13 **Abstract**

14
15 The tectonic evolution of highly oblique continental margins that result from back-arc extension have lithospheric
16 STEP faults is poorly understood. Here, we investigate the case of the Alboran margin in the eastern Betics
17 characterized by crustal thinning of 15-10 km, oblique to the direction of slab retreat. The current deformation patterns
18 indicate that oblique back-arc rifting is underway. However, it is unclear whether these conditions are those that
19 prevailed during the formation of the metamorphic domes and intramontane basins. We review the temporal and
20 spatial evolution of Neogene sedimentary basins and brittle deformation in the eastern Betics, and exploit offshore
21 seismic reflection lines to propose a crustal-scale section across the oblique margin. The history of sediment infill and
22 rates of subsidence combined with the analyses of fault slip data, confirm that brittle extension oriented from N20°E
23 to EW occurred during an interval spanning from the Serravallian-early Tortonian to the late Tortonian (14-8 Ma).
24 This extension is found associated with both normal and strike-slip regimes and the evolution of the strike-slip
25 corridors flanking the metamorphic domes. The transtensional model forms a coherent scheme linking the ductile
26 deformation associated with metamorphic domes and the formation of EW- and NW-SE/NNW-SSE-directed
27 sedimentary basins in the brittle upper crust during the Tortonian. The oblique extension, which is closely associated
28 with STEP faulting, occurred during the regional convergence between Africa and Iberia since the Miocene. Only
29 recently, around 8 Ma, a slab detached, leading to local tectonic inversion. Such a type of narrow oblique rifted
30 margin associated with transform-like plate boundaries is not unique but is expected to be hardly preserved in the
31 geological record due to the transient nature of retreating subduction systems.

32 **1 Tear faulting and the formation of oblique transform margin in the Betics**

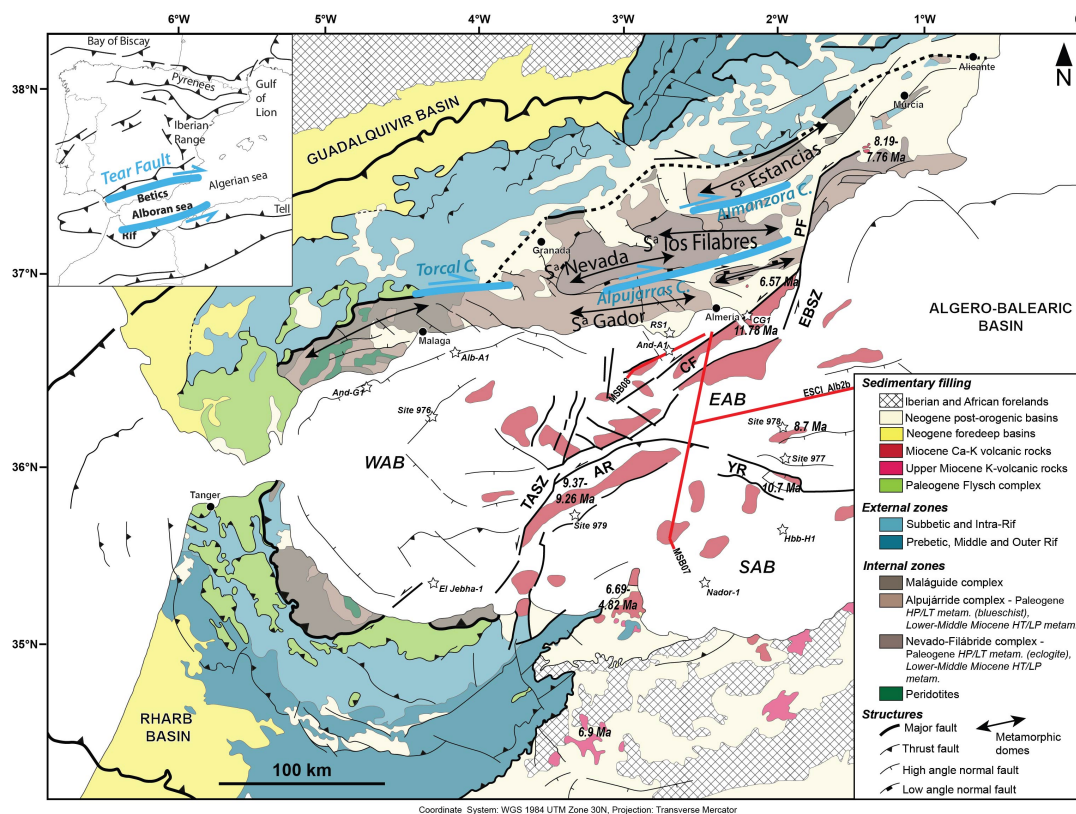

33 Lithospheric tear faults or subduction-transform edge propagator (STEP) faults are propagating strike-slip faults that
34 accommodate the differential motion between the retreating subduction zone and the overriding back-arc plate (Govers
35 and Wortel, 2005). Because of the relative motion between back-arc and surrounding plates, they are also propagating
36 strike-slip faults defined by a sharp contrast in crustal thickness. As noted by Govers and Wortel (2005) such oblique
37 fault boundaries do not necessarily form proper transform plate boundaries but broad zones of distributed deformation,
38 accommodating differential trench-parallel extension, strike-slip motion and rotation. In case the lithospheric tear
39 propagates within the continent-ocean transition, a narrow continental margin forms highly oblique to the direction of
40 back-arc extension. This is documented, for instance, in the Carribean, along the transcurrent Carribean-South
41 America plate boundary (Pindell and Kennan, 2009) or on the margin of the South Orckney microcontinent, along the
42 Scotia-Antarctic plate boundary (Dalziel et al., 2013). Despite the large-scale kinematic picture is relatively well
43 understood, there are only few places where continental crustal deformation associated with this peculiar type of slab-
44 edge continental rift system can be studied.

45 Here, we focus on the Betic Cordillera, on the northern boundary of the Gibraltar arc (**Figs 1 and 2**). There, a rifted
46 margin, defined by decreasing crustal thickness from 30 km in the Alboran basin (Diaz et al., 2016), is seen to
47 develop above a STEP fault (Badji et al., 2014; Gallais et al., 2013; Jolivet et al., 2021a; Mancilla et al., 2015a). The
48 tectonic expression of the transcurrent deformation during crustal extension above the lithospheric tear is however
49 controversial. On the one hand, low-angle ductile extensional detachments with a top-to-the-west sense of shear are
50 the main features accommodating deformation in the overriding plate. Yet, a-type metamorphic domes in the lower
51 crust, elongated parallel to the E-W direction (**Fig. 1**), are viewed to express the transtensional deformation at the tip
52 of propagating tear (Pourhiet et al., 2012). On the other hand, strike-slip faulting is interpreted as a late brittle
53 deformation feature associated with E-W crustal strike-slip brittle faults between the metamorphic domes in the eastern
54 Betics (Alpujarras corridor; Sanz de Galdeano and Vera, 1992; Sanz de Galdeano et al., 1985; Martínez-Martínez et
55 al., 2006) and in the western Betics (e.g. Torcal corridor; García et al., 2016) unrelated to ductile deformation (**Fig.**
56 **1**). In line with the latter interpretation, the dextral motion these strike-slip faults accommodate is assumed to be
57 modest, reflecting a recent post-8 Ma kinematic change that accompanies the end of slab retreat, and onset of
58 compression in the Gibraltar Arc (Do Couto et al., 2014; d'Acremont et al., 2020; Jolivet et al., 2021a; Martínez-
59 García et al., 2017).

60 The lack of structural, temporal constraints and quantification of belt-parallel motion along these faults indicates,
61 however, that we do not yet fully understand their link with the long-term evolution of slab tearing and margin
62 formation. For instance, the current deformation patterns brings critical evidence that both strike-slip faulting and
63 extension operate synchronously, so that brittle strike-slip faulting and ductile extension might reflect the same
64 tectonic episode. This is argued by ongoing extension illustrated by the west-directed GPS velocities increasing
65 westwards, and the west-directed displacements increasing towards the Alboran domain revealing active right-lateral
66 shear deformation (**Fig. 2**). The current transtensional deformation across the Betic Cordillera is also shown by the
67 current stress regime defined by extension direction highly oblique (max. 20°) to the Betic structural trend (or 70°
68 spanned by the direction of extension and normal of the rift trend). Right-lateral transtensional deformation in the

69 Betic agrees with evidence for west-directed lateral extrusion of the Alboran Basin (Borque et al., 2019; Palano et al.,
 70 2015). In the east, the extrusion is accommodated by left-lateral strike-slip displacement along the Eastern Betic Shear
 71 Zone (EBSZ; Borque et al., 2019), which is shaped by the Carboneras Fault (CF) and Palomerias Fault (PF). This fault
 72 extends offshore, across the Alboran Sea, in the larger Trans-Alboran Shear Zone (De Larouzière et al., 1988; Stich
 73 et al., 2006) moving at ~4 mm/yr, equivalent to the regional 5 mm/yr NW-directed convergence between Africa
 74 (Nubia) and Europe (Fig. 2; Echeverria et al., 2013; Koulali et al., 2011; Nocquet, 2012; Palano et al., 2015, 2013;
 75 Vernant et al., 2010). Here, we hypothesize that the present-day oblique extension patterns is at play since the Miocene
 76 and explain the formation of the narrow Alboran rifted margin.
 77

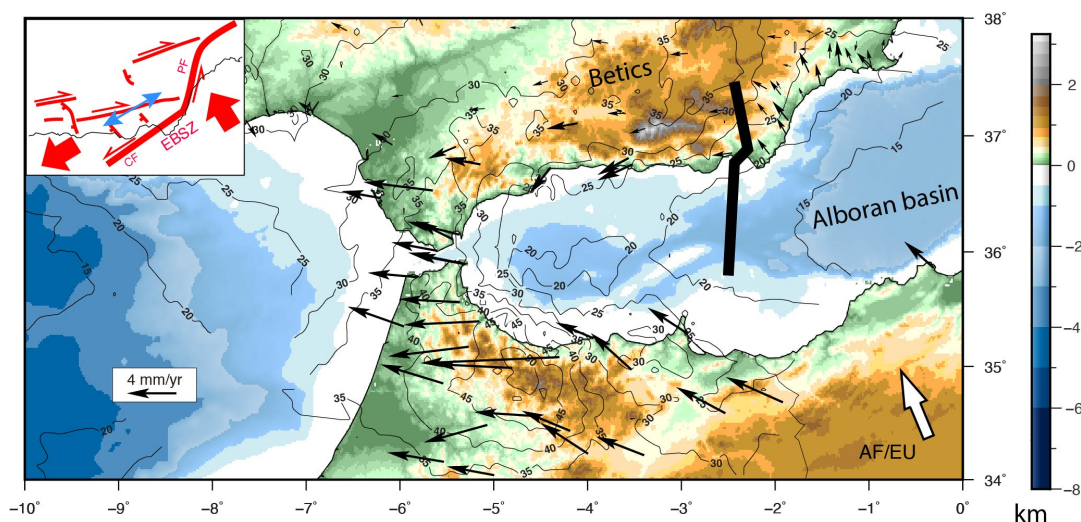

78
 79 **Figure 1** : Geological map of the Betic-Rif arc. Main tectonic units and age of volcanism as well as major structures
 80 and Neogene sedimentary basins are shown. The studied offshore seismic lines (red) is displayed as well as offshore
 81 wells and ODP sites (★) for stratigraphic calibration in the East (EAB), South (SAB) and West Alboran basins
 82 (WAB). CF: Carboneras Fault; PF : Palomerias Fault; AR: Alboran Ridge; YR: Yusuf Ridge; EBSZ : East Betic Shear
 83 Zone; TASZ: Trans-Alboran Shear Zone.
 84

85 Only recently high-resolution 3D numerical models have been able to predict the deep structure of oblique rift
 86 domains. These models can be used as a guide to re-evaluate the evolution of the Betic region. 3D models by Jourdon
 87 et al. (2021) predict that oblique extension results in narrow rifted margins, strike-slip faults and corridors coupled

88 with subsident pull-apart basins, normal faults and block rotations (Fig. 3). The recognition of block rotation in the
89 Betic arc (Crespo-Blanc et al., 2016; Platzman, 1992), strike-slip corridors (Fig. 1) and NW-SE normal faulting, which
90 defines extension direction highly oblique to the margin, (Galindo-Zaldivar et al., 2003; Figs 1 and 2) all support this
91 view. The simulations of Jourdon et al. (2021) also show that the deeper ductile crust experiences thinning (vertical
92 flattening) and stretching perpendicular to the strike of the margin in accordance with stretching lineations parallel to
93 the metamorphic domes and low-angle detachments (Fig. 3). Other types of 3D numerical experiments show that
94 sediment loading of strike-slip faults can result in asymmetric flexural basin with apparent normal fault throw
95 (Neuharth et al., 2021) that can be mistakenly interpreted as resulting from orthogonal extension. Asymmetric basins
96 are indeed intriguing characteristics of intramontane basins in the Betics (Ser et al., 2013; Do Couto et al., 2014).
97 Although primarily found associated with divergent plate boundaries e.g. in the Gulf of California (Fossen et al., 2013;
98 Fossen and Tikoff, 1998) highly oblique extension is also documented in active transform regions along the San
99 Andreas Fault (Teyssier and Tikoff, 1998) or the North Anatolian Fault in Marmara Sea (Okay et al., 2004). A detailed
100 analysis of highly oblique rifting deformation in the Gulf of California recognises similar tectonic elements as for the
101 Betics, such as extensional detachment systems orthogonal to the divergence and upper crustal folds trending parallel
102 to the divergence (Fossen et al., 2013).
103

104 **Figure 2** : Present-day kinematics in the Betic-Rif arc and eastern Betic Cordillera (inset). GNSS-based displacements
105 in the Alboran block and northern Africa shown in a fixed Eurasian reference frame (black arrows after Palano et al.,
106 2015) are oblique to the AF/EU plate convergence (white arrow) inferred from plate tectonic Morvel model (Argus et
107 al., 2011). Labelled contours depict the crustal depth given in kilometers as inferred from deep seismic profiles and
108 receiver functions analysis (Diaz et al., 2016). In the eastern Betic (inset), W-directed stretching is taken up by EW-
109 directed right-lateral strike-slip fault and NW-SE normal faults. Extension direction resolved from focal mechanisms
110 (blue arrows) are after (Stich et al., 2006). CF : Carboneras Fault; PF : Palomeras Fault; AR : Alboran Ridge; YR :
111 Yusuf Ridge; EBSZ : East Betic Shear Zone; TASZ : Trans-Alboran Shear Zone.
112
113

114 Several tectonic features need further discussion however. First, the relevance of strike-slip faulting in the past is
115 debatable as only a few occurrence of crustal-scale strike-slip faults are mapped. Second, the detail of the temporal

116 and spatial relationships between the formation of the oblique/transform margin and STEP faulting remain elusive.
117 We here review the temporal and spatial evolution of Neogene intramontane sedimentary basins and related brittle
118 deformation in the eastern Betics. In addition, we exploit offshore seismic reflection lines to propose a new crustal-
119 scale section across the oblique margin. Based on these constraints we present a tectonic scenario for the formation of
120 the high-obliquity rift margin in back-arc setting controlled by STEP faulting.
121

122
123 **Figure 3** : Sketch showing two steps (after 10 Myrs and 24 Myrs) of a 3D thermo-mechanical model of oblique rifting
124 in plan view (A) and cross-sections (B). Results are redrawn after (Jourdon et al., 2021) for the case of a highly oblique
125 experiment where extension is set with an angle of 15° with respect to the rift axis. Grey regions in (A) are basins
126 adjacent to uplifted domains (cross-circle symbol) associated with right-lateral strike-slip faults. Cross-sections (B)
127 depict the abrupt crustal thinning that occur perpendicular. Crustal thinning is most visible for the lower crust and
128 produces the formation of an abrupt necking domain controlled by rift-parallel normal faults dipping towards the
129 center of the rift and right-lateral strike-slip faults.
130

131 2. Geodynamics and STEP faulting in the Betics

132 The onset of N-directed movement of Africa, by the Late Cretaceous-Paleogene, led to a Laramide-like contraction
133 from Morocco throughout Western Europe (Mouthereau et al., 2021). South of Iberia, in the Betic-Rif domain, the
134 closure of hyper-extended rift systems and oceanic basins of the Atlantic-Alpine Tethys resulted in the development
135 of a proto-Betic accretionary prism, likely largely submerged (Angrand and Mouthereau, 2021; Daudet et al., 2020;
136 Vergés and Fernández, 2012). By about 50 Ma, the acceleration of plate convergence led to the shortening of

137 continental rift and oceanic basins and topographic uplift all over Iberia (Daudet et al., 2020; Mouthereau et al., 2021,
138 2014; Rat et al., 2019; Vacherat et al., 2016; Waldner et al., 2021) associated with onset of continental rifting along the
139 Western European Rift (e.g. Mouthereau et al., 2021). 35 Ma ago, as Africa convergence slowed down, the western
140 Mediterranean sea opened accompanied by retreating slabs (Dewey, 1988; Dewey et al., 1989; Faccenna et al., 2014;
141 Jolivet and Faccenna, 2000; Rosenbaum et al., 2002). Subduction occurred mainly before 30 Ma as argued by age
142 constraints on high-pressure mineral assemblages (Romain Augier et al., 2005a; Bessi re et al., 2021; Booth-Rea et
143 al., 2015; Gomez-Pugnaire and Fernandez-Soler, 1987; Platt and Vissers, 1989; Platt and Whitehouse, 1999) and has
144 been suggested to last until the mid-Miocene in the eastern Betics e.g. (Platt et al., 2013). The timing of formation of
145 the Alboran basin is constrained to 23 to 16 Ma. The oldest deposits found on Alboran basement and by the timing
146 of high-temperature metamorphic overprint and rapid cooling to shallow crustal temperature (Bessi re et al., 2021;
147 Daudet et al., 2020; Janowski et al., 2017; Johnson et al., 1997; Platt et al., 2005; Sosson et al., 1998; V zquez et al.,
148 2011; Zeck et al., 1992).

149 All kinematic reconstructions agree that extension results from the westward migration of the arc front and retreat of
150 the Alboran slab, well imaged below the Gibraltar arc as a steeply-dipping high-velocity anomaly (Bezada et al., 2013;
151 Heit et al., 2017; Mancilla et al., 2018, 2015a, 2015b; Palomeras et al., 2014; Spakman and Wortel, 2004; Villase or
152 et al., 2015). These reconstructions, however, differ according to the paleo-position of Alboran terrane, and hence to
153 the amount and vergence of subduction (Angrand and Mouthereau, 2021; Hinsbergen et al., 2014; Lonergan and
154 White, 1997; Romagny et al., 2020; Rosenbaum et al., 2002; Verg s and Fern ndez, 2012). Seismic tomography
155 reveals that slab detachment and tearing occur along the conjugate Alboran margins of the southern Betics and
156 northern Africa (Govers and Wortel, 2005; Heit et al., 2017; Mancilla et al., 2015a; Meighan et al., 2013; Spakman
157 and Wortel, 2004).

158 In **Fig. 4** we refer to the reconstruction of Angrand and Mouthereau (2021) that has the advantage of reconciling
159 previous western Mediterranean models (Romagny et al., 2020; Verg s & Fern ndez, 2012) with recent
160 thermochronological analyses in western Betics (Daudet et al., 2020) and other geological data (see compilation in
161 Mouthereau et al., 2021). This model accounts for the existence of an upper Cretaceous-Paleogene foreland basin that
162 formed adjacent to a proto-Betic orogen. In this reconstruction about 400 km of slab retreat is estimated since about
163 35 Ma (gray path, blue arrows in **Fig. 4**). It is worth noting that for Romagny et al. (2020) a similar amount (i.e. 400
164 km) is accommodated by back-arc extension of the Alboran crust, implying the same magnitude of displacement along
165 the STEP fault in the Betics. In the reconstruction of Angrand and Mouthereau (2021), however, crustal thinning in
166 Alboran basin is linked to delamination retreat of the Alboran lithospheric mantle towards the west. In such a model,
167 because of the decoupling between crust and mantle, the length of the delaminated slab resolved at depth in seismic
168 tomography, should not be simply translated into the amount of crustal extension in the Alboran domain. This further
169 implies the displacement across the STEP fault must be also less than 400 km. Daudet et al. (2020) suggested that an
170 extension of 110 km estimated from the restoration of low-angle detachment systems in the central and eastern Betics
171 (Mart nez-Mart nez et al., 2002) is likely to be a more accurate crustal estimate of the movement Alboran domain
172 rather than the total slab length.

Figure 4: Kinematics of African plate (AF), Alboran (Al) and Kabyliides (Ka) blocks with respect to fixed European plate since 35 Ma reconstructed after Angrand and Mouthereau (2021). Thick blue lines depicts the position of lithospheric tear faults (between Al and Europe and Africa) and transfer faults (between Al and Ka). Black arrows indicate the regional movement of Al and Ka with respect to Europe along black motion paths presented from 35 Ma to present. Grey motion paths refer to the motion of specific structures relative to Europe, including the motion of the arc front (thick blue dashed line) and faults in red. Dark blue arrow depicts the movement of the arc front due to retreating delamination towards the west.

192

193

194

195

196

197

The most prominent extensional features in the eastern Betics are : 1) E-W elongated ranges that formed metamorphic domes with foliations bearing prominent E-W stretching lineations (**Fig. 5**; e.g. Sierra de los Filabres-Sierra Nevada, Sierra de Gador and the Sierra de las Estancias) and Serravallian-Tortonian sedimentary basins (Tabernas-Sorbas, Alpujarras, Almanzora and Huércal-Overa basins); 2) NNW-SSE/NW-SE normal fault systems and basins oblique to the domes such as the NW-SE trending Guadix-Baza and Alhabia basins (Galindo-Zaldivar et al., 2003; Martínez-Martínez and Azañón, 1997) (**Fig. 5**). They are described as asymmetric half grabens (Do Couto et al., 2014; Martínez-Martos et al., 2017; Pedrera et al., 2010, 2009) formed during the Upper Serravallian-Early Tortonian (Augier et al., 2005b; Augier et al., 2013; Meijninger and Vissers, 2006). Several of these NW-SE faults are active and cut across the metamorphic domes and the sedimentary basins (Augier et al., 2005a; Booth-Rea et al., 2004; Giaconia et al., 2012; Montenat and Ott d'Estevou, 1999).

In addition to these structures there are E-W right-lateral strike-slip faults that define structural corridors, like the Alpujarras corridor/basin between the Sierra de Gádor and the Sierra Nevada, and the Almanzora corridor/basin between the Sierra de los Filabres and Sierra de las Estancias (**Fig. 5**). The left-lateral Carboneras and Palomeras fault

198 system (Reicherter and Hübscher, 2006; Scotney et al., 2000) marks the tectonic limit with the Cabo de Gata volcanic
199 province (Fig. 5).
200 The domes are extension-related features interpreted either as 1) EW-metamorphic domes resulting from the
201 exhumation in the footwall of a regional W-directed extensional low-angle detachments, later folded during post-
202 Tortonian N-S contraction (e.g. Montenat & Ott d'Estevou, 1990; (Sanz de Galdeano and Vera, 1992; Sanz de
203 Galdeano and Alfaro, 2004; Martínez-Martínez et al., 2002; Martínez-Martos et al., 2017; Pedrera et al., 2010, 2007)
204 or 2) Miocene metamorphic domes formed by constrictional ductile strain regime accompanying W-directed
205 stretching of the Alboran domain and trench retreat, with limited overprint by the Tortonian contraction ca. 8 Ma
206 (Augier et al., 2013; Augier et al., 2005; Augier et al., 2005b; Galindo-Zaldivar et al., 2015; Jolivet et al., 2021b;
207 Martínez-Martínez et al., 2002). Low-temperature constraints from the Nevado-Filabride and Alpujarride complexes
208 confirm the west-directed exhumation of the basement that occurred progressively from the Sierra de los Filabres at
209 ~13-11 Ma (Serravallian) in the East to the Sierra Nevada at 8-6 Ma (Tortonian) in the West (Clark and Dempster,
210 2009; Janowski et al., 2017; Johnson et al., 1997; Platt et al., 2005; Reinhardt et al., 2007; Vázquez et al., 2011).
211

212
213 **Figure 5** : Tectonic map of the eastern Betics showing the main structural elements in black after Augier et al. (2005)
214 and Do Couto (2014). CF: Carboneras Fault; PF : Palomeras Fault.
215

216 Tectonic models for the formation of Neogene intramontane sedimentary basins vary depending on the prevailing
217 tectonic regime. EW-directed basins have been early described as pull-apart basins (e.g Alpujarran corridor) (Sanz de
218 Galdeano et al., 1985). Structural analyses then led to re-interpret these structures as transfer zones resulting from

219 differential extension between exhuming core-complexes (and detachment systems) since the Serravallian (13-11 Ma)
220 later refolded during Tortonian (9-8 Ma) compression (Martínez-Martínez et al., 2006).  support to the dominant
221 regional compressional stress regime, Martínez-Martos et al. (2017) proposed the E-W depressions are related to the
222 tectonic reactivation of crustal weakness zone as dextral strike-slip faults in a counterclockwise rotation,
223 accommodating part of the the N-S shortening. There are evidence that at the end of the Tortonian a regional uplift
224 occurred, rising the remnants of late Tortonian marine platform, 7.2 Ma in age, to 1600 m above sea level in the Sierra
225 de Gádor (Braga et al., 2003; Janowski et al., 2017), coincidentally with the onset of contraction in the Sierra Alhamilla
226 and Sierra de los Filabres (e.g. Do Couto et al., 2014), in the Alboran domain (e.g. (Martínez-García et al., 2017) and
227 on the margins of the eastern Betic (Giaconia et al., 2013). 

228 Based on the prevalence in some EW-trending basins, like the Huércal-Overa basin, of EW-trending normal faults,
229 these basins have alternatively been interpreted as resulting from late exhumation stage of the domes, possibly as soon
230 as the Serravallian, but mostly after the early Tortonian (syn-sedimentary faulting) (Augier et al., 2013; Romain Augier
231 et al., 2005b; Meijninger and Vissers, 2006). The NW-SE/NNW-SSE sedimentary basins (Guadix, Baza, Alhabia;
232 **Figs. 5**), in contrast, are extensional basins formed parallel to the direction of the regional compression (Sanz de
233 Galdeano and Vera, 1992; Larouzière et al., 1988). E-W strike-slip corridors, aligned in the direction of the domes,
234 and NW-SE normal faulting patterns are both key features consistent with predictions from models of oblique
235 extension at transform margin (**Fig. 3**). Yet, based on existing structural and tectonic syntheses a clear temporal
236 relationships between E-W ductile stretching in the domes and ~~transcurrent~~ deformation is not established (**Fig. 5**).

238 **3.2 Are the Tortonian rift-related subsidence consistent with oblique extension ?**

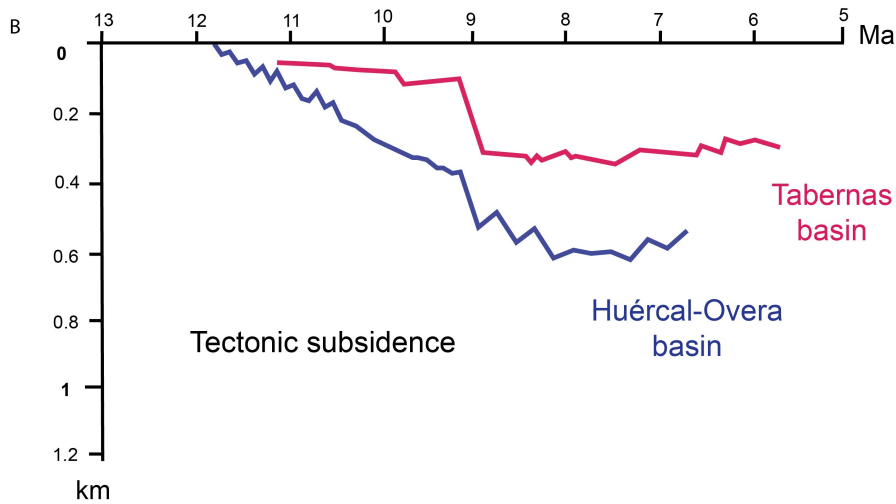

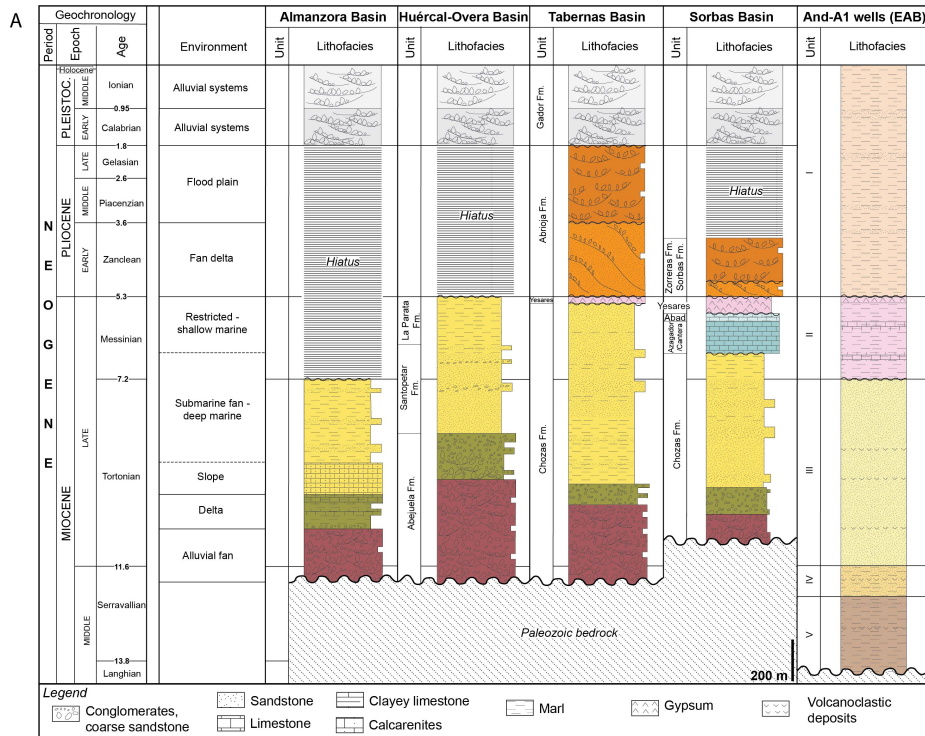

239 The stratigraphic architecture and depositional evolution of Tortonian intramontane basins provides first-order
240 informations on the distribution of crustal thinning. ~~The oldest sediments deposited unconformably on the Paleozoic~~
241 ~~Triassic basins~~  ~~the red alluvial conglomerates and deltaic series dated from Serravallian to lower Tortonian (~11-~~
242 ~~9 Ma) (Fig. 6a).~~ These continental deposits are thicker and well exposed on the flanks of the Almanzora basin and on
243 the northern Huércal-Overa basin (HOB), compared to the Alpujarras Corridor (AC) and Tabernas basin (TB) (**Figs.**
244 **6 and 7a**; Augier et al., 2013; Pedrera et al., 2010, 2007; Poisson et al., 1996).

245 Paleogeographic reconstructions indicate they were deposited on a large emerged domain, stretching from Huercal-
246 Overa to Granada, in the West and in Tabernas, to the South (Braga et al., 2003). Sourced from the Nevado-Filabride
247 metamorphic complex  gson and Haughton, 2004; Kleverlaan, 1989; Meijninger and Vissers, 2006; Pedrera et
248 al., 2010, 2007; Pickering et al., 2001; Weijermars et al., 1985) these deposits mark the onset of surface exhumation
249 of the Sierra de Las Estancias and Sierra de Los Filabres.

250 During this initial stage, HOB is the most subsident basin (**Figs. 6b, 7a and 7b**), accumulating sediments at rates of
251 400 m/Ma while rates are 140-180 m/Ma in the Tabernas basin (**Fig. 6b**) (Augier, 2005). Higher subsidence in the
252 HOB, which also started earlier than in other basins, suggests extension occurred originally to the North associated
253 with the exhumation of the Sierra de Las Estancias. Basal continental conglomerates are overlain by grey coarse-
254 grained Tortonian sandstones found occasionally, e.g. in the Almanzora basin, intercalated with marine marls (**Figure**

255 **6a**). They are topped by mid-Tortonian bioclastic calcarenite and coral reefs (Braga et al., 2003; Martin et al., 1989;
256 Pedrera et al., 2007).
257 During the same interval, TB recorded the deposition of 300 to 400 m of coarse to medium-grained deltaic marine
258 clastics overlying unconformably the lowermost red series (**Fig. 6a**). These sediments pass upwards, e.g. in TB, to
259 deeper marine 1200 m-thick turbiditic and marls series intercalated with regional-scale megabeds, revealing the onset
260 of rapid tectonic subsidence (Haughton, 1994; Kleverlaan, 1989, 1987; Pickering et al., 2001; Weijermars et al., 1985).
261 Details of depositional architecture of the Tortonian suggest that part of this subsidence evolution was controlled by
262 E-W directed strike-slip faults (Haughton, 2000) under transtensional strain.
263 The transition from continental to deep marine sedimentary environments (water depth of 400-600 m according to
264 Poisson et al., 1999) witnesses the rapid rift-related tectonic subsidence achieved during the upper Tortonian times
265 (~9 Ma; **Figs. 6** and **7c**) (Romain Augier et al., 2005b; Montenat and Ott d'Estevou, 1992; Weijermars et al., 1985).
266 At around 8 Ma, accumulation rates drop by a factor of two to 200 m/Ma in HOB and 70 m/Ma in TB, revealing a
267 marked reduction in subsidence. Subsidence then became negative as basement uplifted from around 7 Ma (**Figs. 6b**
268 and **7d**) in both TB and HOB.

270

271 km
 272 **Figure 6** : Stratigraphic evolution and lithologies of intramontane basins in the eastern Betics and offshore A1 well.
 273 (a) Neogene stratigraphy and basin-fill correlation in the Almanzora and Huercal-Overa basins (Mora, 1993), Tabernas
 274 basin (Hodgson and Haughton, 2004; Kleverlaan, 1989; Pickering et al., 2001) and Sorbas basin (Fortuin and
 275 Krijgsman, 2003; Martin and Braga, 1994; Riding et al., 1998). Middle Miocene sedimentary environments in the
 276 Alboran Sea are after (Comas et al., 1992). (a) Neogene tectonic subsidence evolution for Tabernas basin and Huércal-
 277 Overa basin are from (Augier, 2004). The curves are obtained from backstripping techniques incorporating local
 278 eustatic and paleobathymetric corrections.

279

280 The geometry of the Almanzora (Pedrera et al., 2009), Sorbas (e.g. Do Couto et al., 2014) and Huércal-Overa basin
281 basins (Pedrera et al., 2010) inferred from gravity measurements indicate that these basins are asymmetrical and
282 deepening southwards (**Fig. 5**). This sediment infill pattern recalls the formation of asymmetrical basins predicted by
283 numerical models of flexural strike-slip basins (Neuharth et al., 2021). According to this model, the asymmetry
284 observed should reflect the development of strike-slip basins loaded by sediments originated from the North. In
285 addition, a larger subsidence in HOB is an indication of abrupt crustal thinning to the south of Sierra de las Estancias
286 where the crustal thickness of 35 km is the largest (**Fig. 2**). Therefore, at least the Serravallian-Tortonian infill patterns
287 agree with oblique extension.

4. Brittle faulting : pure extension versus transtensional deformation in Neogene basins

4.1. Tectonic regime in the eastern Betics

Figure 8 presents a compilation of 112 fault slip data inversion previously analysed in the eastern Betics combined with new measurements conducted in the Alpujarras Corridor and in the Tabernas basin (**Table S1**). Most faults are syn-Tortonian or cut through the Tortonian. This compilation emphasizes a regional trend of σ_3 stress axes oriented

300 NNE-SSW (N20°E) with subordinate σ_3 oriented E-W. In details, this well-defined regional horizontal extension
 301 reflects a combination of pure normal faulting regime (σ_2 horizontal and oriented NW-SE/WNW-ESE) and strike-
 302 slip faulting regime (σ_2 vertical to steeply-dipping and σ_1 horizontal an striking NNW-SSE). N-S to NW-SE
 303 compression is also reported in the HOB associated with incipient synform and depocenter which is dated to the lower
 304 Tortonian coeval with the prominent EW/WSW-ENE extension (e.g. Pedrera et al., 2010).
 305 We describe below, based on a selection of outcrops in the vicinity of the contact between Tortonian basins and major
 306 metamorphic domes, the expression of EW and NW-SE extensional faulting in the field. We then discuss how they
 307 are linked to the regional stress regimes.
 308

309

310 **Figure 8:** Synthesis of stress regimes resolved from fault slip data inversion in Tortonian basins. Color-coded circles
311 with arrows depict tectonic sites where extension (given as arrows) is horizontal (pure extensional or strike-slip stress
312 regimes). Sites where reverse tectonic regimes prevail are shown as circles highlighted in grey. Below, stereoplots of
313 paleostresses σ_1 , σ_2 and σ_3 show a compilation of all brittle tectonic regimes extracted from Table S1. Collectively
314 they define a prominent extension oriented NNE-SSW with a subordinate E-W-striking extension. CF: Carboneras
315 Fault; PF : Palomerias Fault.

316

317 **4.1 EW-directed faulting: evidence for pre-Tortonian oblique extension ?**

318 In Tortonian intramontane basins, one of the main set of faults is represented by E-W-directed faults, including ENE-
319 WSW to ESE-WNW sets. North of the Alpujarras Corridor (AC), 3 km to the NE of Canjáyar, the contact between
320 the basal Tortonian conglomerates and the series of Alpujarride complex is exposed in the Rambla de Tices. It is
321 shaped by a 2-meter thick fault zone (**Figs. 9a,b**) striking N100°E, which has a normal sense of slip with a right-lateral
322 strike-slip component (**Fig. 9c**). It consists of cataclastic breccias and sheared blocks (boudins) of the host rocks (**Fig.**
323 **9d**). This major fault is found along the 65 km-long Alpujarras fault zone described by Martínez-Martínez (2006) as
324 a major strike-slip dextral transfer zone south of the Sierra Nevada that accommodates both WSW-extension and dextral
325 movement. It is mechanically consistent with NE-SW/ENE-WSW extension under a strike-slip regime as resolved
326 nearby along the same faults system (Martínez-Martínez, 2006). **Fig. 9** indicates the fault is parallel to the basal
327 Tortonian series but cuts across the Alpujarride complex. In the HOB, on the southern flank of the Sierra Limaria, the
328 unconformity between the lower Tortonian red conglomerates and the Alpujarride units (Rambla de Cordoba, 2km
329 NW Arboleas, **Figs. S1a, b**) is found reactivated as a normal fault with a dextral shear component.

330 To the North of TB, a large morphological surface presents a rare exposure of the micaschist basement of the Nevado-
331 Filabrides complex allowing the study of deformation on the southern flank of the Sierra de los Filabres (**Fig. 10**). The
332 deformed NF series shapes a kilometric-size antiform with axial planar surface dipping towards the North. The steeply-
333 dipping cleavages directed NE-SW on its southern flank are deformed by numerous dextral shear zones with lengths
334 ranging from 100 m to less than 5 m (**Fig. 10b, c**). In addition to isoclinal folds parallel to the main foliation that are
335 clearly associated to an early stage of ductile EW-stretching, we recognize close to the strike-slip shear zones, steeply-
336 dipping metric-size open to tight folds inclined to the NE (**Fig. 10d**). To the south, Tortonian conglomerates are
337 overlying unconformably the folded NF foliation. This stratigraphic relationships and the average low dip of Tortonian
338 strata (20°SE) indicate that strike-slip deformation occurred before the deposition of Tortonian conglomerates and
339 after the tilting of the NF foliation (see cross section in **Fig. 10a**). This argues that the transition from W-directed
340 ductile extension in the metamorphic domes known to have started in the Burdigalian and the right-lateral strike-slip
341 faulting occurred around the Langhian-Serravallian (13-14 Ma). This interval is often considered to mark the transition
342 from ductile to brittle extension (e.g. Augier et al., 2013). Because strike-slip faulting postdates folding of the NF
343 foliation, and are consistent with WSW-ENE oblique extension, we suggest that the Sierra de los Filabres metamorphic
344 dome formed in a transtensional strain regime. This hypothesis conforms with prediction of transtension at the tip of
345 the STEP fault (Le Pourhiet et al., 2012) and with model of oblique extension (see **Fig. 3**).

346

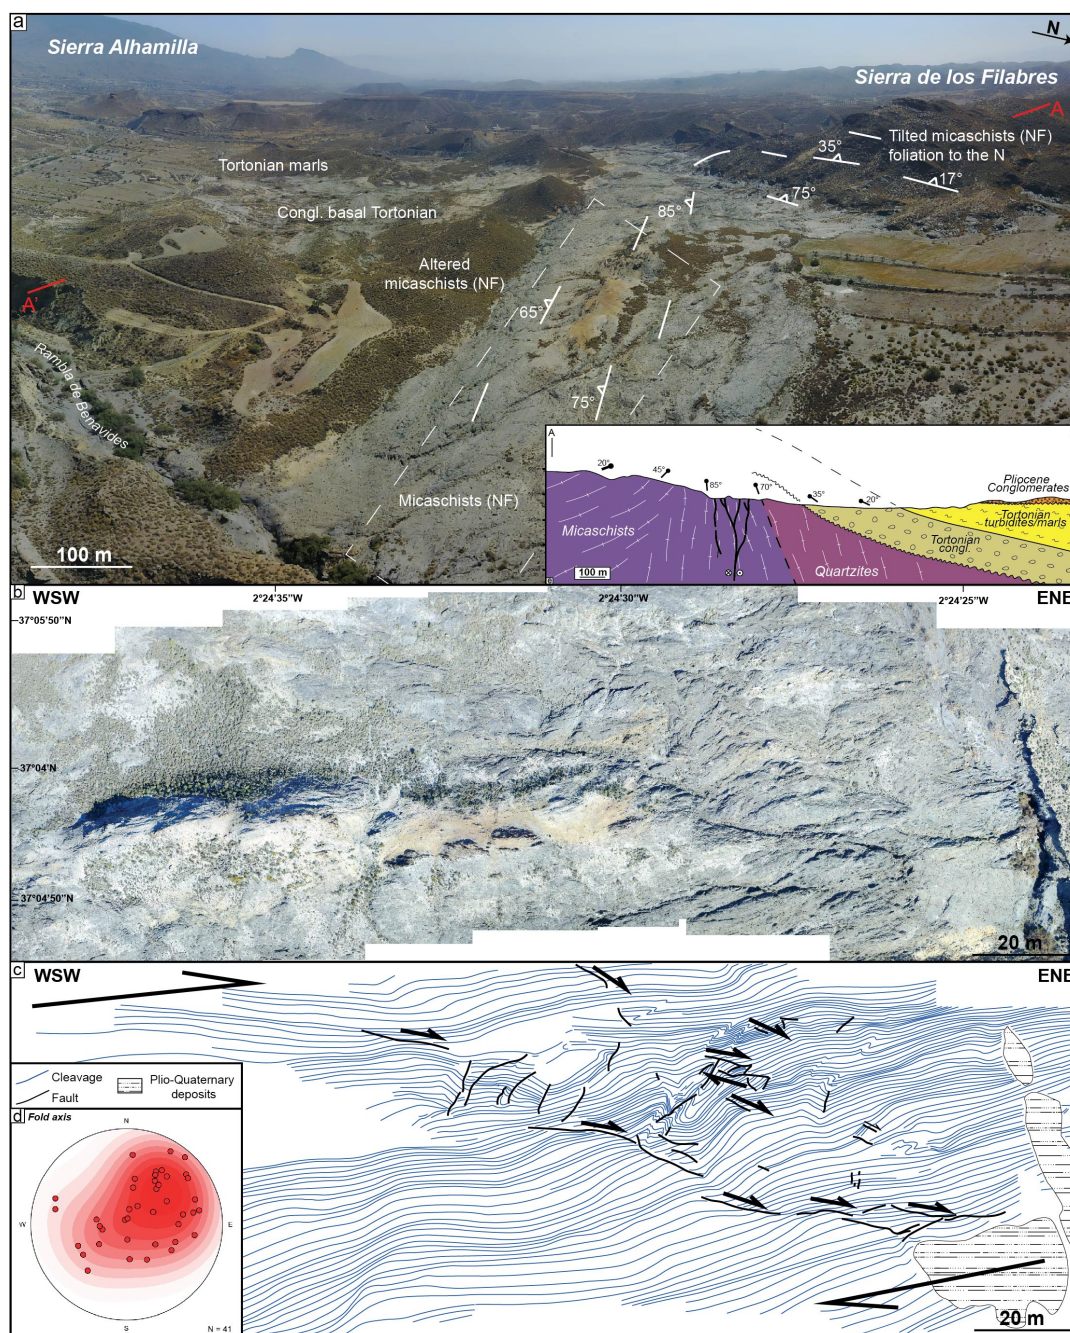

347
 348 **Figure 9.** (a) and (b) Fault zone at the contact between the Tortonian basal conglomerates and the series of the
 349 Alpujarride complex south of AC (Rambla de Tices, see Fig. 5 for location). (c) slickensides on the fault zone reveals
 350 a normal sense of slip with right-lateral strike-slip component found in association with (d) cataclastic breccias,
 351 sheared boudins of metamorphic and sedimentary rocks. Al-d: Alpujarride dolomites; bT-cCg: basal Tortonian
 352 continental Conglomerates; PI-Cg: Pliocene Conglomerates. Coordinates 37.031944°N/-2.716274°E.
 353

354 4.1.2. NW-SE-directed normal faulting

355 A second set is represented by NW-SE directed normal faults (Fig. 8). They are found, for instance, on the border of
 356 the NW-SE Alhabia basin, where they cut across the basement and interrupt the westward continuity of the Sierra de

357 los Filabres. One major fault zone of this system is well exposed in the Arroyo del Verdelecho, 7 km to the west of
358 Tabernas, on the eastern border of the Alhabia basin (**Figs. 11 and S2**). From a regional point of view this large NW-
359 SE fault zone controls the deepening of the Tortonian basin and the position of Pliocene depocenter in its hangingwall,
360 towards the West. NW-SE normal faults also cut across the lower Tortonian conglomerates in the hangingwall but their
361 throw diminishes upward in the upper Tortonian margin sediments, suggesting fault activity during the late Tortonian
362 (**Fig. 11**). One major fault zone is outlined by cataclastic breccias made of marbles originated from the exhumed
363 Alpujarride complex in the Sierra de los Filabres (**Fig. S2**).
364 South of HOB (south of Arboleas), NW-SE faults are seen cutting through the late Tortonian sands and marls series,
365 indicating that NE-SW extension is at least Tortonian (**Figs. S1c, d**).

387 37.061279°N/-2.490309°E. Paleostress orientations are in Table S1.
388

389 Both fault slip data and our own observations argue for a regional pre-Tortonian and syn-early Tortonian NNE-
390 directed extension. This direction of extension is also found associated with less well-developed strike-slip regimes
391 (Fig. 8). It is consistent with the D1-D2 phase of brittle deformation found in HOB (Augier et al., 2013). The fact that
392 extension and strike-slip regimes occurred synchronously, or overlap rapidly in time, supports the view that they
393 reflect the same large-scale tectonic setting. The reason why strike-slip faulting is less apparent in the field than
394 expected in models in Fig. 3 is likely to reflect the fact that oblique extension is not fully partitioned between normal
395 and strike-slip components and is actually distributed along oblique structures. Moreover, where strike-slip faults are
396 found they are associated with narrow corridor basins or near the contact between the cover and basement but not in
397 the center of HOB or TB. The NNE-SSW to NW-SE faults appear to postdate the deposition of the early Tortonian
398 red conglomerates and is synchronous with the deposition of marine Tortonian series (Fig. 12). These normal faults
399 currently form half-graben filled with Plio-Quaternary deposits (Guadix, Baza, Alhabia) and are active today. But the
400 importance of extension-related brittle deformation over brittle compression decreases eastwards. Indeed, a late brittle
401 compressional event oriented roughly N-S is described in the literature as a D3 brittle event (e.g. in HOB) associated
402 with reverse and strike-slip faults (Augier et al., 2013). The post-late Tortonian shortening is seen responsible for fold
403 amplification and reverse faulting on the northern limb of Sierra de Alhamilla and Sierra de los Filabres, and locally
404 in the eastern part of the HOB near the termination of left-lateral strike-slip faulting evolution of the Alhama de Murcia
405 fault (Fig. 8).

They form a long and tight E-W anticlinal crosses the Tabernas basin (see Figure 5 for location). (c, d) Several normal faults observed in Tortonian sandstones and marls (T-Sml). They are mostly oriented NNW-SSE. Coordinates 37.041648°N/-2.399318°E. Paleostress orientations are in Table S1.

412 5. N-S crustal-scale section across the oblique/transform margin of Alboran basin

413 To examine further the structural relationships between extension and strike-slip faulting across the Alboran margin,
414 we explore 2D multichannel seismic lines acquired during the MARSIBAL 1-06 cruise (Comas and MARSIBAL1-
415 06 Scientific Party, 2007) and ESCI cruises (Comas et al., 1995) across the Eastern Alboran basin (EAB). The studied
416 seismic dataset consists of ~300 km and are deep-penetration multichannel seismic reflection studies (12 s two-way
417 travel time - TWTT). Here, we study two lines namely MSB08 and MSB07 (see location in Fig. 1). For stratigraphic

418 and structural correlations between the studied seismic lines, we used the Andalusia-A1 well (**Fig. 6a**) and results
419 from ODP 977 and 978 legs (see location in **Fig. 1**). MSB08 is striking N70°E, slightly oblique to the shoreline. It is
420 close, and runs parallel, to TM08 line of (Peña et al., 2018). It is calibrated by Andalusia-A1 well and ESCI-Alb1 line
421 (Comas et al., 1995). Line MSB07 stretches in the N-S direction between the EAB in Spain and SAB to the north of
422 Morocco parallel to line TM09 (Peña et al., 2018) and crosscuts line ESCI Alb2b presented in Comas et al. (1995)
423 and Booth-Rea et al. (2007) (**Fig. 1**).

424

425 5.1 Offshore structures and stratigraphic architecture

426 The Carboneras Fault is well imaged north of MSB07 (**Fig. 13**). It forms a positive crustal-scale antiformal flower
427 structure related to left-lateral strike-slip faulting that involves a Moho depth variation between 12 s to 9-8 s TWT
428 after Gomez de la Peña et al. (2018). It separates a thin continental crust to the North (25-20 km; **Fig. 2**), from the
429 magmatic calc-alkaline arc crust of the EAB with a thickness of 18 km in the south (Booth-Rea et al., 2007, 2018;
430 Gomez de la Peña et al., 2018, 2020a).

431

432

433 **Figure 13** : Seismic reflection line MSB07 (location on **Fig. 1**). Discontinuous intracrustal reflectors (ICR) imaged
434 between 3 and 6.5 s TWT, have been interpreted as mylonitic zones within the metamorphic basement (Carbonell et
435 al., 1998; García-Dueñas et al., 1994; Gomez de la Peña et al., 2018). VR: Volcanic Ridge; B: Acoustic basement;
436 Top L : Top Langian; Top S: Top Serravallian; Top S-T: top Serravallian-Tortonian; Top M: Top Messinian; SF:
437 Seafloor.

438

439

440
441 Reflection seismic data (**Figs. 13, 14, 15**) collectively show a relatively well stratified crust, corresponding to the
442 sediment cover, down to 2.4-4 s TWT which outlines the acoustic basement with high reflectivity (B). Locally, the
443 top basement reflector coincides with erosional palaeo-relief or high angle normal faults bounding basement highs.
444 These faults are oriented mostly NW-SE to NE-SW and cut across the basement. We recognized on seismic images
445 magmatic additions in the continental crust that are shaped by volcanic edifices exposed on the seafloor (e.g. Chella
446 Bank) or slightly buried (Alboran Ridge) outlined by symmetric downlaps and onlaps of sediments. These
447 constructions form topographic highs such as the Chella Bank on the MSB08 line (**Fig. 14**), the Alboran Ridge on the
448 MSB07 line (**Fig. 13**) and the Maimonides Ridge on the ESCI-Alb2b line (**Fig. 15**). All the reflectors corresponding
449 to layers as old as Tortonian are onlapping against the volcanic ridges confirming that the volcanic activity occurred
450 during the middle to late Miocene times, which is otherwise shown by Duggen et al. (2008). Some reflectors up to the
451 top Messinian (top M) onlap onto the volcanic ridges probably as a result of Pliocene uplift.
452 The stratigraphy offshore, on the continental crustal domain, is defined by the recognition of five seismic stratigraphic
453 units in Andalucia-A1 well (Jurado and Comas, 1992) labeled I-V from top to base (**Figs 6 and 16**) and separated by
454 unconformities. The seismostratigraphic units I to V vary in thickness (**Fig. 16**) and their architecture is conditioned
455 by the occurrence of basement highs and crustal-scale faults.
456 Below the Miocene sedimentary filling, Andalucia-A1 well reveals ~190m of phyllitic and quartzitic meta-sediments
457 (2.4 to 4 s TWT below the Alboran basin, **Figs. 13 and 14**) topped by Langhian to Tortonian marls (top at ~1.6 to 3.4
458 s TWT below the Alboran basin) interbedded with Tortonian-Messinian tuffs and basaltic lavas. These units have
459 been correlated in the magmatic arc crust of EAB after Gomez de la Peña et al. (2020b). The older deposits (Unit V)
460 Langhian-Serravallian in age, consist of clays and marls with intercalated sands and volcano-clastic deposits. The
461 seismic facies of this Unit V is made of moderate amplitude and low frequency discontinuous reflections packages
462 (Figure 18), and is only present in the Northern Alboran Basin. They are correlated with volcanic series in the EAB
463 (vY3) (Gomez de la Peña et al., 2020b). They pass upward into Serravallian sand-silty clay turbidite (Unit IV) possibly
464 correlated with volcanic series in EAB (vY2 after Gomez de la Peña et al., 2020b). This unit exhibiting low to moderate
465 amplitude, moderate frequency drawing continuous sheeted to disrupted reflectors, is unconformably overlying Unit
466 V and locally onlaps onto the basement. Thickness of Unit IV remains rather thin in the North and East Alboran Basin.
467 It can't be properly identified in the South Balearic Basin, east of the Maimonides volcanic ridge (**Fig. 15**). The Unit
468 III dated from late Serravallian to late Tortonian is represented by sandstones interbedded with volcano-clastic levels
469 which correlates in EAB with volcanics vY1 unit. Unit III contains internal reflections characterized by low to moderate
470 amplitude, moderate frequency continuous sheeted reflectors. Its thickness remains relatively constant from the NAB
471 to the EAB, and is identified beneath the Messinian Unit II in the South Balearic Basin. Unit II corresponds to the
472 Messinian evaporite, carbonate, volcanic, and volcanoclastic deposits interbedded with fine-grained sediments and is
473 equivalent to unit III of (Peña et al., 2020b) in EAB. Seismic facies of Unit II is marked in the Alboran domain by
474 lower amplitudes and lower frequency reflectors. In ESCI-Alb2b line, Unit II increases drastically east of the
475 Maimonides ridge, which delimits the western boundary of the salt deposits in the Western Mediterranean basin during
476 the Messinian Salinity Crisis (Haq et al., 2020). Unit II is topped by Unit I made of Pliocene to Quaternary clays and

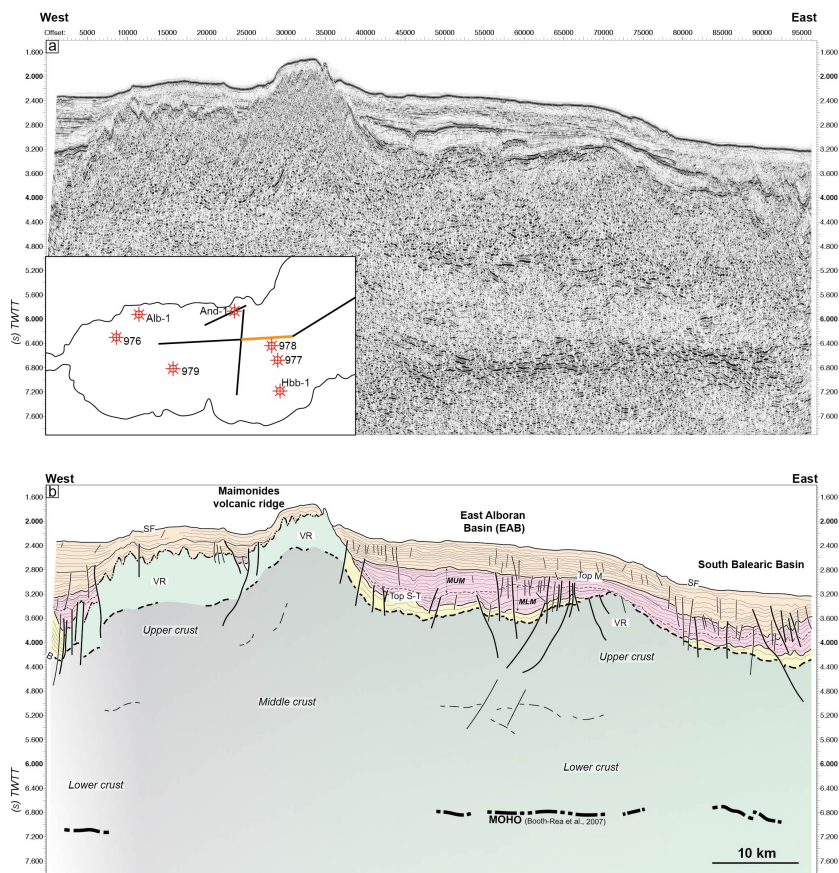

477 sanstones, which are correlated with units II and I in EAB (Gomez de la Peña et al., 2020b). Unit I is marked by thinly
478 bedded, mostly parallel, high-frequency and low amplitudes reflectors (**Fig. 18**). Its thickness fluctuates in response
479 to sedimentary processes (Juan et al., 2016).
480 Along line MSB08 (**Fig. 14**) the Langhian-Serravallian (Unit V) is maximum 1600 m-thick (using a P-wave velocity
481 of 3.2 km/s calculated within Andalusia-A1 well. In EAB, south of Carboneras Fault Zone, the total thickness of Unit
482 V is only ~300 m on MSB07 (**Fig. 13**) and is absent in ESCI-Alb2b (**Fig. 15**). The Serravallian-Tortonian (Unit IV-
483 III) interval shows only very limited sediment accumulation (~300 m) except near the NW-SE oriented normal faults
484 where growth geometries are visible. These normal faults are sealed by the Tortonian-Messinian deposits, indicating
485 a syn-sedimentary faulting during the middle Miocene (**Fig. 13**). With respect to offshore observations this
486 sedimentary infill is more continuous and is also much thinner compared to TB and HOB where they are represented
487 by thick conglomerates and marls/turbidites (> 1km) (**Fig. 7**), and they are eroded or not deposited along the axes of
488 the metamorphic domes. The Messinian deposits (Unit II) are ~150-350 m-thick north of CF (MSB07-08 ; **Figs. 13**,
489 **14**) and increase to about 1200 m eastward in the eastern EAB (ESCI-Alb2b ; **Fig. 15**), and in Algero-Balearic basin
490 (Gomez de la Peña et al., 2020b). The top Messinian reflector is topped by thick horizontal sedimentary strata, with a
491 maximum thickness of 1.2 s TWT (~2.4 km assuming a velocity of 2 km/s) on line MSB07, suggesting an important
492 channel system during the Pliocene.
493 The Pliocene-to-Quaternary series are poorly deformed except in the vicinity of CF and near the Alboran Ridge where
494 this is associated with south-dipping reverse fault (**Fig. 13**). This late and still active compressional tectonics is
495 revealed by the overthrusting of the SAB over the south margin of the EAB e.g. (Martínez-García et al., 2011).
496

504
505

506

507 **Figure 16** : Seismic facies of units I to V seen through seismic lines MSB08 close to the shoreline and the line
508 MSB07, located deeper in the East Alboran Basin.

509 **5.2 N-S crustal cross-section of the Alboran margin accounting for strike-slip faulting**

510 Based on subsurface constraints and field data, we have built a crustal cross-section across the rifted margin from the
511 Sierra de las Estancias and Huerca-Overa basin (HOB), which represents the proximal margin, to the center of the
512 Alboran margin (**Fig. 17**). The proximal margin is defined by a 30-35 km-thick crust. It preserves part of the thickness
513 acquired during former orogenic phase that has been little involved in crustal thinning. The onset of crustal thinning
514 to the south is recorded by the formation of strongly subsident and asymmetric basins of the HOB and TB, shaping
515 the upper neck domain. This domain is characterized by orthogonal and oblique extension during the Tortonian
516 accommodated by normal and strike-slip faulting. This boundary also corresponds to the position of the major STEP
517 fault documented by seismology. From the Sierra de los Filabres to the south, the crustal thickness reduces to 25 km
518 in the Tabernas basin along the Alpujarras strike-slip corridor and below the Sierra Alhamilla. The Nijar basin depicts
519 the transition towards offshore distal domains with a crustal thickness of 20 km. The Tortonian and Messinian marine
520 sediments are also thicker and a number of volcanic bodies accompany crustal thinning. Crustal thinning appears
521 localized along the Carboneras Fault (CF), which juxtaposed crust with different crustal thickness (**Fig. 19**). South of
522 CF, the crust thickness reduces below 20 km and shows increasing magmatic additions making the magmatic arc crust
523 of the EAB (Gomez de la Peña et al., 2018 ; 2020). Interestingly, normal faulting in the EAB is sealed by middle-
524 upper Tortonian deposits. Crustal deformation then shifted to the north in the CF and EBSZ strike-slip fault zones and
525 to the south along the Alboran Ridge where reverse faulting occurred.

Figure 17. Crustal-scale cross section of the Alboran margin in the eastern Betics interpreted based on onshore and offshore constraints presented in the text. Note that in the necking domain the extension of faults downwards to Moho depths is not imaged on the seismics and therefore largely inspired by inferences from 3D numerical models (see Fig. 3).

533 **7. Implications**

534 The question of whether the Miocene tectonic evolution of the Betics reflects crustal thinning associated with oblique
535 back-arc rifting as suggested from present-day strain patterns is unclear in the literature. Back-arc extension, recent
536 tectonic inversion and STEP faulting are generally considered to result from separated processes. We found based on
537 a comparison between numerical models and analyses of basin evolution, fault kinematics and structure of the margin
538 in the eastern Betics compelling evidences that crustal thinning occurred under oblique extension and was not
539 restricted to the post-Tortonian evolution. Rather, oblique rifting possibly operated since at least the middle Miocene,
540 as the slab retreat started in the Alboran basin and is therefore kinematically associated with STEP faulting.

541 One of the most striking tectonic feature of the Alboran margin (**Fig. 17**) is the abrupt N-S crustal thinning, from 35-
542 30 km to 25-20 km, oblique to the direction of slab retreat. The history of sediment infill and rates of subsidence in
543 intramontane basins (**Figs. 6 and 7**) combined with the analyses of fault slip data, confirm that brittle extension
544 oriented from N20°E to EW occurred during an interval spanning from the Serravallian-early Tortonian to the late
545 Tortonian (14-8 Ma). This extension is found associated with both normal and strike-slip regimes. In more details,
546 these data suggest that N20°E extension is more represented in HOB, while the ENE-WSW to EW extension is found
547 related with the evolution of the Almanzora corridor, Alpujarras corridor and Tarbenas basin flanking the metamorphic
548 domes (**Table S1**). There are additional evidence that EW-directed dextral strike-slip faulting did occur during the
549 Tortonian to the South and West of the HOB and represents this main phase of basin subsidence. These large-scale
550 faults are later cut by Tortonian NW-SE faults that argue for more recent EW extension. Therefore, we infer that the
551 domain south of the HOB, which also corresponds to a thinnest crust, has experienced transtensional deformation and
552 EW extension.

553

554

555 **Figure 18:** Tectonic model of the evolution of the northern margin of the Alboran Rift. Large grey and white double
556 arrows depict shortening, which is parallel to the AF/IB convergence, and the highly oblique extension, respectively.
557 The thin black arrows is showing the motion of Alboran relative to Iberia (IB) taken from Figure 4. Half arrows
558 depicts the distributed strike-slip faulting in the Betics. NW-SE directed normal fault and strike-slip basins (yellow)
559 are consistent with the oblique extension. Grey-shaded ellipses represent the metamorphic domes.
560

561 Several key specific tectonic features found in the eastern Betics are predicted by 3D models of oblique extension
562 (**Figure 3**). Those include the E-W trending faults that are prevalent on the upper neck domain (i.e. Sierra de las
563 Estancias and HOB), and E-W strike-slip faults (Almanzora and Alpujarras corridor) and NW-SE normal faults that
564 are found associated with more distal domains where crustal thinning is the highest. Brittle E-W-directed stretching
565 and dextral transcurrent deformation started in the Langhian-Serravallian (14-13 Ma). Tectonic inversion seems, in
566 contrast, to have been increasingly more important when approaching the Carboneras and Palomeras strike-slip faults
567 in the East since the late Tortonian.

568 According to temporal constraints, ductile thinning may have occurred between 23 to 16 Ma prior to brittle faulting
569 at 14-13 Ma (**Figure 18**). The late/post-Tortonian times marks a change in the tectonic evolution of the region (Jolivert
570 et al., 2021a; Mouthereau et al., 2021; Rat et al., 2022) as the mantle slab eventually detached and is responsible for
571 Ca-K magmatism at 11-7 Ma (Duggen et al., 2008, 2004), compression and tightening of the metamorphic domes
572 associated with the formation of the the EBSZ.

573 The strike-slip deformation model has the advantage to explain N-S crustal thinning in the Betics while back-arc
574 extension is oriented E-W, in a continuum of deformation from the Miocene to the present. In this model, ductile
575 stretching and ductile detachment associated with the development of the domes are the expression of oblique E-W
576 extension. This provides a coherent scheme linking the formation of EW-directed basins in the brittle field associated
577 with strike-slip faulting, and NW-SE/NNW-SSE sedimentary basins (Guadix, Baza, Alhabia) formed in transtension
578 during the Tortonian. As such, the oblique extension, which is closely associated with STEP faulting required by slab
579 retreat, is overall a characteristic feature of the regional NW-SE/NNW-SSE convergence since at least the Miocene.
580 Only recently, around 8 Ma, as the slab detached, shortening started to prevail in the vicinity of the EBSZ (**Figure**
581 **18**). As convergence was under way during oblique back-arc extension, high-pressure metamorphism and subduction
582 possibly occurred during the mid-Miocene as argued in eastern Betics (Platt et al., 2013). Moreover, the case of
583 exhumation of high-pressure rocks in oblique convergence setting associated with near-parallel orogeni extension is
584 documented in other active orogen like Taiwan (Conand et al., 2020).

585 This highly oblique northern Alboran margin differs from typical transform fault margin such as those associated with
586 the Atlantic ocean because it accommodates variations in intra-plate extensional movements, triggered by slab roll-
587 back not variations in spreading rates. Strike-slip faults may have originated as low-angle normal which were later
588 reactivated as thrusts during margin inversion. Similar observations, including metamorphism, strike-slip faulting,
589 high geothermal gradients and volcanism has been made in Seram, north of the Banda Arc, which represents an other
590 example of extremely thinned crust formed perpendicular to the direction of the slab retreat (Pownall et al., 2013).
591 Such a narrow rifted margin associated with lithospheric STEP fault defines a class of oblique (and transform) margin
592 that is expected to be hardly preserved in the geological record due the transient nature of retreating subduction
593 systems.

594
595 **Data availability.**This study is based on data compilation. Data used in this study can be found in the appropriate
596 references. Paleostress tensors obtained by the inversion of fault slip data are available online in the Supplement.
