,
211 hence suggesting the presence of a significant sedimentary cover in the central part of the CB.
212 Further modeling, out of the scope of this contribution centered on the use of ambient noise,
213 can provide additional information on the properties of the basin (Yu et al. 2015).

234


235 ***Figure 3:*** *Stacked RFs for the broad-band stations located along the Cerdanya Basin. Dotted*

236 *green line show the direct P-wave time lag for stations along the basin. Large reverberations*

237 *are clearly observed for stations CN07 and CN08, affecting also stations CN04, CN06, CN09*

238 *and CN10. The location map in the inset shows the area with delayed RFs.*

239

240 2   **Autocorrelation methods**

241 Autocorrelation methods are based on the evaluation of the similarity of a seismic trace with a

242 delayed version of itself, as this similarity depends on the subsurface structure. Claerbout

243 (1968) showed that the zero-offset Green's Function of a one-dimensional medium can be

244 recovered from the autocorrelation of transmitted plane waves originated in the subsurface. For

245 2D and 3D media, Wapenaar (2004) has proved that this approach is still valid, although

246 presence of wave fields which are not diffuse does not allow to recover the exact function.

247 However, the obtained result, usually referred to as the empirical Green's function (EGF) to

248 express its approximative character, is now widely used to characterize the subsurface

249 structure.

250

251 Autocorrelation and cross correlation of ambient noise have been applied to dense station

252 deployments to retrieve P wave reflections for crustal-scale imaging (e.g., Ruigrok et al. 2012).

253 More recently, this approach has been used to map the Paleozoic basement in areas as the Ebro

254 Basin (Romero and Schimmel, 2018), as it provides a fast and consistent imaging of the

255 basement structure. However, mapping such shallow structures demands to work in frequency

256 bands between 1 and 25 Hz, a point that may hamper the applicability of the method due to the

257 dominance of local noise overprinting the weak amplitude body wave reflections. Further, the

258 presence of structural complexities complicates the EGFs and often results in ambiguities in

259 the interpretation of the autocorrelations. These ambiguities, nevertheless, can be reduced by

260 using dense station deployments and a priori information arising from well logs.

261

262 In this contribution we have calculated the autocorrelations for all the broad-band stations

263 located along the CB. We have also tried to calculate autocorrelations with the data acquired

264 by the seismic nodes, but the quality of the results is poor, as many resonances do appear. We

265 think that this may be related to the high self-noise of the geophones used by these stations that

266 mask the low-energy reflected signals. We have tested several frequency bands to assess the

267 best choice for imaging the uppermost crustal discontinuities focused on this study. Finally,

268 the pre-processing includes the correction of the raw data to ground velocity, the band-pass

269 filtering from 8 to 20 Hz, the division into one-hour-long non-overlapping sequences, and the

270 rejection of those sequences containing gaps or transient peaks. We compute autocorrelations

271 up to a maximum lag time of 20 s using wavelet phase cross-correlations with a complex

272 Mexican-hat wavelet with 2 voices per octave and no decimation due to its high temporal

273 resolution (e.g., Addison et al., 2002). Then, we smooth the hourly autocorrelations, stacking

274 one-day-long consecutive cross-correlations separated by 12 hours and weighting them by the

275 inverse of the norm between 2 and 3 seconds.

276

277 We identify the reflector associated to the base of the basin manually by selecting the first

278 negative reflector identified after the source reverberations having a time arrival consistent

279 with the a priori knowledge of the area. For most of the broad-band stations located along the

280 CB the signal due to the selected reflectors arrive at two-way travel times ranging between 0.4

281 s and 0.6 s (blue lines in Fig. 4). The Vs models obtained by Gabàs et al. (2016) show velocities

282 between 0.5 and 1.0 km/s in the uppermost layers. From the Vs/Vp relationship proposed by

283 Brocher (2005), these Vs values correspond to Vp in the range 1.75 – 2.25 km/s. Assuming

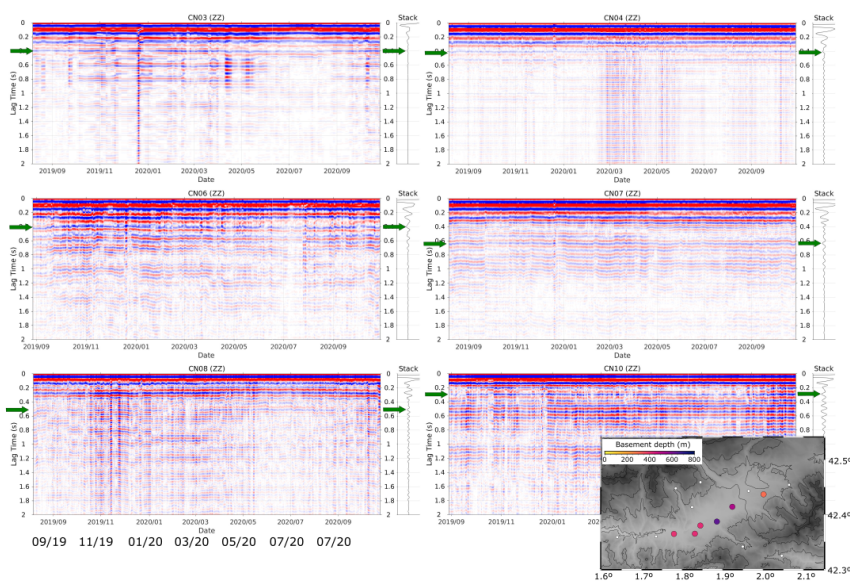
Vp=2 km/s, this results in basement depths ranging between 400 m for CN03, 640 m for station CN07 and 300 m for station CN10. This approach provides our first quantitative estimation of sediment thicknesses in the same area where delayed RFs have been observed. In order to assess the error of these estimations, we have calculated the depths values obtained using Vp=1.75 km/s and Vp=2.25 km/s. The difference between these extrema cases is close to 100 m, and the error associated to the selected velocity is therefore expected to be in the order of +/- 50 m.


Figure 4: Daily autocorrelograms for the vertical components of broad-band stations CN03, CN04, CN06, CN07, CN08 and CN10, all located along the Cerdanya Basin. Dark green arrows show the reflectors interpreted as corresponding to the basement. Vertical axis refers to the two-way travel time (s). Traces are ordered by date, with the total stack shown beside each panel. The inset map shows the basement depth estimations.

3   Ambient noise tomography (ANT)

Ambient noise tomography is based on the extraction of the fundamental mode Rayleigh waves to measure inter-station group and phase velocity dispersion curves (e.g. Campillo and Paul, 2003; Shapiro et al., 2005; Wapenaar et al., 2010). The obtained dispersion curves are then

327 inverted following a hybrid l₁-l₂ norm (e.g. Tarantola, 2005) criterion using the fast marching

328 method (Rawlinson and Sambridge, 2005) on the forward problem to produce velocity maps

329 for a set of periods.

330

331 The data gathered with both the broad-band and the nodes deployments, together with the data

332 at the permanent stations covering the area, have been used to obtain a high resolution ANT

333 model centered in the CB. The data processing includes correcting the raw data to ground

334 velocity from 0.05 to 20 Hz, band-pass filtering from 0.1 to 5 Hz, decimating to 20 samples

335 per second, dividing into one-hour-long non-overlapping sequences, and rejecting sequences

336 containing gaps or high-amplitude signals. We compute symmetric cross-correlations up to a

337 maximum lag time of 90 s using the wavelet phase cross-correlation and time-scale phase-

338 weighted stack (ts-PWS, Ventosa et al., 2017)and then measure Rayleigh phase-velocity

339 dispersion curves following (Ekström et al., 2009). To estimate the average and the confidence

340 of the phase velocity extracted from the cross-correlation ensemble per station we randomize

341 the individual cross-correlation, subsequently stacked with the two-stage ts-PWS, using the

342 jackknife resampling cross-validation technique (Efron and Stein, 1981) following the

343 resampling strategies of Schimmel et al. (2017). Finally, we construct Rayleigh phase-velocity

344 maps solving an inverse problem with l₁-norm misfit function on the data space and a l₂-norm

345 on the model space using the steepest-decent method, and applying the fast marching method

346 (Rawlinson and Sambridge, 2005) to solve the forward problem.

347

348 Although the pointwise inversion to depth of the dispersion curves is still not available, the

349 inspection of the phase velocity maps at short periods provides a good insight on the geometry

350 of the uppermost crustal layers. In scenarios with strong velocity contrast such as a sedimentary

351 basin, sensitivity kernels at short periods are highly sensitive to the low-velocity layer. Broadly,

352 this sensitivity increases as period reduces and the sedimentary layer thickens in strongly non-

353 linear manner. As the Rayleigh-wave phase velocities at periods from 1 to 2 s have their

354 maximum sensitivity at depths ranging between 200 – 800 m, the low velocity zones observed

355 at the shortest periods analyzed can be roughly interpreted as corresponding to sediments in

356 the uppermost layer, with significant variations in thickness along the basin. The map obtained

357 for the shortest period available, 1.0 s, shows a clearly defined low velocity zone covering the

358 central part of the basin, the same area where RFs and autocorrelation methods have already

359 pointed to a significant sedimentary cover (Fig. 5a). The low velocity zone in ANT maps

360 extends to the NE following the direction of the Têt Fault, including the area near Puigcerdà,

376 although with slightly higher Vs values, around 2.0 km/s. To the southwest, the end of the

377 Cerdanya Basin is delineated by velocities around 2.2 km/s, still lower than in the surrounding

378 areas. For periods around 1.5 s, the low velocity area is similar although the velocity contrast is

379 lower and the southern part of the basin has only a slightly lower-than-average velocity (Fig.

380 5b). For periods around 2.0 s, the presence of low velocities related to the sedimentary basin is

381 limited to the central area (Fig. 5c).

382

400

401 **4   Horizontal to vertical spectral ratio (HVSR)**

402 One of the most usual methods to characterize shallow structure using seismic data is the
403 Horizontal to Vertical Spectral Ratio (HVSR) method (Nakamura, 1989; Bard, 2004), as it
404 provides a reliable, fast and low-cost tool to estimate site characterizations. Analyzing the
405 seismic background noise during different time intervals, this method allows to obtain the soil
406 fundamental frequency (f0), related to the strong impedance contrast at the soil-bedrock
407 interface (Field and Jacob, 1993). This soil fundamental frequency can then be used to estimate
408 the depth of the soil-bedrock interface by means of empirical relations with borehole
409 stratigraphies or velocity-depth profiles in places where this kind of results are available (Ibs-
410 Von Seht and Wohlenberg, 1999; Benjumea et al., 2011; Akin and Sayil, 2016; Delgado et al.,
411 2000). HVSR methods were applied by Gabàs et al. (2016) to define the geometry of the CB
412 along a 2D-profile, obtaining f0 values ranging between 0.3 and 1.7 Hz. The use of seismic
413 array methods has allowed the authors to obtain shear-wave velocity-depth profiles and to then
414 infer a scaling law between f0 and basement depths.

415

416 The processing of the data acquired by the broad-band stations and the seismic nodes to
417 calculate the HVSR starts with correcting the instrument response to ground velocity. We
418 filtered the data between 0.05 and 20 Hz, a frequency range wide enough considering the
419 fundamental frequencies we can expect. Following a classical approach, we split all available
420 data, spanning over a year for the broad-band stations and 2 months for the node deployment,
421 are sliced into sequences of 240 s with a 50% of overlap and windowed with a Hann taper, the
422 parametrization providing the best results after performing several tests. Similarly to Konno
423 and Ohmachi (1998), we then smooth their spectra, applying a bank of 261 Hann filters with a
424 quality factor (i.e., bandwidth divided by central frequency) of 20 uniformly distributed in a
425 logarithmic scale along the above frequency range, and subsequently averaging their outputs.
426 Finally, we tested different criteria to determine the optimum HVSR, observing that the best
427 results were obtained when using the least square criteria, i.e., HVSR = sqrt(E{H·V}/E{V·V})
428 where H and V are the horizontal and vertical spectra, and the expectations E{·} is measured
429 as the mean value after removal of outliers. Supplemental Material S2 shows some examples
430 of the obtained HVSR.

448

449 The geophones used by the high-density array have a characteristic frequency of 10 Hz, which

450 means that the recording sensitivity decreases for frequencies below this value. As the f0 values

451 expected in a sedimentary basin are clearly below 10 Hz, these instruments are not the most

452 suitable for this type of study. However, a significant number of the instruments have provided

453 useful f0 values, even below 1.0 Hz. For the broad-band stations along the basin, the lower f0

454 values (0.36-0.38 Hz) are observed at stations CN07 and CN08, with values between 0.40 and

455 0.60 Hz for stations CN04, CN06, CN09, and CN10. Stations outside the basin, mostly located

456 over the Paleozoic massif, do not show clear frequency peaks for frequencies below 20 Hz.

457 Regarding the nodes, we have retained 59 valid measurements from a total of 143 (40%). A

458 large number of the nodes installed in the central part of the basin, near broad-band stations

459 CN06-CN08, have not provided useful HVSR measurements. We interpret that the frequency

460 range of these instruments was not sensitive enough to the low-frequency f0 values expected

461 for the sites located in this area. Figure 6a show the retained f0 measurements over the network.

462

463 As discussed above, Gabàs et al. (2016) have adjusted an exponential law to relate f0 and

464 basement depth, based on their velocity/depth models. Even if this relationship was inferred

465 for the narrow zone covered by their experiment, it still seems to be better suited for application

466 to our case, located in the same sedimentary basin, than experimental laws published for other

467 basins and has therefore been used to translate the new f0 measurements to basement depth

468 estimations (Fig. 6b). Just four broad-band stations, all of them in the central part of the basin,

469 have depths exceeding 450 m, reaching a maximum value of 530 m below station CN07.

470 Stations located near the Puigcerdà area (1.95°, 42.42°) show depth values above 400 m, while

471 large parts of the basin show basement depths ranging between 350 and 450 m. As expected,

472 the thinner values are found at the locations close to the borders of the basin.

473

474 We have interpolated a gridded surface using the nearest neighbor algorithm included in the

475 GMT software package (Wessel et al., 2013), using a search radius of 2 minutes of arc and

476 requiring 3 out of 8 sectors providing data. These values have been selected by trial-and-error

477 in order to avoid artifacts related to the interpolation and to keep a good spatial resolution.

478 Although this surface must be taken with caution, as the interpolation is based on a strongly

479 uneven point distribution, it provides our first quantitative map of the basement.

483

488

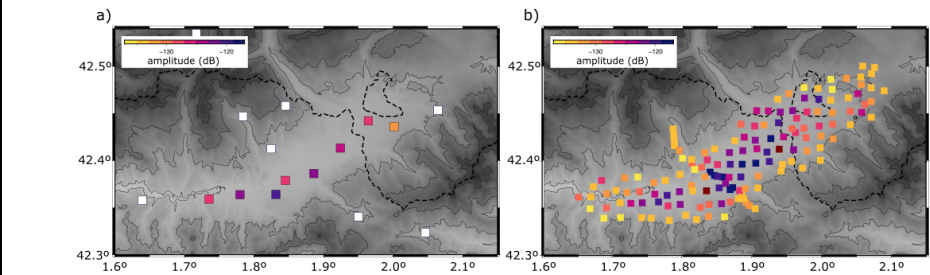
489 5   **Seismic amplitude mapping**

490 Between 0.1 and 1 Hz, in the frequency range commonly known as the microseismic peak, the
491 origin of the ground vibration is mainly related to the interaction of oceanic waves (e.g. Díaz,
492 2016). This explains the great similarity of the spectrograms in this range for all the analyzed
493 stations. Background seismic vibrations at frequencies above 2 Hz in stations located near
494 populated areas are dominated by human activities. The seismic signals show typically a large
495 daytime/nighttime variation, with large amplitudes during working hours and much smaller
496 ones during nighttime and weekends. This point has been evidenced during the recent
497 COVID19 lockdown, when seismic data in the 2-20 Hz has been used as a proxy of human
498 activity, both at local scale (e.g. Diaz et al. 2021; Maciel et al. 2021) or at global scale (Lecocq
499 et al. 2020a). The frequency range between 1 and 10 Hz, located between the microseismic
500 peak and the band dominated by anthropogenic noise, provides the best opportunity to explore
501 the eventual relationship between seismic amplification and geological structure. Other
502 processes, as rainfall or wind bursts can contribute to the observed amplitudes (Diaz et al.,
503 2023), but their effect tend to be limited in time, while the amplification effects due to
504 sediments should be observed continuously.

505

506 In order to analyze the amplitude variations as a function of time, the instrumental response is
507 removed following standard procedures. The Power Spectra Density (PSD) is then calculated
508 to quantify the energy levels at each frequency, using an Obspy implementation (Krischer et
509 al. 2015) of the classical PQLX ("IRIS- PASSCAL Quick Look eXtended") software

(Mcnamara et al., 2009), based on the open-access "SeismoRMS" software package (Lecocq et al., 2020b). The data is divided into 30-minute windows with 50% of overlap and the PSD of each window is computed using the Welch method. The spectrograms retrieved from the PSD analysis show the power of the seismic acceleration, expressed in decibels (dB) referred to 1 $m^2/s^4/Hz$. The inspection of these spectrograms (Fig. 7) confirms that the day/night variations typically related to human activity dominates the spectra at frequencies above 10-15 Hz. It can also be observed that, for frequencies above 40 Hz, episodes of increased amplitudes can be recognized at many of the stations. Recently, Diaz et al. (2023) have shown that the seismic signals at this frequency range are dominated by rainfall episodes and proposed to use seismic data as a proxy of rainfall. These observations confirm that the 1-10 Hz band is the best choice to analyze a possible relationship with the subsoil geology. The effect of anthropogenic noise is still visible in this band, in particular for nodes located close to villages or main roads, but, as shown in Fig. 7, its energy is much lower than for frequencies above 10 Hz.
Figure 7*: Spectrograms for stations distributed along the basin. Red and blue boxes show the frequency bands dominated by meteorologic and anthropogenic sources. Black boxes outline the frequency band related to site amplification.*

542 From the calculated PSD spectrograms, we extract the median value of the power spectra in
543 the 1-10 Hz band for the whole available records (12 months for the broad-band stations, 2
544 months for the nodes). The amplitude of the power spectra is calculated at intervals of 30
545 minutes and expressed in dB relative to 1 $m^2/s^4/Hz$. In a first stage, this procedure is applied to
546 the broad-band stations installed along the basin (Fig. 8a). As observed, the largest values are
547 found in the thickened area identified by RFs, autocorrelation and HVSR.


550 **Figure 8:** *Seismic power amplitude for the BB stations (a) and for the dense nodal*
551 *deployment (b). The color palette represents the median amplitude in the 1-10 Hz band,*
552 *measured in dB. White squares are for broad-band stations with lower median amplitudes*
553 *(out-of-scale). The background shows the topography and the dashed line corresponds to the*
554 *Spanish-French border.*

556 The same approach has then been applied to the dense seismic network available in the
557 Cerdanya Basin. Fig. 8b shows the median values for all the nodes, clearly showing a
558 distribution with low-level amplitude sites around the borders of the basin and large amplitude
559 sites in the center of the basin, over the same areas previously identified as showing the largest
560 sedimentary thicknesses.

562 A visual comparison between the seismic noise amplitude values and the basement depths
563 estimated by Gabàs et al. (2016) along the Ger-Das profile, suggest that it is possible to obtain
564 a scaling law between both datasets (Supplementary Material S3), as there is an agreement in
565 the relative variations along the profile of the estimated basement depths and the new seismic
566 noise amplitude values, with the larger depths and the higher amplitudes located in the central

581 part of the basin. Although a linear relationship can provide a general good adjustment, the
582 better results are obtained using a degree two polynomial adjustment, following the expression:

583 $$depth = 3.97 *dB^2 + 1062.89*dB + 71118.22$$

584 Supplementary Material 3b shows the quality of the adjustment. It can be observed that for
585 depths exceeding 400 m, the power amplitude increases very slowly, suggesting that there is a
586 threshold effect in the relationship between sediment thickness and amplitude amplification.
587 In order to avoid extrapolation effects, we have limited the application of this law to noise
588 values ranging between -133 and -120 dB.

590 **_Figure 9:_** _Basement depths inferred from seismic amplitudes in the 1-10 Hz band (a) and_
591 _including also the HVSR-derived values (b). Thick black line shows the location of the Têt_
592 _Fault. The background shows the topography and the dashed line corresponds to the Spain-_
593 _France border._

595 Following this law, power amplitude values are converted to basement depth estimations and
596 represented in a map (Fig. 9a). As the results derived from the nodal network have a high-
597 density distribution, with a site located every 1.5 km approximately, it is possible to interpolate
598 a continuous grid covering the area. As for the HVSR case, we have used the nearest neighbor
599 algorithm included in the GMT package (Wessel et al., 2013), to obtain a continuous grid,
600 using a search radius of 3 km, an interval of 0.3 km and requiring 6 of 8 sectors with data.

602 Finally, in order to check the consistency of our results, we have interpolated, using the same
603 parametrization, a new grid using as input the basement depth estimations arising from
604 autocorrelations, HVSR and seismic noise analysis (Fig. 9b). As observed, both models are
605 very similar, with the deeper values, reaching values exceeding 600 m, located in the central
606 part of the basin and a secondary maximum with depths around 300 m in the western part of

616 the basin. The interpolation grid of all the datasets allows to obtain an averaged basement depth
617 estimation, which is considered our final result.

618

6   Discussion and conclusion

620 Ambient seismic noise data acquired in the Cerdanya Basin has been used to assess the
621 suitability of different methodologies to investigate the 3D geometry of this sedimentary basin
622 located in the Eastern Pyrenees. Autocorrelation relies on the reflection of body waves of
623 unconstrained origin, ambient noise tomography is based on the propagation of surface waves
624 of unknown origin between the receivers, HVSR considers the horizontal and vertical
625 components and provides measurements in terms of frequency and seismic amplitude provides
626 measurements in terms of energy. Therefore, all approaches are complementary, reduce
627 ambiguities and provide a more complete picture of the Cerdanya Basin geometry. The new
628 results provide a 3D regional scale map of the depth of the basement beneath the Neogene-
629 Quaternary sedimentary deposits, clearly improving the knowledge on the depth of the CB,
630 limited till now to the narrow profile analyzed by Gabàs et al. (2014) (Supplementary Material
631 S4).

645

655

The analysis of the autocorrelations of the broad-band stations within the basin has shown that reflectors associated to the sediment/basement discontinuity can be identified in most of these sites. Reflections in autocorrelations need to be calibrated using boreholes for their correct interpretations. Unfortunately, no borehole data is available in the Cerdanya Basin, but using

662 realistic Vs values, we have estimated that the vertical sedimentary thickness ranges between
663 420 and 670 m, which agrees with the maximum preserved Miocene-Quaternary sedimentary
664 infill accumulative thickness of almost 800 m (Cabrera et al., 1988). A more quantitative result
665 arises from the use of HVSR to the broad-band stations and the high-frequency geophones
666 deployed with short interstation distances in the basin. Using the empirical formula proposed
667 by Gabàs et al., (2016), the f0 measurements have been translated to depths. The high frequency
668 geophones used in the node deployment, with a natural frequency cut-off of 10 Hz, does not
669 allow us to recover the f0 frequencies in the deeper part of the basin, but provide interesting
670 values for the thinner parts, hence providing a first 3D vision of the basin geometry. The results
671 clearly evidence that the thicker sedimentary successions are those already identified from the
672 autocorrelation analysis, although the obtained thicknesses are lower. Finally, the analysis of
673 the seismic noise amplitude in the 1-10 Hz band, can be interpreted as an excellent proxy of
674 the sediment thickness along the basin. Passing from amplitudes measured in dB to basement
675 depth is possible by correlating the noise measures at the locations studied by Gabàs et al.
676 (2016) with the corresponding basement depths. The polynomial correlation obtained allows
677 us to determine a 3D map of the basin, which is consistent with the HVSR and autocorrelation
678 estimation. Additional confirmation of the results arises from the ambient noise tomography,
679 obtained using the high-density dataset. Although results for the depth inversion of this dataset
680 are not yet available, the velocity maps at short periods, sensitive to the uppermost parts of the
681 crust, show low velocity areas clearly consistent with the results obtained from the rest of
682 methodologies.
683
684 It is difficult to provide a quantitative evaluation of the consistency of the different approaches,
685 as most of the sites do not provide simultaneous measurements of autocorrelations, f0 and
686 seismic noise amplitudes. Although we have noted that there is an overall similarity in the
687 results arising from the different methodologies, it is also clear that relevant variations do
688 occur, in particular for some specific areas. In order to get an insight of the order of magnitude
689 of these variations, we have represented in Fig. 10 the basement depths estimations from
690 autocorrelations, HVSR and seismic noise along a profile crossing the whole basin.   In
691 addition, we have represented the velocity variations along the same profile in the ANT models
692 for T=1.0, 1.5 and 2.0 s, sampling the uppermost part of the crust. The figure includes a
693 geological map with the basement depths estimations derived from all the methodologies
694 represented by squares colored using the same palette than for the grid in Fig. 9b. The western
695 section of the profile shows basement depths around 300m, with the HVSR estimations thinner

than those from seismic noise and autocorrelations. Near 1.8°E, in the zone where the CB orientation changes, the basin seems to vanish, to reach its thicker section immediately to the NE. Between 1.8°E and 1.9°E the agreement of the results is high, with differences in the 50-100 m range. Further north, between 1.9° E and 2.0°E, although all the results show a NE directed thinning, the differences are much larger, with the HVSR grid varying from 400 m to 250 m and the seismic noise estimations passing from 200 m to just around 50 m. The only autocorrelation estimation available in this area is close to the HVSR values. Near the NE termination of the profile, the results are again consistent. In general, the basement depths estimations derived from the seismic noise amplitudes in areas with relatively low amplitude are underestimated. As discussed above, the law to pass from amplitude dB to basement depths was derived using the data published by Gabas et al. (2016). As the amplitudes in the area covered by their profile are higher than in other parts of our region of interest, it is possible that the relationship between amplitudes and basement depth needs to be revised for the sites with low amplification (Supplementary Material S4). Further data will be needed to verify this point. Regarding the ANT results, all the profiles show a clear thickening in the central part of the basin and a gradual thinning towards the terminations of the profile. Although a more accurate comparison will only be possible once this dataset has been inverted to depth, the relative variations observed in these profiles are consistent with the basement depth estimations from the other methods. The velocity variations are larger for T=1.0 s, the period with a sensitivity kernel closer to the surface.

The differences between the results from each methodology are attributed to the different hypotheses used in each case, from the choice of a certain frequency band for the seismic noise, the formulas used to convert amplitudes of f0 values to depths or the velocities used to pass from autocorrelation TWT to depths. However, we want to highlight that the order of magnitude and the relative thickness variations derived from all the methodologies are consistent, proving that these approaches, quicker to obtain than tomography inversions, are a good option to assess the geometry of sedimentary basins.

743

751 *lines show the location of the Têt Fault, projected from the geological cross-section by Calvet*
752 *et al. (2022).*

753

754 Figure 11 shows the basement depth transect along the high-density node profile crossing the
755 central domain of the Cerdanya Basin, altogether with two profiles crossing its northern and
756 southern domains, following the geological models shown in Calvet et al. (2022). The northern
757 profile shows the base of the basin displaying a gentle deepening towards the SE with its
758 deepest part located in its central part close to the town of Puigcerdà. This deepest part of the
759 basin nearly coincides with the limit between the areas covered by alluvial fans of granitic and
760 non-granitic sources. As reflected in the geological maps (Instituto Geológico y Minero de
761 España and Bureau de Recherches Géologiques et Minières, 2009), the western part is covered
762 by alluvial materials of granitic origin transported from the north. To the east, the basin is
763 covered by alluvial fans from slate or limestone source reaching the basin from the ENE
764 (Cabrera et al. 1988). The seismic noise amplitudes in this eastern zone are low, resulting in
765 basement depths of just 100 – 50 m, clearly below the geological models in Calvet et al (2022).
766 The results from HVSR and autocorrelations are scarce in this area, but tend to provide thicker
767 depth estimations. The basement depth estimations derived from ambient noise seems to be

Moved (insertion) [10]

Deleted: The CB can be divided in two main sections, the eastern NE-SW trending section and the E-W trending western part (Fig. 9f). This geometry is clearly related to the position of the Têt Fault, which shows a similar change in orientation (Calvet et al. 2022). The thicker sedimentary succession of the basin is located in its eastern part, extending between 1.85ºE and 2.95ºE. This area has a sedimentary thickness exceeding 600 m and seems to thicken to the SE, ¶
towards the Têt Fault. The E-W oriented western part of the section shows a sedimentary depocenter reaching 300 m that seems to be disconnected from the one in the eastern sector. ¶

underestimated in this area of relatively low amplitude, either because the used law to pass from dB to depths does not work properly for low amplifications or because the alluvial materials have a different seismic amplification than more consolidated sediments. Further geological and seismic studies will be needed to fix this point. The central profile shows a sedimentary thickness reaching 700 m and a steep margin in the location of the Têt Fault limiting the basin along its SE side. Although the results from seismic noise and HVSR show some differences, they are generally consistent with the en-echelon geometry proposed for the central profile in Calvet et al. (2022) south of the Segre River. However, our results suggest that the sedimentary basin reaches the Segre River, a point not documented in the geological profile. The seismic noise and the HVSR results clearly depicts the location of the Têt Fault. The profile crossing the westernmost part of the CB along a north-south direction shows a basin thickening to the south and a step discontinuity beneath the trace of the Têt Fault, an image consistent with previous models based on geological observations (Cabrera et al., 1988; Calvet et al., 2022).

The conclusion of this study is that the analysis of ambient noise and HVSR in dense (large-N) seismic networks is a useful tool to obtain information on the 3D geometry of sedimentary basins. Although the obtained estimations must be taken with caution, as significant differences between the estimations derived from both methods can appear, in particular for areas with low amplification, the overall models provide a simple procedure to estimate the uppermost crustal structures. Ambient noise tomography is expected to provide better constrained results, but the processing and inversion requirements are clearly higher and the inversion of the dispersion curves to depth benefits from a previous knowledge of the crustal structure, a point that can be provided by the previously described methods. Besides, autocorrelation methods provide an independent procedure to check the consistency of the results and can provide useful constraints, in particular if well log data are available.

The results on the geometry of the Cerdanya Basin derived from this study are expected to provide additional constrains to better understand the role of the Têt Fault in defining the geometry of the Cerdanya Basin and its present-day degree of tectonic activity. On the other hand, our results can contribute to refine the seismic risk maps in this area with important touristic activity, as a good knowledge of sedimentary basins is a key point to estimate the seismic vulnerability.

Deleted: ¶
The consistency between the results from all the methodologies used provides solid constraints to our basement depth estimation and confirms that these approaches, quicker to obtain than tomography inversions, are a good option to assess the geometry of sedimentary basins, especially in lightly eroded to non-eroded basins, or with dense forestation. In this sense, both autocorrelation and seismic amplitude analysis can easily provide information on the relative thickness of the investigated area. In order to get absolute depths, it its necessary to have some kind of additional data, as boreholes or Vs profiles. We want to highlight that to obtain detailed 3D information of a sedimentary basin using seismic data is only possible if dense temporary (large-N) arrays are deployed over the area as, with exception of tomography, all used approaches provide results which are refer to the structure beneath each station. As a good knowledge of sedimentary basins is a key point to refine seismic risk maps we conclude that the cost-benefit ratio of using large-N deployment recording background seismic noise is very positive. We are convinced that these results will provide additional constrains to the geomorphological characterization of the basin, as they increase significantly the knowledge of its 3D geometry.¶

Supplemental Materials

Supplementary Material S1: Details of the RFs calculation

In order to obtain the RFs presented in this contribution, we have followed a classical approach, already used in a prior RFs study in the eastern Pyrenees published by the same author team (Diaz el at., 2018).

The first step in data processing was to select teleseismic events with magnitude higher than 5.5, epicentral distances between 35º and 95º and clear P arrivals. We then calculated the corresponding RF by frequency domain deconvolution (Langston, 1979) of the vertical component from the horizontal components in the time window corresponding to the P arrival and its coda. Prior to the RF calculation, data has been high-pass filtered with a corner frequency of 0.1 Hz to avoid problems due to low-frequency signals. The deconvolution was performed using the classical "pwaveqn" software (Ammon, 1997), using a value of 10 for the low-pass gaussian filter parameter, equivalent to pulse width around 0.5 s, to preserve the high frequency content of the signals and hence allow a better delineation of the crustal discontinuities. A standard value of 0.05 is used as water level parameter to avoid numerical problems during deconvolution. An automatic workflow has been implemented to calculate RFs, retaining only those signals with large signal-to-noise ratio of the incoming phases. In a second step, the selected events have been visually inspected in order to discard unclear records. The number of finally retained events ranges between 22 and 57, with a mean value of 46 retained RFs per station.

The traces shown in Figure 3 are obtained by applying Ps-moveout correction to a reference ray parameter of 0.065 s/km to the selected RFs and sum the corrected traces for each of the stations located along the Cerdanya Basin.
