10 **Abstract.** Soil water isotope datasets are useful for understanding connections between the  
11 hydrosphere, atmosphere, biosphere, and geosphere. However, they have been underproduced  
12 because of technical challenges associated with collecting those datasets. Here, we present the  
13 ~~full results of~~ testing and automation of the Soil Water Isotope Storage System (SWISS). The  
14 unique innovation of the SWISS is that we are able to automatically collect water vapor from the  
15 critical zone at a regular time interval and then store that water vapor until it can be measured  
16 back in a laboratory setting. Through a series of quality assurance and quality control tests, we  
17 ~~rigorously~~ tested that the SWISS is resistant to both atmospheric intrusion and leaking in both  
18 laboratory and field settings. We assessed the accuracy and precision of the SWISS through a  
19 series of experiments where water vapor of known composition was introduced into the flasks,  
20 stored for 14 days, and then measured. From these experiments, after applying an offset  
21 correction ~~to report our values relative to VSMOW~~, we assess the precision of the SWISS at  
22  $\pm 0.9\%$  and  $\pm 3.7\%$  for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively. We deployed three SWISS units to three  
23 different field sites to demonstrate that the SWISS stores water vapor reliably enough that we are  
24 able to differentiate dynamics both between the sites as well within a single soil column. Overall,  
25 we demonstrate that the SWISS ~~is able to can reliably faithfully~~ retains the stable isotope  
26 composition of soil water vapor for long enough to allow researchers to address a wide range of  
27 ecohydrologic questions.

## 28 **1 Introduction**

29 Understanding soil water dynamics across a range of environments and soil properties is  
30 critical to food and water security (e.g. Mahindawansa et al., 2018; Quade et al., 2019; Rothfuss  
31 et al., 2021); understanding biogeochemical cycles, such as the nitrogen and phosphorus cycles  
32 (e.g. Hinckley et al., 2014; Harms and Ludwig, 2016); and understanding connections between  
33 the hydrosphere, biosphere, geosphere and atmosphere (e.g. Vereeken et al., 2022). One  
34 approach that can be used to understand water use and movement in the critical zone is the stable  
35 isotope geochemistry of soil water (e.g. Sprenger et al., 2016; Bowen et al., 2019). Variations in  
36 the stable isotope ratios of oxygen and hydrogen of soil water ( $\delta^{18}\text{O}$ ,  $\delta^2\text{H}$ ) track physical  
37 processes like infiltration, root ~~water~~ uptake and evaporation. In particular, stable water isotopes  
38 are useful for disentangling complex mixtures of water from multiple sources (e.g. Dawson and  
39 Ehleringer, 1991; Brooks et al., 2010; Soderberg et al., 2012; Good et al., 2015; Bowen et al.,  
40 2018; Gomez-Navarro et al., 2019; Sprenger and Allen 2020). Despite the long-recognized  
41 utility of measuring soil water isotopes for understanding a range of processes (e.g. Zimmerman

42 et al., 1966; Peterson & Fry., 1987), soil water isotope datasets have been under-produced as  
43 compared to groundwater and meteoric water isotope datasets (Bowen et al., 2019).

44 The primary barrier to producing soil water isotope datasets has been the arduous nature  
45 of collecting samples. Historically, there are two primary methods for collecting soil water  
46 samples: either by digging a pit and collecting a mass of soil to bring back to the lab for  
47 subsequent water extraction or via lysimeter. The former method disrupts the soil profile each  
48 time a sample is collected, inhibiting the creation of long-term records of soil water isotopes.  
49 Lysimeters on the other hand provide the means to collect multi-year soil water isotope datasets  
50 (e.g. Green et al., 2015; Groh et al., 2018; Hinkley et al., 2014; Stumpp et al., 2012, Zhao et al.,  
51 2013), but the choice of lysimeter can affect the portion of soil water (i.e. mobile vs. bound) that  
52 is sampled (Hinkley et al., 2014; Sprenger et al., 2015) and the soil conditions that are  
53 sampleable (i.e. saturation state). Soil water samples collected from both ~~from~~ bulk soil samples  
54 and ~~from~~ lysimeters often require manual intervention at the time of sampling.

55 Building off of innovations in laser-based spectroscopy for stable isotope geochemistry,  
56 the ecohydrology community developed a variety of in situ soil water sampling methods over the  
57 last 15 years that enables the creation of high throughput, high precision analyses of soil water  
58 isotopes (e.g. Wassenaar et al., 2008; Gupta et al. 2009;- Rothfuss et al., 2013; Volkmann and  
59 Weiler, 2014; Gaj et al., 2015; Oerter et al., 2016; Beyer et al., 2020; Kübert et al., 2020). These  
60 methods have ~~shed light on~~ provided insights into a range of ecohydrologic questions from  
61 evaporation and water use dynamics in managed soils (e.g. Oerter et al., 2017; Quade et al.,  
62 2018) to better understanding where plants and trees source their water (e.g. Beyer et al., 2020).  
63 These innovations have allowed researchers to ask new questions about ecohydrologic dynamics,  
64 but current methods require field deployments of laser-based instruments. Field deployments are  
65 technically possible and have been conducted successfully (e.g. Gaj et al., 2016; Volkmann et al.,  
66 2016; Oerter et al., 2017; Quade et al., 2019; Künhammer et al., 2021; Seeger and Weiler., 2021;  
67 Gessler et al., 2022), but require uninterrupted AC power, adequate shelter, as well as safe and  
68 stable operating environments for best results. These prerequisites are ~~not~~ often ~~un~~available at  
69 most many field sites, especially in more remote locations and for longer sampling time frames.  
70 Given these logistical constraints, these studies have mostly been done near the institutions  
71 performing those studies. Traditionally, soil water samples are taken by digging a pit, and  
72 collecting a mass of soil to bring back to the lab for subsequent water extraction, disrupting the  
73 soil profile each time a sample is collected. To circumvent issues related to this style of  
74 sampling, the ecohydrology community has developed a variety of in situ water sampling  
75 methods over the last 10 years (e.g. Rothfuss et al., 2013; Volkmann and Weiler, 2014; Gaj et al.,  
76 2015; Oerter et al., 2016; Beyer et al., 2020). These methods have helped to shed light on a range  
77 of ecohydrologic questions from evaporation and water use dynamics in managed soils (e.g.  
78 Oerter et al., 2017; Quade et al., 2019) to better understanding where plants and trees source their  
79 water (e.g. Beyer et al., 2020).

80 The expansion in situ sampling methods allows for a greater understanding of  
81 ecohydrologic dynamics temporally, but with current methods these studies are often done in  
82 close proximity to the institutions performing the studies because of logistical constraints. The  
83 Spatial constraints limit the questions that researchers can ask about what we can learn about  
84 soil hydrology in remote and traditionally understudied landscapes. For example, in the  
85 geoscience community there is significant interest in improving the research community's  
86 understanding of how and when paleoclimate proxies (e.g. stable isotope records from pedogenic  
87 carbonate, branched glycerol dialkyl glycerol tetraethers, etc.) form in soils, because that informs

88 our ability to accurately interpret records from the geologic past. ~~But~~ However, those projects  
89 commonly have environmental constraints like soil type or local climate ~~state~~ characteristics that  
90 may not be located near institutions performing those studies. To be able to study a broader  
91 range of questions about ecohydrology, there is a need for a system that is capable of  
92 autonomously collecting soil water vapor for isotopic analysis in remote settings.

93 Beyond the ecohydrology community, the creation of high temporal resolution soil-water  
94 isotope data sets is useful to a broader set of stakeholders. For example, long-term temporal  
95 records of soil water can be used to better understand geologic proxy development (e.g. stable  
96 isotope records from pedogenic carbonate, br-GDGTs, etc.). These projects, however, commonly  
97 have environmental constraints like soil type or local climate state that may not be located near  
98 institutions performing those studies, creating the need for a system that is capable of collecting  
99 water vapor from remote settings in an automated way.

100 In this contribution, we report on the further development and testing of a field  
101 deployable system called first introduced in Havranek et al., (2020) the Soil Water Isotope  
102 Storage System (SWISS). The SWISS was built to be paired with ACCURELL PP V8/2HF  
103 vapor permeable probes that have been previously tested for soil water isotope applications  
104 (Rothfuss et al., 2013; Oerter et al., 2017). Our system uses three basic components to store  
105 water vapor produced by the vapor permeable probes: glass flasks, stainless steel tubing and a  
106 flask selector valve (Fig. 1, Supplemental Table 1). Previously, we demonstrated through a  
107 series of lab experiments that the glass flasks used in the SWISS units can reliably store water  
108 vapor for up to 30 days (Havranek et al., 2020). That proof-of-concept study demonstrated that  
109 the flasks retain original water isotope values, but the laboratory system was not field deployable  
110 ~~or~~ and did not have customizable automation. Here, we present a fully autonomous, field-ready  
111 system that has been thoroughly tested under both laboratory conditions and field conditions,  
112 including development and testing of a solar-powered, battery backed automation system that  
113 enables pre-scheduled water vapor sampling without manual intervention in remote field  
114 locations.

115  
116 To test the accuracy and precision of the SWISS, we completed quality assurance and  
117 quality control (QA/QC) tests. This system is now capable of independently sampling soil water  
118 vapor in situ, storing that water vapor for a period of time until the samples can be brought back  
119 to a laboratory to be measured. In our case, we used a Picarro L-2130i water isotope analyzer  
120 (Picarro, Inc. Santa Clara, CA) to measure both water concentration and the oxygen and  
121 hydrogen isotope ratios of the soil water vapor. *i* water isotope analyzer (Picarro, Inc. Santa  
122 Clara, CA) to measure both water concentration and the oxygen and hydrogen isotope ratios of  
123 the soil water vapor. Here, we present the testing and optimization of the Soil Water Isotope  
124 Storage System (SWISS). First, we present a quality assurance and quality control (QA/QC)  
125 procedure that we strongly recommend any future user to complete prior to deploying this kind  
126 of system for either a field or lab experiment. ~~Second~~ Here, we demonstrate the viability of this  
127 system under field conditions through two field suitability experiments. ~~Lastly~~ In addition, we  
128 sampled three different field sites to show that the automation schema works on a monthly  
129 timescale and that the system preserves soil water vapor isotopes signals with sufficient precision  
130 to distinguish between three different field settings and vertical profile differences.

131 **2 Background**  
132 **Field Sites**

133 In recent years, a number of technical innovations have made it easier to sample and measure  
134 soil water for stable isotope analysis. Advances in laser-based instrumentation (e.g. cavity ring-  
135 down spectroscopy, CRDS) have made high throughput, high precision measurements of both  
136 water concentration and water stable isotopes possible. Field deployments with laser-based  
137 instruments are technically possible and have been conducted successfully (e.g. Oerter et al.,  
138 2017; Quade et al., 2019; Künhammer et al., 2021), but require uninterrupted AC power,  
139 adequate shelter as well as safe and stable operating environments for best results. These  
140 prerequisites are not often available at most field sites, especially in more remote locations and  
141 for longer sampling time frames.

142 Second, the testing and adoption of vapor permeable tubing provides a way to sample soil water  
143 vapor with minimal disturbance to the soil profile (e.g. Rothfuss et al., 2013; Quade et al., 2018;  
144 Oerter and Bowen, 2019; Beyer et al., 2020; Kubert et al., 2020). This method works by flushing  
145 dry nitrogen (or dry air) through the vapor permeable membrane (Accurell PP V8/2HF, 3M,  
146 Germany), creating a water vapor gradient from inside the probe to the soil, thus inducing water  
147 vapor movement across the membrane. Water vapor is then entrained in the dry nitrogen and  
148 flushed to either a CRDS system or into a storage container. The adoption of vapor permeable  
149 tubing has been a large step forward for the ecohydrology community, and opened the possibility  
150 of creating long term soil water stable isotope records, particularly when paired with  
151 measurement in the field by spectroscopic instruments. While this application is a major  
152 advancement, it has many practical limitations for remote field sites, therefore, we aimed to  
153 develop a system, termed the SWISS, that is capable of independently collecting samples and  
154 can then store those samples for a period of time before being returned to the lab for analysis.

154

155 **2.1 Soil Water Isotope Storage System details and previous work**

156 The Soil Water Isotope Storage System (SWISS) uses three basic components for water  
157 vapor storage of multiple samples: glass flasks, stainless steel tubing and a flask selector valve  
158 (Fig. 1, Supplementary Table 1). The ability of the SWISS to reliably store water vapor for up to  
159 30 days was demonstrated previously using a series of lab experiments (Havranek et al., 2020).  
160 This proof of concept demonstrated that the flasks retain original water isotope values, but the  
161 laboratory system was not field-deployable or have customizable automation. Here, we present a  
162 fully autonomous, field-ready system that has been thoroughly tested under both laboratory  
163 conditions and field conditions, including development and testing of a solar-powered, battery  
164 backed automation system that enables pre-scheduled water vapor sampling without manual  
165 intervention in remote field locations.

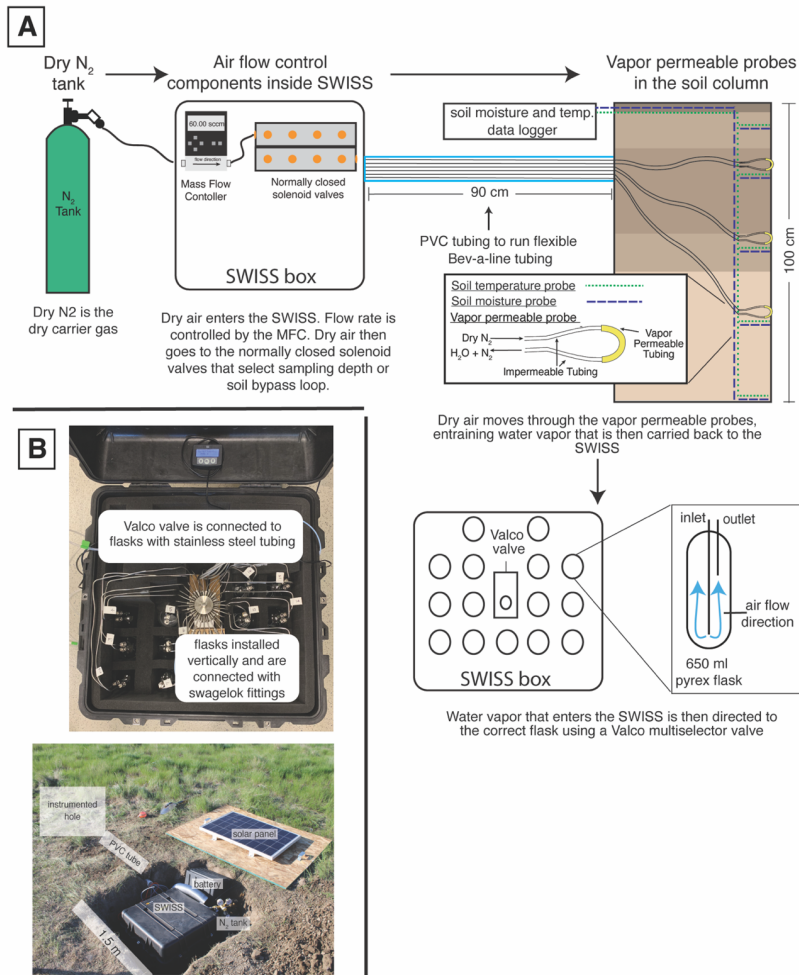

166

167 **2.2 Field Sites:**

168 **2.2.1 Site Set-Up**

169 In figure 1 we show the field-setup employed at all of our field sites. At each site we dug  
170 two holes; in figure 1 we shows the field-setup employed at all of our field sites. One hole was  
171 instrumented with soil moisture and temperature data loggers at 25 cm, 50 cm, 75 cm, and 100  
172 cm depths, as well as the water vapor permeable probes at 25 cm, 50 cm and 75 cm depths (Fig  
173 1A). We deployed all probes were deployed >9 months before the first samples were collected  
174 to allow the soil to settle and return to natural conditions as much as possible. This timeframe

175 was longer than other studies (e.g. Kübert et al., 2020) and included infiltration of spring and  
176 early summer precipitation. -During probe deployment we took care to retain the original soil  
177 horizon sequence and horizon depths as much as possible. In the ~~The second hole, is where we~~  
178 stored the SWISS unit, dry nitrogen tank, and associated components to power the SWISS are  
179 stored (Fig 1B). The water vapor probes, which connected to the SWISS units with Bev-A-Line  
180 impermeable tubing, were run through a PVC pipe buried at approximately 15 cm depth. We  
181 chose to run the impermeable tubing underground to limit the effect of diurnal temperature  
182 variability on the impermeable tubing, so as to limit prevent condensation as water travels from  
183 the relatively warm soil to the SWISS.  
184  
185

186  
 187 **Figure 1.** A) The sampling flow path. To sample soil water, dry nitrogen is regulated at a specific rate  
 188 using a mass flow controller, and then directed to one of the three sampling depths, or the soil bypass loop  
 189 using a set of solenoid valves. Both the mass flow controller and solenoid valves are housed inside the  
 190 SWISS. Once directed to the correct sampling depth, dry nitrogen is carried to the vapor permeable  
 191 probes via gas impermeable tubing that is buried approximately 15 cm depth. After passing through the  
 192 vapor permeable probe, the entrained soil water vapor is carried back to the SWISS where it is directed to  
 193 the correct flask using a Valco multiselector valve. B) Photos of a built-out SWISS and the layout of a  
 194 field site. Each of the system components (i.e., solar panel, battery,  $N_2$  tank, SWISS, PVC tube) are  
 195 labeled, in addition to the location of the instrumented hole in which all of the probes are buried. The hole  
 196 which houses the SWISS, power, and  $N_2$  tank is approximately 1.5 m wide.

197 *much as possible. The second hole is where the SWISS unit, dry nitrogen tank, and associated*  
198 *components to power the SWISS are stored (Fig 1B). The water vapor probes, which connect*  
199 *to the SWISS with Bev-A-Line impermeable tubing, are run through a PVC pipe buried at*  
200 *approximately 15 cm depth. We chose to run the impermeable tubing to the SWISS*  
201 *underground to limit the effect of diurnal temperature variability on the impermeable tubing,*  
202 *so as to limit condensation as water travels from the relatively warm soil to the SWISS.*  
203

### 2.2.2 Site descriptions

204  
205 We deployed the SWISS at three field locations: Oglala National Grassland, Nebraska,  
206 USA; Briggsdale, Colorado, USA; and Seibert, Colorado, USA.  
207 The Oglala National Grassland site (Lat: 42.9600/Long:, -103.5979/elev: 1117 m) is located in  
208 northwestern Nebraska, USA in a cold semi-arid climate. The soil at this site is described as an  
209 Aridisol with a silt-loam texture. It is part of the Olney series (Natural Resources Conservation  
210 Service, 2022).  
211 The Briggsdale site (Lat: 40.5947/Long: -104.3190/elev: 1480 m) is located in northeastern  
212 Colorado, USA in a cold semi-arid climate. The soil at this site is described as an Alfsol with a  
213 loamy sand - sandy loam texture. It is part of the Olnest series (Natural Resources Conservation  
214 Service, 2022). Long term meteorological data from the Briggsdale site is available from the co-  
215 located CoAgMet site (CoAgMet, Colorado Climate Center).  
216  
217 The Seibert site (Lat: 39.1187/Long: -102.9250/Elev: 1479 m) is located in eastern  
218 Colorado, USA in a cold semi-arid climate. The soil at this site has been described as an Alfsol,  
219 that has a sand loam texture in the top 50 cm of the profile, and a silt loam texture between 50 -  
220 100 cm. It is part of the Stoneham series (Natural Resources Conservation Service, 2022). Long  
221 term meteorological data from the site is available from the co-located CoAgMet site (CoAgMet,  
222 Colorado Climate Center).

## 223 3 Materials

### 224 3.1 SWISS Hardware components

225 In each SWISS there are 15 custom made ~650 ml flasks. These flasks are designed  
226 similarly to those used for other water vapor applications. For example, a similar flask is  
227 currently used in an unmanned aerial vehicle to collect atmospheric water vapor samples for  
228 stable isotope analysis (Rozmiarek et al., 2021). The flasks have one long inlet tube that extends  
229 into the flask almost to the base, and one shorter outlet tube so that vapor exiting the flask is well  
230 mixed and representative of the whole flask (Fig. 1A). The large flask volume is advantageous  
231 because there is a low glass surface area to volume ratio, and therefore we are able to reliably  
232 measure vapor from the flasks on a CRDS instrument without interacting with vapor bound to  
233 the flask walls. The 15 glass flasks are connected to a 16-port, multi-selector Valco valve. We  
234 chose to use a Valco valve because these have previously been shown to sufficiently seal off  
235 sample volumes for subsequent stable isotope analysis (Theis et al., 2004). The valve and flasks  
236 are connected by  $\frac{1}{8}$ - $\frac{1}{8}$  inch stainless steel tubing and stainless steel  $\frac{1}{4}$ - $\frac{1}{4}$  inch to  $\frac{1}{8}$ - $\frac{1}{8}$  inch  
237 union Swagelok fittings; we use PTFE ferrules on the glass flasks with the Swagelok fittings.  
238 The first port of the Valco valve is  $\frac{1}{8}$ th inch stainless steel tubing that serves as a flask bypass  
239 loop, which enables flushing of either dry air or water vapor through the system without  
240 interacting with a flask. All components are contained in a 61 cm x 61 cm x 61 cm Pelican case  
241 (Pelican 0370) with 3-three layers of Pick n' Pluck foam and convoluted foam (Pelican Products

242 [Inc., Torrance, Ca, USA](#)). This case is ~~thermally insulated, and insulated and~~ provides enough  
243 protection to ~~allow reliable safely~~ transport of the SWISS by vehicle to field sites.

### 245 3.2 Soil Probes

246 There are three components for the collection and ~~interpretation analysis~~ of soil water  
247 vapor: vapor permeable probes, soil temperature loggers, and soil moisture sensors (Fig 1B,  
248 ~~SuppSupplemental~~ Table 1).

249 Here, we use a vapor permeable membrane (~~A~~Accurrell PP V8/2HF, 3M, Germany) that  
250 was first tested ~~for soil water isotope applications~~ by Rothfuss et al., (2013). ~~This method works~~  
251 ~~by flushing dry nitrogen (or dry air) through the vapor permeable membrane, creating a water~~  
252 ~~vapor concentration gradient from inside the probe to the soil, thus inducing water vapor~~  
253 ~~movement across the membrane. Water vapor is then entrained in the dry nitrogen and flushed to~~  
254 ~~either a CRDS system or into a storage container~~. We opted to use this tubing because it has been  
255 shown to deliver reliable data over time (i.e. Rothfuss et al., 2015; [Oerter et al., 2019](#); [Kübert et](#)  
256 [al., 2020](#); [Seeger and Weiler, 2021](#); [Gessler et al., 2021](#)), and ~~it~~ is easy to use and customize to  
257 individual needs ([Beyer et al., 2020](#); [Kübert et al., 2020](#)). We previously observed that variability  
258 in the length of the vapor permeable tubing can lead to systematic offsets in the stable isotope  
259 composition of measured waters ~~that arise from its variability of e~~ ~~vapor permeable tube surface~~  
260 ~~area~~ ([Havranek et al., 2020](#)). Therefore, we were careful to construct all probes such that the  
261 length of the Accurrell vapor permeable tubing was 10 cm long, and the impermeable Bev-A-  
262 Line IV connected on each side of the vapor permeable tubing was 2 m long. ~~We cut the Bev-A-~~  
263 ~~Line connections to identical lengths to control for memory effect and to treat all samples~~  
264 ~~identically~~. We also constructed the vapor permeable probes to be used in the lab setting for  
265 standards in an identical fashion.

266 Soil temperature loggers (Onset HOBO MX2201), used for applying a temperature  
267 correction to all soil water vapor data ~~and to provide key physical parameters of the soils for~~  
268 ~~other goals beyond this study~~, were buried at the same depths as the vapor permeable probes.  
269 Soil moisture sensors (Onset S-SMD-M005) were also buried at the same depths as the vapor  
270 permeable probes.

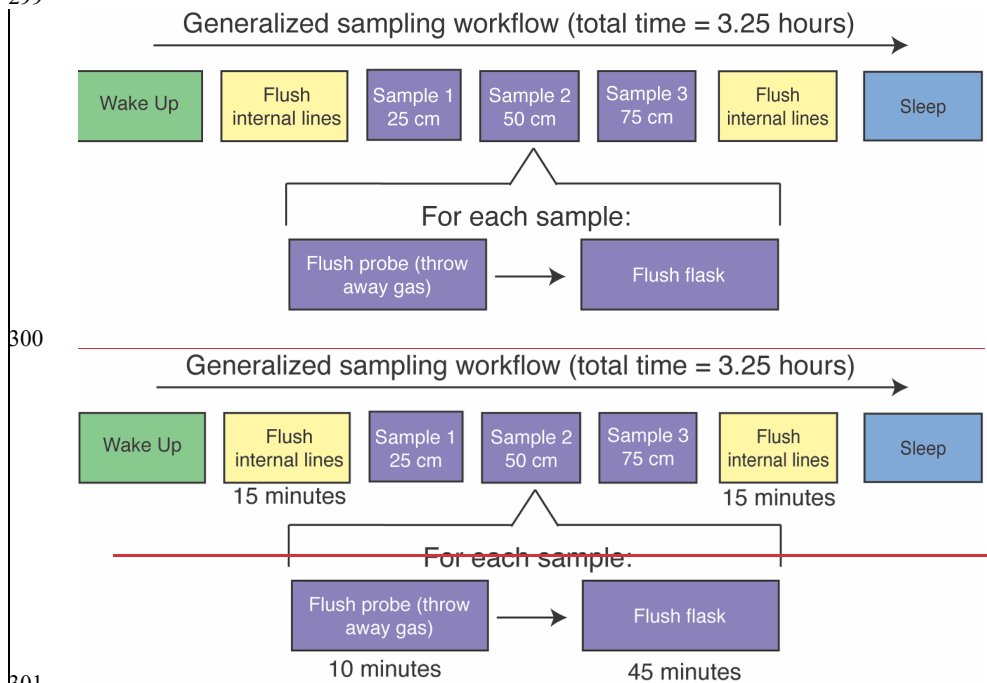

### 272 3.3 Automation components, code style, and remote setting power

273 The philosophy behind the automation of the SWISS was to make it as easy to reproduce  
274 as possible, and as flexible as possible to meet different users' sampling needs. We therefore use  
275 widely available hardware components and electronics parts; for each product there are  
276 numerous alternatives which should be equally viable and could be swapped to better meet each  
277 user's needs. In an effort to make our system as accessible and customizable as possible for the  
278 scientific community, all automation code is completely open source and will continue to be  
279 refined for future applications and hardware improvements. We note that all code is provided as  
280 is and should be tested carefully for use in other experiments.

281 The overall sampling scheme used in this paper is described in figure 2 and table 1. Our  
282 experimental goal was to create a time series of soil water vapor data from three discrete  
283 sampling depths (25 cm, 50 cm, 75 cm). Prior to sampling any soil water vapor, we ~~bypassed the~~  
284 ~~soil probes and flushed the lines within the SWISS. flushed away any water vapor present in the~~  
285 ~~lines within the SWISS prior to flushing the sample loops~~. Then, at the start of sampling for each  
286 depth, we also flushed the water vapor probe ~~to~~ remove condensation or 'old' water vapor. The

287 gas from both of those steps was expelled via the flask bypass loop. Each soil depth was then  
 288 sampled for 45 minutes by flushing through the next flask designated in the sequence.  
 289 Supplemental Figure SI-1 shows the components of the automation system. To automate  
 290 and program the sampling scheme, we used: (1) a microcontroller to run the automation script;  
 291 (2) a coin-cell battery powered real time clock so that the microcontroller was always capable of  
 292 keeping track of time through power losses, and therefore maintain the sampling schedule; (3) an  
 293 RS-232 to TTL converter for serial communication with the Valco valve; (4) solenoid valves that  
 294 were used to control which depth was being sampled and the associated direct current (-VDC)  
 295 power relay; (5) a mass flow controller used to control the rate at which dry nitrogen (1 ppm  
 296 H<sub>2</sub>O) is flushed through the probes; and (6) a power relay used to power the Valco valve and  
 297 mass flow controller. All parts are described in detail in Supplemental Table 2.

probes; and (6) a power relay used to power the Valco valve and mass flow controller. All parts are described in detail in Supplemental Table 2.

In a remote setting, the SWISS units are powered using the combination of a 12 voltV deep-cycle battery andwith a 12VDC, 100 wattW solar panel that is used to charge the battery. The solar panel is mounted to a piece of plywood that covers the hole where the SWISS is deployed (note, the hole is uncovered in Fig. 1B for illustrative purposes). We opted for this setup because the underground storage of all parts of the system creates a discreet field site that attracts minimal attention from other land users, and helps reduce exposure to temperature and precipitation extremes. In the field, we used a 12VDC-120VAC power inverter to provide simple plug and play power for the Valco valve and mass flow controller. This simple combination was suitable for summertime in the Western U.S. where there are a great number of sunnymany hours of direct sunlight, and the solar panel was able to easily charge the 12V battery. This setup may need to be adjusted based on location and desired sampling time. Like the automation system, there are many commercial options available for products, and they can be easily adjusted for users' needs; example parts are described in detail in Supplemental Table 2. We also note that in areas where it is possible to plug into a power grid, the deep cycle battery, solar panel and power inverter can be removed.

## 4. Methods

We completed all water vapor isotope analyses in the Stable Isotope Lab at the Institute of Arctic and Alpine Research (INSTAAR SIL) at the University of Colorado Boulder between October 2020 and August 2022. In our case, we used a Picarro L-2130i water isotope analyzer (Picarro, Inc. Santa Clara, CA) to measure both water concentration and the oxygen and hydrogen isotope ratios of the soil-water vapor.

### 4.1 QA/QC: Testing the SWISS under lab conditions

The highest order concern for the SWISS is that it remains leak-free, because any leaks would introduce the potential for fractionation or mixing of atmosphere that would alter the stable isotope ratio of the water vapor in the flask. To mitigate leaks, we developed a three-part quality assurance and quality control (QA/QC) procedure that must be completed for each new SWISS prior to the first deployment. The first step detects any significant large, fast leaks using helium detection methods; the second step detects medium scale leaks using a dry air test to detect medium scale leaks; and the third step detects slow, small scale leaks using a water vapor test to detect slow leaks. Below, we quickly summarize each of these QA/QC steps. Full procedural descriptions are available in the supplementary material and the data processing code is available via GitHub.

#### 4.1.1 Step 1: Use helium to detect large, fast scale leaks

After initial assembly of the SWISS plumbing, we looked for large leaks from the cracking of inlet or outlet tubes on the glass flasks that occasionally occurred while tightening the Swagelok fittings. To do this, we filled the flasks with helium and used a helium leak detector (Leak Detector, Catalog #22655, Restek, Bellefonte, PA, USA) to find large leaks. Typically, the kinds of leaks we were able to detect with this method were due to cracking of the inlet or outlet on the glass flask that occurred while tightening the swagelok fittings. Another easy alternative to a helium leak test is to complete a very short dry air test (methods described below) where the hold-time is on the order of that requires on the order of 12-24 hours.

#### 4.1.2 Step 2: Use dry air to tests detect medium scale leaks

Once we felt sure that there were no major leaks in our systems, we completed a dry air test. The goal of this test was to catch any second order, medium-scale leaks associated with either Valco valve fittings or Swagelok fittings that were under tightened. Typically, this test found swagelok fittings that had been under tightened. The advantage of this kind of test is that it is easy and quick to complete.

##### Step 2A: Fill flasks with dry air

To start every experiment, we filled flasks. This test started with a dry air fill. A dry air fill consists of flushing flasks with air that is filtered through Drierite (which has a water vapor mole fraction of less than 500 ppm), at 2 L/min for 5 minutes. With a flask volume of 650 ml, this means the volume of the flask is turned over 15 times.

##### Step 2B: Hold period

370 Flasks were then sealed and left to sit for seven days. This time period can be adjusted by  
371 other users to fit their climate or needs assembly.

### 373 Step 2C: Measure water vapor mole fraction using dead-end pull sample introduction

374 At the end of the seven-day period, we measured each flask using a the dead-end pull  
375 sample introduction (note, italicized terms are specific methods, and are explained in greater  
376 detail in supplementary material) method on a Picarro L2130-i Isotope and Gas Concentration  
377 Analyzer. For this sample introduction method, the inlet to the Valco valve was sealed with a  
378 1/4 inch-1/4" Swagelok cap and there was no introduction of a carrier gas. As a result, air was  
379 removed from the flask based on the flow rate of the Picarro CRDS-analyzer (typically 27 - 31  
380 ml/min). Flasks were measured for five minutes, which resulted in ~150 ml of air being  
381 removed from the flasks. All components within the SWISS are capable of being fully  
382 evacuated. Water vapor mole fractions determined by Picarros are not standardized, so it is impossible to know  
383 for sure the exact magnitude of water vapor mole fraction change between the input analysis and the final value at  
384 the end of the dry air test. However, these instruments are remarkably stable over weeks, and so the relative changes  
385 observed (e.g. increase or decrease of mole fraction relative to the initial amount) are likely reliable, particularly for  
386 the larger magnitude changes.

387 isotope were If a flask had a water vapor mole fraction of less than 500 ppm, it “passed”  
388 step 2 of QA/QC.

389 If a flask had a water vapor mole fraction greater than 500 ppm, it “failed” step 2 of  
390 QA/QC, and we tightened both the Swagelok connections on the flasks as well as the fittings  
391 between the stainless steel tubing and the Valco valve. We found that in a low-humidity  
392 environment, we needed a week to really see leaks, but this timescale would likely be shorter in  
393 more humid locations. Additionally, this test could be modified based on available equipment  
394 (for example, if an instrument is available to measure trace atmospheric gases, that could be used  
395 instead). To ensure that SWISS units continue to operate as expected, this test should be done  
396 between field deployments on every SWISS unit.

397 We repeated dry air tests on any given SWISS unit until the majority (typically at least  
398 13/15) of the flasks had a passed step 2 of QA/QC, water vapor mole fraction value of less than  
399 500 ppm at the end of the seven-day experiment. Water vapor values from the CRDS have not  
400 been independently calibrated, but relative variations are believed to be reliable.

### 402 4.1.3 Step 3: Water vapor tests detect small scale leaks

403 The purpose of this experiment was to mimic storage of water vapor at concentrations  
404 similar to what we might expect in a soil, and for durations similar to those of our field  
405 experiments. These tests experiments were meant to test demonstrate that whether during field  
406 experiments, flasks filled early in the sampling sequence during field deployments do not leak by  
407 the time samples are returned to the lab for measurement. Additionally, these tests were used to  
408 demonstrate that flasks that were filled early in the sampling sequence did not leak by the time  
409 the samples were returned to the lab for measurement. For this experiment, we filled flasks were  
410 filled with water vapor of known isotopic composition and water vapor mole fraction known  
411 concentration, sealed the flasks for 14 days, and then we measured the water vapor concentration  
412 mole fraction and isotope values of each flask. We performed 11 water vapor tests that were  
413 done across three analytical sessions using six different SWISS units. Across these three  
414 sessions, we measured 164 flasks both at the start of the 14-day experiment, and at the end.

### 416 Step 3A: Flush flasks with dry air

417 Prior to putting any water vapor into the flasks (either in the field or in the lab), we  
418 completed a dry air fill (as ~~defined-described in QA/QC step 2A above~~) that served to purge the  
419 flasks of any prior water vapor that might exchange with the new sample.

420  
421 *Step 3B: Fill flasks with water vapor and measure input isotope values*

422 To supply water vapor to the flasks, we used the vapor permeable ~~tubing-probes that were~~  
423 ~~constructed identically to those deployed in the field. We~~ immersed the probes up to the  
424 ~~connection between the vapor permeable and impermeable tubing in~~ water, taking care to not  
425 ~~submerge the connection point and inadvertently allowing~~ liquid water to enter the inside of the  
426 ~~vapor permeable tubing. We flushed the flasks at a rate of 150 ml/min for 30 minutes, and~~  
427 ~~measured the  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values and mole fraction of water vapor as each flask was filled. To~~  
428 ~~fill 15 flasks sequentially, the probes were submerged in water for approximately 7.5 hours.~~

429 Across three different ~~measurement~~ sessions, we used three different waters that are used  
430 ~~as~~-tertiary standards in the INSTAAR SIL lab to complete these experiments: a light water made  
431 from melting and filtering Rocky Mountain snow ( $\sim -25.5\%$  and  $-187.5\%$  VSMOW, for  $\delta^{18}\text{O}$   
432 and  $\delta^2\text{H}$ , respectively), an intermediate water that is deionized (DI) water from the University of  
433 Colorado Boulder Campus ( $\sim -16.2\%$  and  $-120.7\%$  VSMOW for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively)  
434 and a heavy water that is filtered water sourced from Florida, USA ( $\sim -0.8\%$  and  $-2.8\%$   
435 VSMOW for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively). All ~~secondary-tertiary~~ lab standards are characterized  
436 relative to international primary standards obtained from the International Atomic Energy  
437 Agency and are reported relative to the V-SMOW/SLAP standard isotope scale. ~~We flushed the~~  
438 ~~flasks at a rate of 150 ml/min for 30 minutes, and measured the  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values and mole~~  
439 ~~fraction of water vapor as each flask was filled.~~ To calculate the input value, we averaged  $\delta^{18}\text{O}$   
440 and  $\delta^2\text{H}$  values over the last three minutes of the filling period.

441 ~~Then, we~~ then stored the water vapor in the flasks for 14 days. At the end of the 14-day  
442 storage period, we measured each flask to evaluate if the ~~isotope composition~~  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$   
443 values had significantly changed over the storage period.

444  
445 *Step 3C: Measure the water vapor isotope values*

446 At the end of the 14-day storage period, we measured each flask to evaluate if the isotope  
447 composition had significantly changed over the storage period. To mitigate memory effects  
448 between flasks, we ran dry air via the flask bypass loop (port one~~4~~ of every ~~Valeo valve~~ SWISS  
449 unit) for ~~five~~5 minutes between each flask measurement. To verify that the impermeable tubing  
450 between the SWISS and the Picarro was sufficiently dried, we waited until the water vapor  
451 mixing ratio being measured by the Picarro was below 500 ppm for  $>30$  seconds.

452 During this ~~5-minute~~ five-minute window, we used a heat gun to manually warm each  
453 flask. ~~The purpose of the heating was to help create a longer, more stable window of~~  
454 ~~measurement time. We believe heating the flasks creates a more stable measurement by limiting~~  
455 ~~water vapor bound to the glass walls of the flask and by helping to homogenize the water vapor~~  
456 ~~within the flask. While we did not strictly control or regulate the temperature of the flasks was~~  
457 ~~not strictly controlled or regulated, they were all warm to the touch.~~

458 Once we warmed the flask ~~was warmed~~ and dried the impermeable tubing ~~dried~~, water  
459 vapor was introduced to the CRDS using one of two methods: 1) the dead-end pull sample  
460 introduction method described above, or 2) a dry air carrier gas sample introduction method.  
461 During the dry air carrier gas sample introduction method, dry air is continuously flowing  
462 through the flask at a rate of 27-31 ml/min for the entire 12-minute measurement period. To

463 reach a water vapor mole fraction of approximately 25,000 ppm (the optimal humidity range for  
464 the Picarro L2130-*i*), we diluted the water vapor with dry air at a rate of 10 ml/min. Without  
465 dilution, the concentration out of the flasks is as high as 35,000 - 40,000 ppm, which leads to  
466 linearity effects on a Picarro L2130-*i* that can be challenging to correct for. The dead-end pull  
467 method is preferable when the water vapor mole fraction inside the flask is low (<17,000 ppm),  
468 because there is no additional introduction of dry air. The introduction of dry air decreases the  
469 water vapor mole fraction throughout the measurement, and in fairly dry flasks, using the dry air  
470 carrier gas method, can lower the water vapor mole fraction to below 10,000 ppm. Below 10,000  
471 ppm, there are large linearity isotope effects associated with the measurement on a Picarro  
472 L2130-*i*, and the isotope values are challenging to correct into a known reference frame, just as  
473 with high water vapor mole fractions. ~~But,~~ The major downside of the dead-end pull method is  
474 that condensation ~~is more likely to can~~ forms in the stainless steel tubing that connects the flasks  
475 to the Valco valve, as well as the Valco valve itself, ~~far more commonly as compared than~~  
476 ~~to compared to~~ the dry air carrier gas method. During the dry air carrier gas method, dry air is  
477 continuously flowing through the flask at a rate of 27-31 ml/min for the entire 12 minute  
478 measurement period. Additionally, to reach a water vapor mole fraction of approximately 25,000  
479 ppm (the optimal humidity range for the CRDS Picarro L2130-*i*), we diluted the water vapor  
480 with dry air at a rate of 10 ml/min. Without dilution, the concentration out of the flasks is as high  
481 as 35,000 - 40,000 ppm, which leads ~~as happens under low water vapor mole fractions,~~ The dry  
482 air to saturation issues on a Picarro L2130-*i*. ~~Providing a~~ carrier gas method prevents  
483 condensation from forming in the Valco valve and tubing, and prevents fractionation that may  
484 occur because of changing pressure within the flask. It is possible that during a dead-end pull on  
485 the flask, ~~that~~ heavier isotopes may remain attached to the walls of the flask, coming off later as  
486 the pressure drops. ~~For these reasons,~~ The dry air carrier gas sample introduction method is  
487 our preferred method for sample introduction in most cases.

488 For each flask, we looked at the stability of the isotope values as well as either a stable  
489 water vapor mole fraction if the dead end pull method was being used or a steady, linear decrease  
490 in water vapor mole fraction if the dry air carrier gas method was being used. we looked at signal  
491 stability individually, and ~~F~~ for approximately 90% of the flasks we found that after excluding  
492 the first three minutes of measurement of each flask, the subsequent three minutes were the most  
493 stable ~~and consistent~~. For the remaining ~10% of the flasks, using a time window that started  
494 either ~30 seconds earlier or ~30 seconds later to create an average isotope value offered a more  
495 stable isotope signal with smaller instrumental uncertainties. For some flasks, using either a later  
496 portion of the measurement period, or slightly earlier offered a more stable signal. Any flask that  
497 would benefit from required specialized individual treatment during the data reduction process  
498 was flagged during measurement.

### 500 *Step 3D: Data correction*

501 During these experiments, we monitored instrument performance (e.g.i.e. drift) and  
502 stability were monitored in two ways. First, to run standards identically to how samples were  
503 collected, we introduced tertiary standards, described above, using vapor probes. The water  
504 vapor produced by the vapor permeable probes was flushed through the SWISS unit via the flask  
505 bypass loop and diluted with a 10 ml/min dry air flow to reach a water vapor mole fraction of  
506 approximately 25,000 ppm before entering the Picarro. Second, we introduced using a suite of  
507 four secondary standards that have been calibrated against primary standards, and reported  
508 against VSMOW/SLAP four waters of known composition ~~via~~ that were introduced to the CRDS

509 using a flash evaporator system, described in detail by Rozmiarek and others (2021). This flash  
510 evaporator system described by Rozmiarek and others (2021) can be used to adjust the water  
511 vapor mole fraction to create linearity corrections at high and low water vapor mole fractions.  
512 Additionally, instrument stability was assessed by measuring water vapor of known composition  
513 that was produced using the vapor probes, in a fashion that is identical to how the flasks were  
514 flushed.

515 After correcting data into a common reference frame, we calculated the difference  
516 between the input isotope values and the ending isotope values.

517 The results of these tests were used to carefully document flasks that do not perform well,  
518 and any idiosyncrasies of SWISS units. That way, during field deployment suspicious those  
519 flasks could be easily identified and investigated.

## 521 **4.2 Field suitability and field application experiments:**

### 522 **4.2.1 Field suitability experiment #1: Long term field leak-dry air test**

523 As a complement to the QA/QC we did under lab conditions, we also completed long  
524 term dry air tests at our field sites. We had three goals associated with these experiments. The  
525 first e purpose of these experiments was to demonstrate that test whether, even under field  
526 conditions, where daily temperature and relative humidity fluctuations are different than in a lab  
527 setting, the flasks were still resistant to atmospheric intrusion. Furthermore, Second, we used  
528 these is-leak tests was used to demonstrate that evaluate whether the flasks that were flushed  
529 with soil water vapor near the end of a sampling sequence do not take took on an atmospheric  
530 isotope composition prior to sampling. Lastly, we chose these time intervals because they  
531 bracket the typical length of a deployment, which helped us determine how quickly flasks should  
532 be measured after bringing a SWISS back to the lab.

533 filled last during the sampling sequence had not taken on an atmospheric isotope  
534 composition prior to sampling.

535 Like all field deployments, we started with a dry air fill, and then one SWISS unit was deployed  
536 to each of our three field sites. No soil water was collected during these deployments. The  
537 duration between filling the flasks with dry air to measuring the flasks was anywhere between 34  
538 - 52 days. The 34 and 52 day tests were as done during June 2022 and August 2021, respectively,  
539 and therefore tests the SWISS under warm summertime conditions. The 43 day test was done in  
540 October 2021, which included nights where air temperatures fell below 0°C. Though the SWISS  
541 is not directly exposed to the air in its deployment hole, the only barrier between air and the  
542 SWISS in its deployment hole was only a plywood board, and so this deployment tested the  
543 suitability of the SWISS to maintain integrity under freezing conditions. The 52 day test was  
544 done in August 2021 and also tests the SWISS under warm, summertime conditions

### 547 **4.2.2. Field suitability experiment #2: Mock field tests**

548 To demonstrate that test whether the automation code and sampling scheme we  
549 proposed developed worked as expected on short, observable timescales, we set up an experiment  
550 to simulate field deployment of one SWISS unit (Meringue) near the University of Colorado  
551 Boulder. This test used applied the automation components and remote power setup described in  
552 the materials section. During this field-simulation experiment, our goal was to collect three  
553 discrete samples each sampling period, to simulate the collection of samples water vapor from  
554 three soil depths. An important goal of this test was to at each field site. Importantly, we wanted

555 ~~to demonstrate that test whether~~ the sampling scheme ~~does not~~ introduced ~~significant~~ memory  
556 effects between samples. We followed the sampling protocol described in figure 2 and table 1.  
557 The day before the experiment began, all flasks were flushed with dry air as described in  
558 section 4.1.2. Over the course of 25 hours, all 15 flasks were filled with three different vapors  
559 according to a set schedule as would be done in the field. Two of the vapors were created by  
560 immersing the water vapor permeable probes in the  
561 ~~were water vapors, created from the~~ light water and intermediate water as described ~~above~~ in  
562 section 4.1.3 the water vapor test section. The third was water vapor from the ambient  
563 atmosphere. All three vapors were sampled using vapor permeable probes constructed identically  
564 to those deployed in the field. For this experiment, we filled three flasks per cycle with each one  
565 of the waters (e.g. Flask 2 = light, Flask 3 = intermediate, Flask 4 = ~~a~~Atmosphere). The choice to  
566 sample atmosphere alongside two waters reflects our second goal of this test, which was to  
567 demonstrate that sampled water vapor isotope values do not drift towards atmospheric values  
568 (Magh et al., 2022).

569 Following the sampling schedule, we stored the SWISS unit  
570 For seven days, the SWISS unit was stored in a simulated field setting for seven days, while  
571 the water vapor remained in the flasks. At the end of the seven days, we measured the flasks. For  
572 flasks that had a high water vapor mole fraction (i.e. flasks with a higher water vapor mole  
573 fraction (light and intermediate water vapor samples) we used the dry air carrier gas sample  
574 introduction method were measured using the carrier gas sample introduction method. For flasks  
575 that had a , whereas those with a low water vapor mole fraction (i.e. atmosphere, ~15,000 ppm)  
576 we used the were measured using the dead end pull sample introduction method.

577  
578 To create average values for each flask, we followed the same averaging protocol  
579 described in section 4.1.3. We used equations 2A and 2B from Rothfuss et al., (2013) to convert  
580 from water vapor to liquid values. Then, using secondary and tertiary standards, data were  
581 corrected into the VSMOW data frame isotope scale. Finally, the SWISS unit offset correction  
582 (detailed below in section 6.1.2) was applied.

#### 583 584 **4.2.3 Full field deployment experiment** *Example Field Deployment: One month period*

585 We deployed one SWISS unit each to the three field sites described in summer 2022.  
586 Before deployment, all SWISS units were flushed with dry air following the protocol outlined in  
587 section 4.1.2. Flasks were flushed with dry air one to three days prior to field deployment.

588 At each site, wWe sampled at three depths (25 cm, 50 cm, and 75cm) on each sampling  
589 day, following the protocol described in figure 2 and table 1. We sampled at each depth every 5  
590 days soil water from all three depths every five days (protocol length = 25 days total). At Oglala  
591 National Grassland, sSamples were taken every five days from 2022-06-25 to 2022-07-14. At  
592 the Briggsdale, CO site sSamples were taken every five days between 2022-07-17 and 2022-08-  
593 06. At the Seibert, CO site, sSamples were collected every five days between 2022-06-19 and  
594 2022-07-04.

595 At the end of a 28--day period, the SWISS units were returned to the lab, and measured.  
596 SWISS units were measured within five days of returning from the field. The maximum number  
597 of days a flask held sample water vapor during these deployments was 32 days. The  
598 measurement protocol and data reduction averaging protocol follows the procedures described in  
599 the water vapor QA/QC test section above section 4.1.3. The data correction scheme follows as in  
600 the section above 4.2.2.

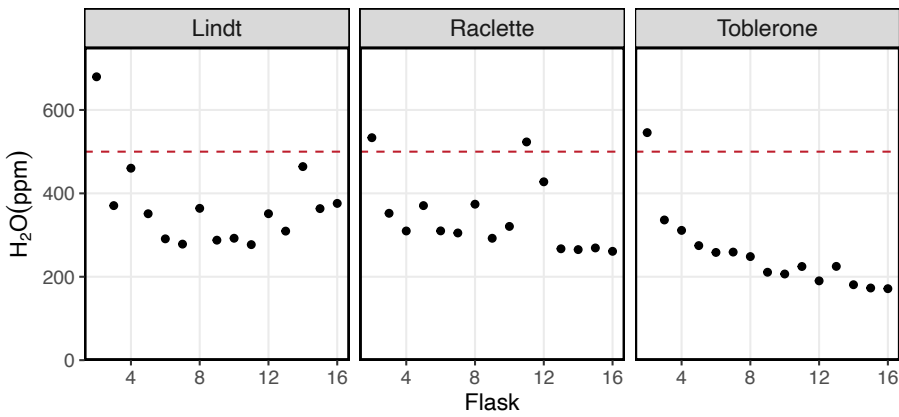

601 **5 Results**

602 **5.1 QA/QC Results**

603 **5.1.1 Dry air test**

604 Figure 3 shows the results of a seven-day dry air test for three SWISS units (marked by  
605 the ~~box-unit~~ name) (SI Table 3). For all three SWISS units, at least 13/15 of the flasks  
606 maintained a water vapor mole fraction value of less than 500 ppm over the seven-day period. In  
607 two of the three SWISS units (Lindt and Raclette), the water vapor mole fraction for flasks was  
608 randomly distributed around approximately 350 ppm. In Toblerone there was a systematic  
609 decrease in water vapor mole fraction from flask ~~two2~~ through flask 16, matching the order in  
610 which the flasks were filled with dry air initially. In ~~both-all three Lindt and Toblerone~~ SWISS  
611 ~~units~~, flask ~~two2~~ had the highest water vapor mole fraction of all the flasks. ~~Supplemental figure~~  
612 ~~2 shows the results of successive dry air tests on the SWISS unit Toblerone where Swagelok~~  
613 ~~fittings were tightened between tests. There was a significant decrease in measured water vapor~~  
614 ~~mole fraction for many flasks, but particularly for flasks 10 and 11 as a result of tightening the~~  
615 ~~fittings.~~

617

618 **Figure 3. Results of a dry air test from three different SWISS units named: Lindt, Raclette and Toblerone. The majority**  
619 **of the flasks maintain a water vapor mixing ratio of less than 500 ppm.**

620

### 621 5.1.2. Water vapor test

622 In panels a and b of figures 4 and 5, we show the results of 11 different water vapor tests  
623 performed across three analytical sessions using 6 different SWISS units. This dataset includes  
624 water vapor tests using three different water vapors (light, intermediate and heavy) and uses both  
625 the dead-end pull and dry-air carrier gas methods to introduce water vapor to the CRDS. Across  
626 these three sessions, we measured 164 flasks while filling them with water vapor and at the end  
627 of the two week hold period. After correcting for instrument drift, we calculated the difference  
628 between the starting and end values to assess drift in water vapor isotope values due to leaking or  
629 other measurement bias.

630 Figure 4 shows the  $\delta^{18}\text{O}$  results of 11 water vapor tests performed using six different  
631 SWISS units. Ideally, we expect a normal distribution centered about 0 within the uncertainty  
632 limits of the water vapor probes (Oerter et al., 2016). For  $\delta^{18}\text{O}$ , the mean difference between the  
633 start and end values for the flasks is 1.1‰ with a standard deviation of 0.72‰ (outliers  
634 removed). There is a consistent positive offset, with a few clear outliers (Fig. 4A). We do not  
635 observe a consistent difference between water vapor sample introduction methods  
636 (SuppSupplemental- Fig. 32). After removing outliers ( $< Q1 - 1.5 * IQR$  or  $> Q3 + 1.5 * IQR$ ,  $n =$   
637 15) from the dataset, we compared the kernel density estimate shape to a normal distribution  
638 calculated from the mean and standard deviation of the dataset to assess dataset normality (Fig.  
639 4B). A normal distribution slightly overestimates the center of the data, but captures the overall  
640 shape fairly well. Therefore, we used the median offset (1.0‰) to correct our water vapor isotope  
641 values, and used the interquartile range of the dataset (outliers removed) to estimate uncertainty  
642 of the SWISS as  $\pm 0.9\text{‰}$ . In figure 5C, for simplicity, we just present the results from 45 flasks  
643 (three SWISS units), with the 1.0‰ offset correction applied. After correction, data are randomly  
644 distributed about 0, and are within the uncertainty range of  $\pm 0.9\text{‰}$  (Supp. Table 4).

645 Figure 5 shows the  $\delta^2\text{H}$  results of 11 water vapor tests. For  $\delta^2\text{H}$ , the mean difference  
646 between the start and end values is 2.63‰ with a standard deviation of 2.85‰ (outliers  
647 removed). Similarly, to  $\delta^{18}\text{O}$ , we ideally expected a normal distribution of differences centered  
648 around 0. As with  $\delta^{18}\text{O}$ , there was a consistent positive offset with some outliers (i.e.,  $< Q1 -$   
649  $1.5 * IQR$  or  $> Q3 + 1.5 * IQR$ ) (Fig. 5A). After removing outliers ( $n = 26$ ) from the dataset, we  
650 compared the kernel density estimate to a normal distribution calculated from the mean and  
651 standard deviation of the dataset to assess dataset normality (Fig. 5B). As for with  $\delta^{18}\text{O}$ , the  
652 center of the dataset is overestimated by the mean, but the overall peak shape is roughly  
653 captured. We therefore use the median value of 2.3‰ as an offset correction, and estimate  
654 uncertainty at  $\pm 3.7\text{‰}$  for  $\delta^2\text{H}$  from the interquartile range. In figure 5C, we present the results  
655 from 45 flasks (three SWISS units), with the 2.3‰ offset correction applied. Data are randomly  
656 distributed about 0, and are within the uncertainty range of  $\pm 3.7\text{‰}$  (SuppSupplemental-  
657 Table 4).

658 When we compared the results in figures 4C and 5C, we found that flasks that performed  
659 adequately in oxygen isotope space for  $\delta^{18}\text{O}$  did not always perform adequately in hydrogen  
660 isotope space for  $\delta^2\text{H}$ . The results from the SWISS unit Lindt display this trend behavior  
661 particularly well. Less commonly, some flasks that were within uncertainty of the system for  
662 hydrogen isotope values  $\delta^2\text{H}$  were not within uncertainty of the system in oxygen isotope  
663 values for  $\delta^{18}\text{O}$ , like flask 8 in the SWISS unit Toblerone (Figs. 4C, 5C). In a dual isotope

664 plot, there is a strong positive correlation between  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  with a slope of 3.14 and an  $R^2$   
665 value of 0.62 (Supplemental Fig. 4).

## 666 **5.2 Field suitability and field deployment experiment results**

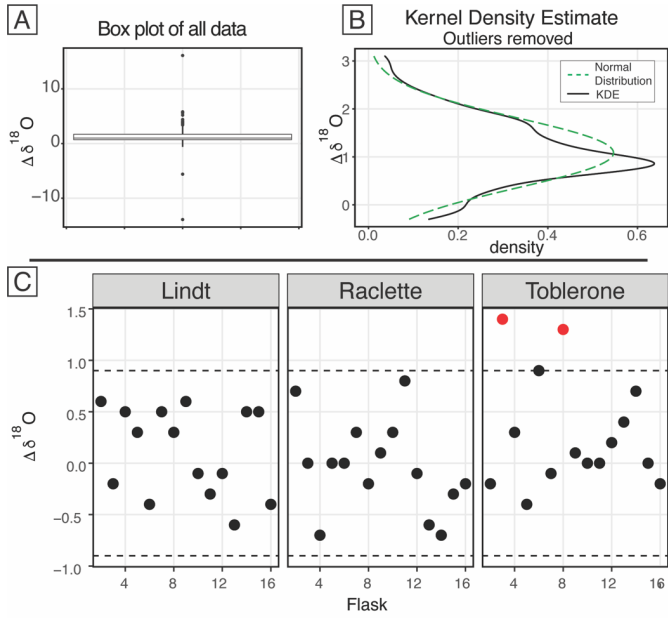

### 667 **5.2.1. Dry air test**

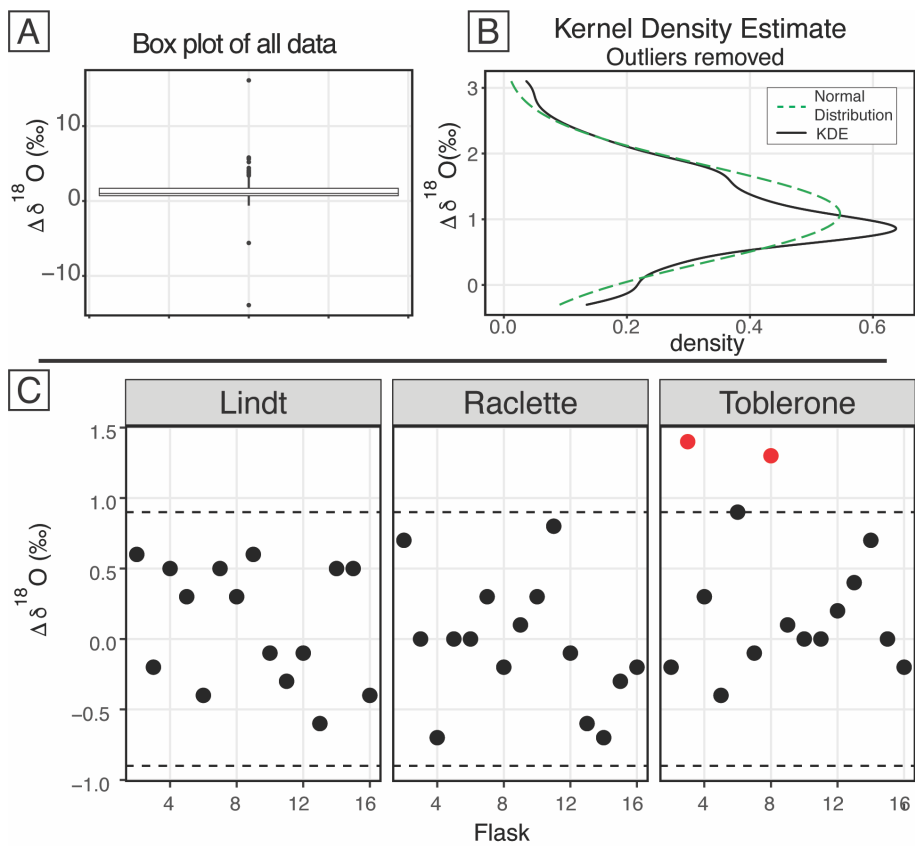

668  
669 Figure 6A shows the result of placing SWISS units that were flushed with dry air out into  
670 field conditions over the course of 34–52 days (SI Table 3). We chose these time intervals  
671 because they bracket the typical length of a deployment, which helped us determine how quickly  
672 flasks should be measured after bringing a SWISS back to the lab. At the timescale of 34–43  
673 days, 13 of the 15 flasks typically maintained a water vapor mole fraction of less than 1000 ppm.  
674 At the timescale of 52 days, eight of the 15 flasks had a water vapor mole fraction between 1000  
675 –2500 ppm, and the remaining seven flasks had a water vapor mole fraction of less than 1000  
676 ppm. Given that these tests were completed with different SWISS units, these data also include  
677 some of the inter-unit variability.

729 **5.2 Field suitability test and field deployment experiment results**

730 **5.2.1 Dry air test**

731 Figure 6A shows the result of placing three different SWISS units, that were flushed with  
732 dry air, out into the field conditions over the course of for 34 - 52 days (SI Table 3). This  
733 timescale (4-6 weeks) is similar to most field deployments. We chose these time intervals  
734 because they bracket the typical length of a deployment, which helped us determine how quickly  
735 flasks should be measured after bringing a SWISS back to the lab. At the timescale of 34 - 43  
736 days, 13 of the 15 flasks typically maintained a water vapor mole fraction of less than 1000 ppm.  
737 At the timescale of 52 days, eight of the 15 flasks had a water vapor mole fraction between 1000  
738 -2500 ppm, and the remaining seven flasks had a water vapor mole fraction of less than 1000  
739 ppm. Given that these tests were completed with different SWISS units, these data also include  
740 some of the inter-unit variability. Over the 52 days, seven flasks maintained a water vapor mole  
741 fraction less than 1000 ppm and the remaining 8 had a water vapor mole fraction between 1000 -  
742 2500 ppm.

743  
744 **5.2.2 Automation test**

745 Figure 6B shows the results of using the automation code to collect and store water vapor  
746 of known composition for seven days (Table 2). In both plots, the known values of the water are  
747 shown as a long-dash line. Uncertainty on those measurements is estimated at  $\pm 0.5\%$  and  $\pm 2.4\%$   
748 for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively (Oerter et al., 2016), shown as the dotted lines. We estimated the  
749 isotope value of the atmosphere at the time of sampling with water vapor mole fraction,  $\delta^{18}\text{O}$ ,  
750 and  $\delta^2\text{H}$  data from the CRDS in the lab. The isotope value, that was corrected as described in  
751 section 4.2.2, of each flask is shown, with uncertainty associated with the SWISS units estimated  
752 at  $\pm 0.9\%$  and  $\pm 3.7\%$  for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively.

753 Seven of the nine flasks filled with flash-evaporated water vapor overlap within  
754 uncertainty of the known  $\delta^{18}\text{O}$  value for those standards (top plot, Fig. 6B), and four of the five  
755 flasks filled with atmospheric vapor overlap within uncertainty of our estimated  $\delta^{18}\text{O}$  value.  
756 Flasks that fall outside of the bounds of uncertainty have lower  $\delta^{18}\text{O}$  values than the expected  
757 value. For  $\delta^2\text{H}$ , (bottom plot, Fig. 6B) only three of the nine flasks filled with flash-evaporated  
758 water vapor overlap within uncertainty of the known value of those standards, while four of the  
759 five flasks filled with atmospheric vapor overlap within uncertainty of the estimated  $\delta^2\text{H}$  value.  
760 Flasks that fall outside of the bounds of uncertainty have higher  $\delta^2\text{H}$  values than the expected  
761 value.  
762

**5.2.2. Automation test**

Figure 6B shows the result of using the automation code to collect and store water vapor of known composition for seven days (Table 2). In both plots, the known values of the water are shown as a long-dash line. Uncertainty on those measurements is estimated at 0.5‰ and 2.4‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  respectively (Oerter et al., 2016), shown as the dotted lines. We estimated the isotope value of the atmosphere at the time of sampling with data from the CRDS in the lab. The corrected isotope value of each flask is shown, with uncertainty associated with the SWISS units estimated at 0.9‰ and 3.7‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively.

Seven of the nine flasks filled with water vapor overlap within uncertainty of the known  $\delta^{18}\text{O}$  value for those standards (top plot, Fig. 6B), and four of the five flasks filled with atmospheric vapor overlap within uncertainty of our estimated  $\delta^{18}\text{O}$  value. Flasks that fall outside of the bounds of uncertainty tend to have lower  $\delta^{18}\text{O}$  values than the expected value. For  $\delta^2\text{H}$ , (bottom plot, Fig. 6B) only three of the nine flasks filled with water vapor overlap within uncertainty of the known value of those standards, while four of the five flasks filled with atmospheric vapor overlap within uncertainty of the estimated  $\delta^2\text{H}$  value. Flasks that fall outside of the bounds of uncertainty typically have higher  $\delta^2\text{H}$  values than the expected value.

SWISS	Flask	water	$\delta^{18}\text{O}$ (‰)	$\delta^2\text{H}$ (‰)
Meringue	2	DI	-14.4	-122.2
Meringue	3	Atmosphere	-10.1	-105.6
Meringue	4	Light	-24.6	-193.7
Meringue	5	DI	-15.0	-130.8
Meringue	6	Atmosphere	-9.4	-103.4

Table 2. Results of the Automation test

839  
840

841 **5.2.3 Example Field deployment results**  
 842 Figure 7 shows the results from three field deployments in Oglala National Grassland,  
 843 Nebraska; Briggsdale, Colorado; and Seibert, Colorado (table 3).

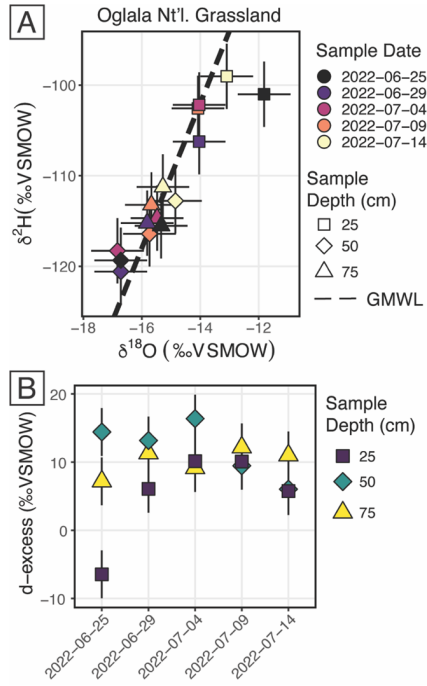

844

845  
846 **Figure 7.** Results from all three field deployments to **A)** Oglala National Grassland, NE, **B)** Briggsdale,  
847 CO and **C)** Seibert, CO. Note, the y-axis scale for all three plots is different.  
848  
849

850  
851 — There are 15 samples from Oglala National Grassland (Fig. 7A, Table 3); five from 25  
852 cm depth, five from 50 cm depth and five from 75 cm depth. ~~Samples were taken approximately~~  
853 ~~every five days from 2022-06-25 to 2022-07-14.~~ Four of the five samples from 25 cm overlap  
854 within uncertainty in  $\delta^{18}\text{O}$  value, and all five samples overlap with uncertainty in  $\delta^2\text{H}$  value.  
855 There is a significant decrease in the  $\delta^{18}\text{O}$  value at 25 cm between 2022-06-25 and 2022-06-29.  
856 There is no similar shift in  $\delta^2\text{H}$  value over the same time period. The first three samples from 50  
857 cm overlap in both  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values, then the final two samples ~~drift shift~~ to higher isotope  
858 values. ~~All five samples from 75 cm overlap in  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values.~~ Similar to the samples from  
859 50 cm, there is a trend towards higher  $\delta^2\text{H}$  values for the last three samples. ~~All five samples~~  
860 ~~from 75 cm overlap in  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values. On a dual isotope plot, data from 50 cm and 75 cm~~  
861 ~~cluster together at lower values, and while the Overall,  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values from 25 cm are~~  
862 ~~significantly higher (Figs. 7A, 8A) than the values from 50 and 75 cm depth. All of the data~~  
863 ~~overlap overlap within uncertainty with the global meteoric water line, except for the 25 cm~~  
864 ~~depth sample from 2022-06-25 (Fig. 8A). The calculated D-excess values all overlap are all~~  
865 ~~within uncertainty of, and with 10% and each other between 2022-06-29 and 2022-07-14 (Fig~~  
866 ~~8B), except for t. The 25 cm depth sample from 2022-06-25, which has a D-excess value of -~~  
867 ~~6.6%, consistent with evaporative enrichment of soil water at that depth and time. Generally,~~  
868 ~~samples from 50 cm depth have lower  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values than samples from 75 cm depth.~~

869  
870  
871  
872  
873  
874

**Figure 8.** Results from the Oglala National Grassland, NE field site. A)  $\delta^2\text{H}$  vs.  $\delta^{18}\text{O}$ , where the dashed line is the global meteoric water line. The shapes for ~~of~~ the different depths sampled matches figure 7, and the color of the points is the date on which the soil water was sampled B) A plot of d-excess. Note, both the color and shape match figure 7.

875 There are 10 samples from Briggsdale, CO (Fig. 7B, Table 3); five samples each are  
876 from a vapor probe buried at 50 cm depth and five samples are from a vapor probe buried at  
877 75 cm depth. Data from 25 cm at Briggsdale, CO were excluded because the water vapor mole  
878 fractions from all of the flasks with samples at this depth had were extremely low water vapor  
879 mole fractions (<13,000 ppm). We excluded these data because these samples are associated  
880 with a very dry soil (VWC < 0.05), and so it is not clear how much sampling gas (N<sub>2</sub>) is  
881 injected into the soil using the vapor permeable tubing under very dry conditions (Quade et al.,  
882 2019), and therefore how representative these isotope data are of soil water. Moreover, below  
883 13,000 ppm there are large linearity effects on a Picarro L2130-i, and it is very challenging to  
884 correct those data if they were measured using the dry-air carrier sample introduction method.  
885 *those data may either represent atmosphere or soil gas from an extremely dry soil. Samples were*  
886 *taken every five days between 2022-07-17 and 2022-08-06. A While all samples overlap within*  
887 *uncertainty infor both δ<sup>18</sup>O and δ<sup>2</sup>H values, however the absolute values of samples from 50 cm*  
888 *are clearly consistently offset to higher values for both δ<sup>18</sup>O and δ<sup>2</sup>H as compared to samples*  
889 *from 75 cm.*

890 There are 128 samples from Seibert, CO (Fig. 7C, Table 3); four samples are from a  
891 vapor probe buried at 25 cm depth and four samples are from a vapor probe buried at 50 cm  
892 depth from each sampling depth (25, 50 and 75 cm). Samples collected from 75 cm depth at  
893 Seibert, CO were discarded because there were significant problems with condensation while  
894 measuring these flasks, and so all data were considered spurious. Samples were collected every  
895 five days between 2022-06-19 and 2022-07-04. At 25 cm depth, δ<sup>18</sup>O values of three of the four  
896 samples overlap within uncertainty, while the 25 cm sample from 2022-06-29 that does not  
897 overlap has a higher δ<sup>18</sup>O value than the other three samples. At 25 cm depth, δ<sup>2</sup>H values  
898 overlap within uncertainty for all four samples. At 50 cm depth, there is a steady decrease in  
899 δ<sup>18</sup>O value over the sampling period, while δ<sup>2</sup>H values for all four samples remain steady. All  
900 samples from 50 cm depth and overlap within uncertainty. At 75 cm depth, samples have a very  
901 large range of δ<sup>18</sup>O values between -8.5‰ and 7.4‰, and δ<sup>2</sup>H values range between -55.7‰ and  
902 15.1‰. Almost all of the samples from 75 cm depth were associated with condensation in the  
903 sample introduction lines during measurement.

904

**Table 3.** Results from the three field deployments of SWISS.

Site	Date	Sample Depth (cm)	Flask	T (°C)	$\delta^{18}\text{O}$ (‰)	$\delta^{18}\text{O}$ (‰) Analytical Error	$\delta^2\text{H}$ (‰)	$\delta^2\text{H}$ (‰) Analytical Error

908

## 909 **6. Discussion**

### 910 **6.1 QA/QC and field suitability tests**

#### 911 **6.1.1 Dry Air tests**

912 ~~In Colorado, where these tests were completed, the ambient atmosphere during the~~  
913 ~~summertime typically sits at a water vapor mole fraction between 10,000 - 20,000 ppm, and in~~  
914 ~~winter the water vapor mole fraction can drop as low as 4000 ppm. If the flasks had been slowly~~  
915 ~~equilibrating with the atmosphere, the flasks would have drifted to much higher water vapor~~  
916 ~~molar fractions. If the flasks did not drift towards higher water vapor mole fractions, we felt~~  
917 ~~confident that the flasks are resistant to atmospheric intrusion after they have been flushed with~~  
918 ~~dry air. We chose a timescale of seven days for the dry air tests because we found that in a low-~~  
919 ~~humidity environment, seven days was enough time to meaningfully observe leaks, while being a~~  
920 ~~short enough timescale to be able to continue to work through the QA/QC process efficiently.~~  
921 ~~For example, in supplemental figure 4, we show the results of two sequential dry air tests on the~~  
922 ~~SWISS unit Toblerone (supplemental figure 24). We show that it is possible to~~  
923 ~~drastically reduce leaks that allow ambient water vapor in the air from intruding into the flasks~~  
924 ~~by tightening and/or replacing problematic fittings (both those attached to the glass flasks and~~  
925 ~~those on the Valco valve) and in some cases the glass flask itself. During the final seven-day~~  
926 ~~dry air tests, the most flasks were able to maintain a water vapor mole fraction typically less~~  
927 ~~than 400 ppm, and all flasks maintained a water vapor mole fraction of less than 700 ppm (Fig.~~  
928 ~~34). In Colorado, the ambient atmosphere during the summertime typically sits at a water vapor~~  
929 ~~mole fraction between 10,000 - 20,000 ppm, and in winter the water vapor mole fraction can~~  
930 ~~drop as low as 4000 ppm.~~

931 ~~Across all of the SWISS units, there is a bias towards a higher water vapor mole fraction~~  
932 ~~for the first flask that is measured (port one on every valve is the flask bypass loop, so the first~~  
933 ~~flask is flask two), which suggests a methodological source of higher water vapor concentration~~  
934 ~~rather than an issue with Swagelok fitting tightness problems. There are two potential sources of~~  
935 ~~for this issue. First, it is possible that not all of the atmospheric water vapor was flushed from the~~  
936 ~~line that connects to the CRDS prior to the start of the measurements, but by the time the second~~  
937 ~~flask is measured, the lines between the SWISS and CRDS have been sufficiently flushed, and so~~  
938 ~~there is creating bias in the first flask measured. But, by the second flask, the lines between the~~  
939 ~~SWISS and CRDS have been sufficiently flushed. This hypothesis could be tested by taking care~~  
940 ~~to flush all of the gas lines with dry air until the water vapor mixing ratio is below 200~~  
941 ~~ppm to progressively lower water vapor mixing ratios prior to measuring any flasks, to see what~~  
942 ~~minimum ratio is required to eliminate this bias. Lab protocols can then be adjusted to flush all~~  
943 ~~gas lines to this level. Similarly, it is possible that during the filling phase, not all of the~~  
944 ~~atmospheric vapor has been flushed out of the Drierite system before starting the fill process.~~  
945 ~~This hypothesis is supported by the systematic decrease in water vapor mole fraction across~~  
946 ~~flasks in the Toblerone unit (Fig. 3, right panel). As a result of these biases, we now flush the~~  
947 ~~Drierite for at minimum 30 minutes prior to the start of the experiment.~~

948 ~~This shows we can reduce the leakiness of the flasks. In addition to testing the overall~~  
949 ~~leakiness, the dry air test is also provided an easy useful baseline test that from which allowed us~~  
950 ~~to test building materials. For example, in supplemental figure 5, we show the results of~~  
951 ~~sequential seven day and 27-day dry air tests where we replaced stainless steel tubing and fittings~~

Commented [KS1]: this seems useful to put earlier in the paragraph, as an expectation statement of what we are trying to prevent happening.

Commented [REH2R1]: Help

952 with PTFE Swagelok fittings with 1/8 inch PTFE tubing. We thought that PTFE fittings would  
953 be advantageous because they are much easier to install and are significantly lighter, and would  
954 therefore be helpful when there are weight constraints. However, based on the very limited  
955 testing we did, PTFE fittings and tubing may be sufficient to store water for up to a single week,  
956 but on longer timescales (e.g. 27 days) we observed greater exchange and leaking than with the  
957 stainless steel fittings. We encourage any future user using this modification to rigorously test  
958 these fittings on a timescale appropriate for their application.

959 We found that in a low humidity environment, we needed a week to really see leaks, but  
960 this timescale would likely be shorter in more humid locations. If the flasks allowed in a  
961 significant amount of atmosphere, the flasks would have had much higher water vapor molar  
962 fractions. This suggests that the system is resistant to atmospheric intrusion.

963 There seems to be a systemic bias towards a high water vapor mole fraction for the first  
964 flask that is measured (flask 2). There are two potential analytical sources of this. First, it's  
965 possible that during the filling phase, not all of the atmospheric vapor has been flushed out of the  
966 system before starting the fill process. Similarly, it is possible that not all of the atmospheric  
967 water vapor was flushed from the line that connects to the CRDS prior to the start of the  
968 measurements.

### 969 6.1.2 Water vapor tests

970 Our initial goal with the water vapor tests was to show that test whether the measured  
971 water vapor isotope values at the end of the two-week holding period were normally distributed  
972 about 0 within the uncertainty limits of the water vapor probes (Oerter et al., 2016). This was a  
973 reasonable goal given the similarities in probe set-up and the plumbing design between the  
974 SWISS and the IsoWagon system. But, the most salient result of the water vapor tests is that  
975 there is a consistent positive offset between the input isotope values and the isotope values  
976 measured at the end of the two-week experiments (Figs 4B, 5B). The positive offset in both  $\delta^{18}\text{O}$   
977 and  $\delta^2\text{H}$  values is consistent across 11 different tests, using six different SWISS and three  
978 different input water isotope values.

979 The in-lab water vapor tests served three functions: 1) they allowed us to test the best method for  
980 measuring soil water vapor at fairly high water vapor mole fractions that might be representative  
981 of field conditions (i.e.  $>25,000$  ppm), 2) to test if there is any systemic bias introduced through  
982 the building materials or measurement schema, and, 3) test whether soil water vapor samples can  
983 yield reliable stable isotope values.

984 We completed 11 water vapor tests using 6 SWISS units and three analytical sessions, resulting  
985 in 164 measurements of water vapor. Across the three analytical sessions, three waters with  
986 different isotopic compositions were used to produce water vapor (1 heavy, 1 intermediate, and 1  
987 light). If there was alteration of original values due to leaky flasks, we might expect the  $\delta^{18}\text{O}$  and  
988  $\delta^2\text{H}$  values to converge on the  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  value of the atmosphere. For example, we might  
989 expect water vapor from the light water test to have the most significant change in isotope value,  
990 towards that of the ambient atmosphere. Instead, the  
991 Figures 4 and 5 demonstrate that there is a consistent offset in both  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  of the water  
992 vapor from the start of storage to the end for all three analytical sessions. After removing outliers  
993 from the dataset, there remains a consistent bias across all SWISS boxes and analytical sessions  
994 (Figs 5B, 6B). The consistency across  $>135$  flasks, different starting water vapor isotope values,  
995 sample introduction methods, and multiple analytical sessions suggests that this difference is a  
996 function of the storage and measurement process. Additionally, in particular, the normality of the  
997

1098 distribution suggests whatever the origin of the offset is, that there is a systematic bias that we  
1099 can reliably correct for.

#### 1001 *6.1.2.1 Offset correction*

1002 To correct our data ~~create an~~ for this offset correction, we chose to use the median value  
1003 as an offset correction ~~over~~ rather than the mean of the normal distribution, because the median is  
1004 not biased by major outlier isotope values that reflect abnormal values that go beyond analytical  
1005 noise, such as a slow but major leak that changes the values far beyond the basic offset seen in  
1006 the dataset. The calculated average offset is 1.0‰ and 2.6‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively.  
1007 After applying these values as an offset correction to the data, the most flasks also fall within the  
1008 uncertainty of the water vapor permeable probes ( $\delta^{18}\text{O} = \pm 0.5\text{‰}$  and  $\delta^2\text{H} = \pm 2.4\text{‰}$ , Oerter et al.,  
1009 2016), and the values are distributed about 0 (Figs. 4C, 5C).

1010 However, the uncertainty of the SWISS system ~~overall~~ is higher than that of the probes  
1011 alone. Based on the results of the water vapor tests, we estimate the uncertainty of the SWISS at  
1012  $\pm 0.9\text{‰}$  and  $\pm 3.7\text{‰}$  for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively using the interquartile range (IQR) of the  
1013 water vapor test results after removing outliers from the dataset. We prefer the IQR over the  
1014 calculated standard deviation of the normal distribution, because IQR is not biased by outlier  
1015 values. This level of uncertainty is large relative to other methods, but is sufficient for many  
1016 critical zone applications, given the magnitude of seasonal variability in the top ~50 cm of a soil  
1017 profile that can be observed in natural systems (e.g. Oerter et al., 2017; Quade et al., 2019). We  
1018 also expect that uncertainties will decrease ~~In the future, this uncertainty estimate can be~~  
1019 ~~improved both by with further future~~ lab-based or near research facility testing and by comparing  
1020 the SWISS against other soil water extraction methods.

1021 The relationship between  $\delta^2\text{H}$  values and  $\delta^{18}\text{O}$  values in a dual-isotope plot gives us  
1022 ~~some~~ provides insight into the mechanism driving the offset correction. Without an offset  
1023 correction applied, the slope of the relationship between  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  is 3.14 ( $R^2 = 0.62$ )  
1024 (Supplemental Fig. 4). This slope is only slightly higher than evaporation under pure diffusion  
1025 (Gonfiantini et al., 2018). This suggests that the offset correction is likely driven by diffusion and  
1026 will likely vary according to climate of the lab. For example, in a dry climate like Colorado, the  
1027 water vapor concentration in the flask is significantly higher than the atmosphere, creating a  
1028 larger diffusive gradient potential than for a lab in a more humid climate. We therefore, strongly  
1029 encourage future users to test their SWISS under climate conditions ~~appropriate~~ similar for their  
1030 applications. Further, we encourage users who might use the SWISS as part of a tracer study that  
1031 uses labeled heavy water to test the SWISS with labeled waters prior to their field experiments to  
1032 verify reliability.

1033  
1034 *In figures 5C and 6C, we show the results of 3 water vapor tests from the August 2022 analytical*  
1035 *session, with an offset correction applied. 43 of the 45 measured flasks faithfully retained the*  
1036 *starting  $\delta^{18}\text{O}$  value of the water vapor, and 37 of the 45 measured flasks faithfully retained the*  
1037 *starting  $\delta^2\text{H}$  value of the water vapor. Additionally, after the offset correction was applied, most*  
1038 *flasks also fall within the uncertainty of the water vapor permeable probes ( $\delta^{18}\text{O} = 0.5\text{‰}$  and*  
1039  *$\delta^2\text{H} = 2.4\text{‰}$ ).*

1040 Supplemental figure 6 shows a kernel density estimate plot of the results from two water  
1041 vapor test sessions, with the offset correction applied. During the March 2022 session, flasks  
1042 were measured using the dead-end pull sample introduction method and during the August 2022  
1043 session, flasks were measured using the dry air carrier gas sample introduction method. There is

1044 no significant difference in the measured difference between the two sample introduction  
1045 methods. ~~W~~That said, we prefer the dry air carrier gas method, because it is far simpler to control  
1046 the water vapor mixing ratio, and optimize the concentration to be around 25,000 ppm, which is  
1047 the concentration at which the Picarro L2130-*i* is most reliable. The dry air carrier gas method  
1048 also makes it ~~far~~ easier to control for and monitor for condensation in the stainless-steel tubing  
1049 and vapor impermeable tubing, which can bias a measurement.  
1050

Table 3. Results from the three field deployments of SWISS.

1052  
1053

1054 suggests that there is a systematic bias that we can reliably correct for. We chose to use the  
1055 median value as an offset correction over the mean of the normal distribution, because the  
1056 median is not biased by higher isotope difference values that are a complex combination of  
1057 systematic bias and slow leaking. The calculated average offset is 1.0‰ and 2.6‰ for  $\delta^{18}\text{O}$  and  
1058  $\delta^2\text{H}$ , respectively.

1059 Based on the results of the water vapor tests, we estimate the uncertainty of the SWISS at  
1060 0.9‰ and 3.7‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively using the interquartile range (IQR) of the water  
1061 vapor test results after removing outliers from the dataset. We prefer the IQR over the calculated  
1062 standard deviation of the normal distribution, because IQR is not biased by outlier values. In  
1063 figures 5C and 6C, we show the results of 3 water vapor tests from the August 2022 analytical  
1064 session, with an offset correction applied. 43 of the 45 measured flasks faithfully retained the  
1065 starting  $\delta^{18}\text{O}$  value of the water vapor, and 37 of the 45 measured flasks faithfully retained the  
1066 starting  $\delta^2\text{H}$  value of the water vapor. Additionally, after the offset correction was applied, most  
1067 flasks also fall within the uncertainty of the water vapor permeable probes ( $\delta^{18}\text{O} = 0.5\%$  and  $\delta^2\text{H}$   
1068  $= 2.4\%$ ).

1069 Supplemental figure 3 shows a kernel density estimate plot of the results from two water  
1070 vapor test sessions, with the offset correction applied. During the March 2022 session, flasks  
1071 were measured using the dead-end-pull-sample introduction method and during the August 2022  
1072 session, flasks were measured using the dry air carrier gas sample introduction method. There is  
1073 no significant difference in the measured difference between the two sample introduction  
1074 methods. We prefer the dry air carrier gas method, because it is far simpler to control the water  
1075 vapor mixing ratio, and optimize the concentration to be around 25,000 ppm, which is the  
1076 concentration at which the Picarro L2130-i is most reliable. The dry air carrier gas method also  
1077 makes it far easier to control for and monitor for condensation in the stainless steel tubing and  
1078 vapor impermeable tubing, which can bias a measurement.

### 1080 6.1.3 Field suitability tests

1081 The long dry air tests in the field are a useful complement to the shorter in-lab tests  
1082 because they test the reliability of the system at field-deployment timescales. It is clear from the  
1083 34 and 43 day tests that the flasks are reasonably resistant to leaks on the timescale of a normal 4  
1084 – 6 week deployment to be able maintain the composition of vapor in the flasks (Fig. 6A). These  
1085 tests also give us confidence that flasks filled later in the sampling sequence do not take on an  
1086 atmospheric signal prior to sampling. There are a few possibilities to explain the poorer  
1087 performance of the Toblerone SWISS unit during the 52-day test. (Fig. 6A). The first is that  
1088 there is a real threshold past which the SWISS are no longer able to retain samples. However,  
1089 this explanation would suggest that there should be a gradual decrease in performance across the  
1090 three tests, which we do not observe. The alternative explanation is that the poor performance is  
1091 a result of inter-unit variability. The 52-day test was the first long-term test and was performed in  
1092 August 2021. In August 2021, we were continuing to build new SWISS units and continuing to  
1093 learn from each successive round of QA/QC, so it seems plausible that there were unidentified  
1094 problems with the SWISS unit Toblerone that were solved before the water vapor tests in August  
1095 2022.

1096  
1097 In Figure 7A, we observe that the flasks typically maintained a low water vapor mole fraction ( $< 1000$   
1098 ppm) under field conditions, and at timescales relevant to 4–6 week field deployments (34–  
1099 43 days). The 34 day test was done during June 2022, and therefore tests the SWISS under warm

1100 summertime conditions. The 43-day test was done in October 2021, which included nights where  
1101 temperatures fell below 0°C, and therefore tests the suitability of the SWISS to maintain integrity  
1102 under freezing conditions. We observe that the SWISS did considerably worse at maintaining a  
1103 low water vapor mole fraction over a 52-day time period during similar summertime conditions  
1104 as compared to the 34–43-day time period. Over the 52 days, seven flasks maintained a water  
1105 vapor mole fraction less than 1000 ppm and the remaining 8 had a water vapor mole fraction  
1106 between 1000–2500 ppm. Though the SWISS performed considerably worse after 52 days than  
1107 it did from 34–43 days, it is important to note that the atmospheric water vapor mole fraction  
1108 during the storage time period was likely 15,000–20,000 ppm, and so the measured values  
1109 demonstrate that the SWISS are still quite resistant to atmospheric intrusion at that timescale.  
1110 In figure 67B, the data show that the flasks faithfully preserved the  $\delta^{18}\text{O}$  value of both flash-  
1111 evaporated and atmospheric water vapor produced using the vapor-permeable probe and the  
1112 atmosphere over a seven-day period. One flask was removed from the dataset (flask eight),  
1113 because there was noticeable visible condensation in the clear impermeable tubing during the  
1114 measurement phase, with an increase of > 5‰ for  $\delta^{18}\text{O}$  during the measurement period. The  
1115 condensation appeared as small (<1 mm) bubbles of water all along the impermeable tubing, but  
1116 the bubbles were concentrated near the connection between the SWISS and the impermeable  
1117 tubing. Notably, the two flasks whose  $\delta^{18}\text{O}$  oxygen-isotope values do not overlap within  
1118 uncertainty are more negative than expected, rather than drifting towards atmospheric values or  
1119 values expected with from kinetic-diffusive fractionation. It is possible that those samples were  
1120 also affected by condensation at the start of the experiment; during condensation, we expect that  
1121  $^{18}\text{O}$  will preferentially go into the liquid phase, and that the water vapor that enters the flask will  
1122 have a lower than expected  $\delta^{18}\text{O}$  value.  
1123 In contrast to the oxygen-isotope  $\delta^{18}\text{O}$  value results, Surprisingly, only 3 flasks filled with either  
1124 flash evaporated DI or light water vapor overlap within uncertainty of the known  $\delta^2\text{H}$  values,  
1125 while four of the five flasks overlap within uncertainty of the estimated atmosphere isotope  
1126 value. The flasks tend to drift towards the value of the atmosphere, but retain the overall data  
1127 pattern from the oxygen isotope values.  
1128 The relatively high failure rate of this ‘mock’ field test was somewhat surprising given  
1129 the results of the water vapor tests done in the laboratory. Going into the test, we suspected that  
1130 flasks six and eight were slightly leaky based on previous water vapor tests; these were flasks  
1131 that previously performed poorly, but did not ‘fail’ during the water vapor test. Once we  
1132 collected the data, we compared the data for flasks six and eight relative to other flasks  
1133 in the sequence. During the measurement of flask eight, we observed condensation in the sample  
1134 introduction lines, and because the isotope values were so different relative to other flasks, we  
1135 felt confident in our exclusion of flask eight. Flask six, had oxygen  $\delta^{18}\text{O}$  and hydrogen isotope  
1136  $\delta^2\text{H}$  values similar to others from the same sampling source, and seemed to fall within the pattern  
1137 as expected. Therefore, we chose to keep this data point in the dataset.  
1138 We hypothesize that one major problem with the mock field test dataset was the creation  
1139 of condensation in the sampling lines, as others have experienced in their setups (e.g. Quade et  
1140 al., 2019; Kühnhammer et al., 2019). Of particular interest are the flasks that had a lower than  
1141 expected oxygen isotope  $\delta^{18}\text{O}$  value (flasks four and nine).  
1142 It is possible that those samples were also affected by condensation, but in contrast to flask eight,  
1143 which was excluded because of condensation during measurement, we think that these samples  
1144 may have been altered because of condensation at the sampling stage. During condensation, we  
1145 expect that  $^{18}\text{O}$  will preferentially enter the liquid phase, and that the water vapor that enters the

1146 flask will have a lower than expected  $\delta^{18}\text{O}$  value. The unique advantage of the SWISS is that it  
1147 can operate independently, but with that comes the trade-off that ~~it may~~ we cannot currently be  
1148 possible to identify observe condensation in the lines as it is happening during sample collection.  
1149 To prevent condensation from forming, other users have warmed the impermeable tubing  
1150 between the probes and the Picarro. The ‘mock’ field test data suggest that in many situations it  
1151 may be worthwhile to warm the transfer tubing, but this should be done in a way that does not  
1152 alter the thermal structure of the soil, and in remote settings, can operate safely independently.

#### 1153 **6.1.4 Lessons learned and recommendations from the QA/QC and field suitability tests:**

1154 Our QA/QC process was a relatively efficient way to test the soundness of the SWISS  
1155 units. Through the QA/QC process we were able to identify problems with units, and  
1156 appropriately address them before deploying units to the field. We strongly recommend that any  
1157 user deploying SWISS to the field to undertake the same, or similar, QA/QC process.

1158 The dry air test is a time-efficient and low-cost method for identifying flasks that are  
1159 leaky and will not preserve the sampled water vapor isotope values. It is useful during the  
1160 building stage to identify fittings that need to be tightened or flasks that need to be replaced, and  
1161 therefore we recommend these tests as a required step prior to field pre-deployment step for  
1162 future SWISS units. We found that it was most time and energy efficient to move onto the next  
1163 level of QA/QC once 13 out of 15 flasks of a SWISS unit had passed the dry-air test, because  
1164 frequently the remaining two flasks still had relatively low water vapor mole fractions (i.e. 500 –  
1165 700 ppm), and we could sufficiently tighten the fittings prior to the start of the water vapor tests  
1166 for them to be successful. The dry air test is a low time and expense burden that it can also be  
1167 used to monitor SWISS units for normal wear-and-tear (e.g. a flask that cracked during transport)  
1168 during deployment periods. Therefore, to ensure that SWISS units continue to operate as  
1169 expected, we also recommend that dry air tests be done between field deployments on every  
1170 SWISS unit. Lastly, we note that ~~it~~ therefore we recommend these tests as a required step prior to  
1171 field deployment of future SWISS units. For example, supplemental figure 4 shows that it is  
1172 possible to drastically reduce the water vapor mole fraction in a flask filled with dry air between  
1173 tests by tightening and/or replacing problematic fittings (both those attached to the glass flasks  
1174 and those on the valve) and in some cases the glass flask itself. This shows we can reduce  
1175 the leakiness of the flasks. The dry air test is also an easy baseline test that also allowed us to test  
1176 building materials. For example, in supplemental figure 5, we tested using PTFE swagelok  
1177 fittings with  $\frac{1}{4}$ " PTFE tubing rather than stainless steel. These materials would be advantageous  
1178 because they are much easier to install and are significantly lighter. We found that these fittings  
1179 and tubing may be sufficient to store water for up to a single week, but on longer timescales (e.g.  
1180 27 days) we observed greater exchange and leaking than the stainless steel. We encourage any  
1181 future user using this modification to rigorously test these fittings on a timescale appropriate for  
1182 their application. ~~he~~ dry air test could be modified based on available equipment (for example, if  
1183 an instrument is available to measure trace atmospheric gases, that could be used instead).

1184 Based on the results of the long, field dry air test, we recommend that the water vapor  
1185 storage time doesn't exceed 40 days for reliable results, or that the user undertake multiple dry  
1186 air tests with either lower concentration benchmarks or longer duration -if deployments may  
1187 exceed 40 days.

1191 From the water vapor tests, we get a sense of the accuracy and precision of the SWISS.  
1192 The calculated uncertainty of the flasks (0.9‰ and 3.7‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively) is  
1193 somewhat larger than the uncertainty associated just with the use of the water vapor probes  
1194 (0.5‰ and 2.4 ‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively, Oerter et al., 2016), but is sufficient for many  
1195 critical zone applications, given the magnitude of seasonal variability that can be observed in  
1196 natural systems (e.g. Oerter et al., 2017; Quade et al., 2019).

1197 We opted to use a large flask volume because it allows us to measure a sample for long  
1198 enough on a CRDS that we get reliable data, without interacting with vapor bound to the flask  
1199 walls. The drawback of this, however, is that we must sample soil water vapor for a relatively  
1200 long period of time (45 minutes). In supplemental figure 6, we show that the sampling regime,  
1201 and particularly the length of time we pump dry air through the tubing, does not significantly  
1202 alter the soil moisture content of the soil. Additionally, we demonstrate that the sampling regime  
1203 we use does not introduce significant memory effects.

1204 Based on the results of the long, field dry air test, we recommend that the water vapor  
1205 storage time doesn't exceed 40 days for reliable results, or that the user undertake multiple dry  
1206 air tests with lower concentration benchmarks if deployments may exceed 40 days.

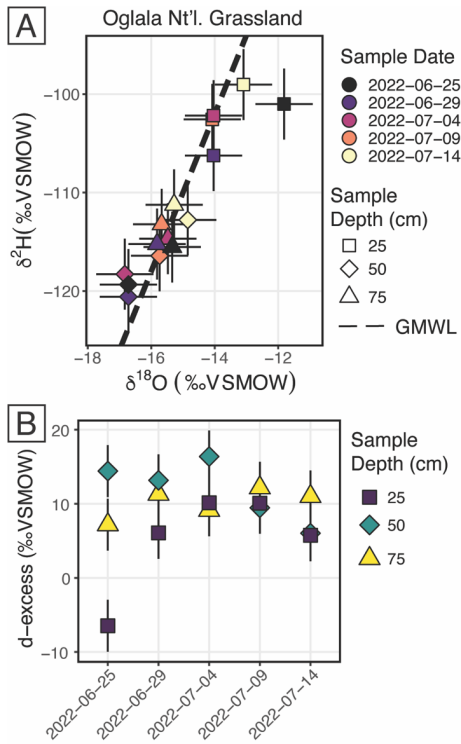

1207 Overall, the quality control and quality assurance as well as the field suitability tests the  
1208 field suitability tests demonstrate that the SWISS units are able to faithfully can retain the isotope  
1209 values of water vapor collected using water vapor permeable probes. Like many other systems  
1210 that measure dual isotopes, each system (i.e.  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ ) must be evaluated separately. In  
1211 general, we interpret oxygen isotope data with a higher degree of confidence than the hydrogen  
1212 isotope data. As the automation test revealed however, even when the absolute  $\delta^2\text{H}$  value is not  
1213 correct, the general pattern can reveal information about soil water dynamics.

1214 Finally, we opted to use a large flask volume because it allows us to measure a sample  
1215 for long enough on a CRDS that we get reliable data, without interacting with vapor bound to the  
1216 flask walls. The drawback of this, however, is that we must sample soil water vapor for a  
1217 relatively long period of time (45 minutes). In supplemental figure 7, we show that the sampling  
1218 regime, and particularly the length of time we pump dry air through the tubing, does not  
1219 significantly alter the soil moisture content of the soil. Additionally, we demonstrate that the  
1220 sampling regime we use does not introduce significant memory effects.

1221 One particular challenge with the vapor permeable probes, that others have noted, is  
1222 condensation in any portion of the system (e.g. Quade et al., 2019; Kühnhammer et al., 2019).  
1223 As much as possible, it is helpful to have the impermeable tubing at warmer temperatures than  
1224 the soil or water it is sampling. In many situations it may be worthwhile to warm the transfer  
1225 tubing, but this should be done in a way that does not alter the thermal structure of the soil, and  
1226 in remote settings, can operate safely independently. Additionally, taking care to ensure that the  
1227 SWISS is evenly and lightly warmed in the lab setting helps to prevent condensation from  
1228 forming in the stainless steel tubing and Valeo valve.

## 1230 6.2 Field Deployments

1231 In Figure 7 we show the results of three field deployments completed during summer  
1232 2022 (Table 3). At the Oglala National Grassland site, we used the SWISS unit named Lindt to  
1233 collect samples. During the August 2022 water vapor test on Lindt, all of all the oxygen isotope  
1234  $\delta^{18}\text{O}$  values fall within uncertainty of the system, and nine of the fifteen flasks hydrogen isotope  
1235  $\delta^2\text{H}$  values fall within uncertainty of the system. Therefore, we interpret the  $\delta^{18}\text{O}$  values with a  
1236 higher greater amount of confidence and the  $\delta^2\text{H}$  values with a lower amount of confidence (Figs.

4C and 5C). We note that most of the  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values broadly follow the same trends, and fall on the global meteoric water line (Figs. 7 and 8A). In general, soil water from 25 cm had higher  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values than soil water from both 50 and 75 cm (Fig. 8A). Given that 4 of the 5 samples from 25 cm overlap with the GMWL and have a d-excess that overlaps within error of  $10 \pm 2.6\%$ , the soil water from that depth may reflect summer precipitation with higher  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values. Soil water from 75 cm had intermediate  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values for most of the study period, and soil water from 50 cm depth had the lowest  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values for most of the study period, which may reflect a more mean-annual or winter precipitation biased value. The d-excess value of soil water collected from 75 cm is centered around a global meteoric water line value of 10‰ (Fig. 8B). Based on data available from the National Weather Service (Chadron, NE), there were likely significant precipitation events on 2022-06-25 and 2022-07-08 at the field site. There is a significant shift to lower  $\delta^{18}\text{O}$  values at a sampling depth of 25 cm between 2022-06-25 and 2022-06-29, as well as a marked increase in the d-excess value (Fig. 8A). We interpret

1265 this shift as infiltration of precipitation with lower  $\delta^{18}\text{O}$  values, and which is supported by a  
 1266 return of d-excess values to  $\sim 10\%$  (Fig. 8A). The National Weather Service reported 21.33 mm  
 1267 (0.84 inches) 0.84 inches of rain at Chadron Municipal Airport, approximately 50 km from the  
 1268 study site on 2022-07-08, which likely was associated with at least some precipitation at our field  
 1269 site. Following the significant rain event on 2022-07-08, we observe a marked increase in the  
 1270 stable isotope value of water vapor from a sampling depth of 50 cm, towards values that are  
 1271 much closer to those at 25 cm depth. These data suggests that soil water isotopes at 50 cm in this  
 1272 silt-loam Aridisol may be fairly sensitive to large individual precipitation events, while at 75 cm  
 1273 soil water isotopes remain comparatively uniform. Future work should address how drought  
 1274 conditions, storm size, pore size distribution, and soil clay mineralogy influence the variability of  
 1275 soil water isotopes with depth. This indicates that after a large precipitation event, there is  
 1276 mixing and the creation of a far more uniform soil water isotope profile to a depth of 50 cm, but  
 1277 at the depth of 75 cm, the oxygen isotope data remain fairly uniform across the sampling period.

Figure 8. Results from the Oglala National Grassland, NE field site. A)  $\delta^2\text{H}$  vs.  $\delta^{18}\text{O}$ , where the dashed line is the global meteoric water line. The shape of the depth sampled matches figure 7, and the color of the points is the date on which the soil water was sampled B) A plot of d-excess. Note, both the color and shape match figure 7.

At Briggsdale, CO we used the SWISS named Raclette to collect soil water vapor samples. Data from 25 cm depth at Briggsdale, CO were discarded because the water vapor mole fraction was much lower than would be expected given the soil temperature (i.e. < 15,000 ppm). The gravimetric water concentration at that soil depth at the time of sampling was approximately 4% through the sampling period. Given the low water concentration, it is possible that there was simply not enough water vapor to sufficiently sample. Data from 25 cm depth at Briggsdale, CO were discarded because the water vapor mole fraction was much lower than would be expected given the soil temperature (i.e. < 15,000 ppm). The gravimetric water concentration (GWC) at that soil depth at the time of sampling was approximately 4% through the sampling period. Future work should include a multiple-method (e.g. cryogenic extraction, centrifugation, etc.) comparison of soil water isotopes at low water contents to better understand what these samples might represent, and if they are actually representative of soil conditions.

Based on the results of the August 2022 water vapor test done on Raclette where all flasks fell within uncertainty of the SWISS system for both  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , except for flask 11 (Figs. 4C and 5C), which corresponds to the 25 cm depth sample from 2022-07-27, we interpret all of the data with a higher level of greater confidence. This sample Flask 11 corresponds to the 25 cm depth sample from 2022-07-27, and was already removed/culled from the dataset because of low water vapor mole fraction associated with the very dry soil. The soil water  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values from a sampling depth of 50 cm and 75 cm overlap within uncertainty, but the soil water  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values from 50 cm have a higher isotopic value are higher than the samples/isotope values from 75 cm. All of the data from within each sampling depth group (i.e. 50 cm and 75 cm) overlap within uncertainty, conforming to the expectation that soil water from these sampling depths should be fairly invariant (e.g. Oerter et al., 20197). There were precipitation events at the study site on 2022-07-24, 2022-07-28 and 2022-07-31. It is possible that the slight negative shift in both  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  on 2022-08-01 reflects infiltration of precipitation to those depths, but this is not certain given that all of the measurements from within a sampling depth overlap within uncertainty.

1329 At Seibert, CO we used the SWISS named Toblerone to collect soil water vapor samples.  
1330 The soil water isotope data from 75 cm depth at this site offer a few useful lessons for future  
1331 users. The two first most basic key observations of the data from 75 cm depth are that ~~is that for~~  
1332 ~~the first two samples, the isotope values are unreasonably high (i.e. have~~  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values are  
1333 ~~much higher than the other two sampling depths d~~ ~~oxygen isotope values), and that the hydrogen~~  
1334  ~~$\delta^2\text{H}$  and oxygen isotope~~  $\delta^{18}\text{O}$  values do not move in parallel with each other. While measuring  
1335 these samples we observed condensation in the impermeable tubing at the point where the  
1336 SWISS connects to the impermeable tubing. Additionally, when we heated the stainless steel  
1337 tubing that connects the tubing flask and Valco valve we observed a rapid increase in water  
1338 vapor mole fraction (1000's of ppm over <30 seconds) that was accompanied by a rise in stable  
1339 isotope value. During these measurements, we were rarely able to get a stable isotope value  
1340 measurement window, and instead the stable isotope value of the vapor increased continually  
1341 through the measurement. It is for these reasons that we feel confident in discarding the stable  
1342 isotope data from 2022-06-19 – 2022-06-29. The final measurement from 75 cm depth on 2022-  
1343 07-04 approaches a reasonable isotope value when compared to isotope values from the other  
1344 two depths, and that sample had far fewer condensation problems during measurement.  
1345 However, ~~but~~ because we have no sequential context for what a reasonable value for this depth  
1346 is, we ~~have chosen to discarded~~ ~~discard~~ that value as well. For that final 75 cm sample, we were  
1347 more successful because we warmed the entire length the vapor impermeable tubing, as well as  
1348 the stainless-steel tubing, flask, and Valco valve evenly so that there were no temperature  
1349 gradients across the vapor path. If the condensation had only been in the impermeable tubing it  
1350 would have been much easier to 'rescue' successfully analyze these samples by just closing off  
1351 the flask and running dry air through the tubing to remove condensation, but because  
1352 condensation was also occurring in the stainless steel tubing between the flask and Valco valve,  
1353 it became much more challenging to 'rescue' samples this was not possible. It remains unclear  
1354 why condensation was such a significant problem for samples from that depth as opposed to  
1355 samples from different depths in the same SWISS. Future work should include further testing of  
1356 the SWISS across different water contents and temperatures to better understand why the  
1357 phenomenon may have occurred.

1358 Data from 75 cm depth at Seibert, CO were discarded because of evidence of  
1359 condensation during the measurement of the flasks associated with that sampling depth. Based  
1360 on the results of the August 2022 water vapor test done on Toblerone, we interpret all ~~of the~~ data  
1361 from 50 cm and 25 cm depth with a high degree of high confidence, except for Flask 3, which is  
1362 the 50 cm sample from 2022-06-19 (Figs. 4C and 5C). Unlike data from the other two field sites,  
1363 soil water from 25 cm and 50 cm overlap within uncertainty. There were two precipitation events  
1364 at the field site during the sampling period on 2022-06-25 and 2022-07-01, but both events were  
1365 quite small (<0.50-0.02 inches mm, CoAgMet). There is no significant influence of the  
1366 precipitation events on the  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values. The >1.0‰ increase in  $\delta^{18}\text{O}$  values on 2022-06-  
1367 29 is surprising given that there is not a comparable magnitude increase in  $\delta^2\text{H}$  value, and that  
1368 the values measured from 2022-07-04 more closely match the  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values from the two  
1369 earlier sampling days. There are two potential explanations for this data. First, that ~~this shift~~ is a  
1370 real signal from an evaporation driven increase in the  $\delta^{18}\text{O}$  value, and the ~~reset~~ ~~shift back~~ to a  
1371 lighter ~~lower~~  $\delta^{18}\text{O}$  value on 2022-07-04 is due to the infiltration of precipitation. ~~A different way~~  
1372 ~~to see this is through the~~ This explanation is corroborated by a, which could also explain the ~~low~~  
1373 ~~d-excess~~ value associated with this measurement (Supplemental Fig. S1 8-9). The second  
1374 possible explanation is that the 25 cm sample from 2022-06-29 is influenced by condensation at

1375 the time of sampling. Dew point at the field site on 2022-06-29 significantly decreased as  
1376 compared to the other sampling days to a monthly minimum of 20.6°C (CoAgMet). It is possible  
1377 that environmental conditions encouraged the formation of condensation in the impermeable  
1378 tubing at the time of sampling. There were no obvious signs of condensation during the time of  
1379 measurement in the lab. These results highlight the utility of having broad contextual  
1380 environmental data to aid in the interpretation of soil water isotope data.

1381 All together, these three soil water isotope datasets demonstrate two main findings. First,  
1382 data from these samples show that the differences between field sites isare easily resolvable  
1383 using the SWISS. For example, at 50 cm depth the oxygen isotopes range between -14.4 to -  
1384 16.3‰, -9.9 to -10.3‰, and -7.4 to -9.3‰ for the Oglala, Briggsdale and Seibert sites,  
1385 respectively. These differences likely reflect differences in the stable isotope composition of  
1386 precipitation and infiltration and evaporation dynamics. Second, the sample data retrieved from a  
1387 SWISS are sufficiently precise to be able to meaningfully resolve vertical profile soil water  
1388 isotope data. For example, at the Oglala National Grassland field site, soil water from 25 cm  
1389 clearly has higher  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values as compared to soil water from a depth of 50 and 75 cm.  
1390

1391

### 1392 **6.3 Future improvements and future work**

1393 One significant SWISS unit hardware improvement that could be made would be to  
1394 install a heating implement to the flasks. One source of uncertainty on the current system is the  
1395 potential effect of uneven heating of the flasks prior to measurement which may create  
1396 temperature gradients that are large enough to allow for condensation when warm vapor meets a  
1397 slightly colder spot. This could be improved in subsequent iterations of the SWISS with the  
1398 addition of heat tape or blankets that can deliver controlled heat and create consistent amounts of  
1399 heattemperatures. This improvement would also help limit the amount of manual intervention  
1400 needed during measurement, and could improve automation of flask measurement. Additionally,  
1401 finding a way to safely and automatically heat the impermeable tubing that connects the water  
1402 vapor probes and the SWISS in a way that doesn't change the inherent thermal structure of the  
1403 soil, and is safe for unmonitored use, would help to prevent the formation of condensation in the  
1404 field and reduce limit the number of uncertainties on related to measurementssampling.

1405 In addition,

1406 -We have made a few improvements to the automation system that were not  
1407 implemented for the data presented in this contribution, but will be part of future deployments.  
1408 First, we will track conditions inside the SWISS with a temperature and relative humidity sensor  
1409 inside the case. Second, we plan to eliminate the power inverter by powering both the Valco  
1410 valve and mass flow controller with VDC using a power step up controller. Lastly, we will add  
1411 an IoT cellular router to be able to remotely monitor and control the SWISS units. This would be  
1412 particularly helpful if there is a sampling day that is unexpectedly cold or when the dew point at  
1413 the field site is unexpectedly low and we expect condensation to form more readily form in the  
1414 field, or if there is a precipitation event that we are really interested in capturing, because with  
1415 the IoT cellular router we could remotely alter the sampling plan.

1416 While the improvements and additional testing we have done to the SWISS in this  
1417 contribution represent a significant step forward, additional work should be done to make the  
1418 system more useable by the ecohydrology community. We have rigorously tested the SWISS in  
1419 the lab, and demonstrated a few ways in which the SWISS can fail in field settings. A full  
1420 comparison of how soil water isotope data collected using a SWISS as compared to other in situ

1421 (~~both vapor probes and lysimeter~~) and destructive sampling methods would shed light on the  
1422 accuracy and precision of our system, and the applicability of our lab-based experiments to the  
1423 field. These experiments should be carefully designed ~~to take~~with considerations of soil grain  
1424 size, soil water content, expected isotope values, and climate. Finally, there are two future  
1425 considerations for field deployments. The first is finding a way to safely and automatically heat  
1426 the impermeable tubing that connects the water vapor probes and the SWISS in a way that  
1427 doesn't change the inherent thermal structure of the soil, and is safe for unmonitored use.  
1428 Additionally, we plan to test SWISS unit resilience during air travel so that these units can be  
1429 used at field sites that are not within driving distance of a research facility.

## 1430 Conclusions

1431 We presented the evolution of the soil water isotope storage system (SWISS) from a  
1432 prototype to a fully built out and tested system. We also presented a quality control and quality  
1433 assurance procedure that ~~we strongly recommend future users undertake can be used~~ to ensure  
1434 the reliable storage of soil water vapor over long time periods (up to 40 days). In addition, these  
1435 quality control and quality assurance tests shed light on the accuracy and precision of the  
1436 SWISS. After applying an offset correction, we determine the ~~overall~~ precision of the SWISS to  
1437 be  $\pm 0.9\%$  and  $3 \pm 3.7\%$  for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively. In a field setting, flasks reliably resist  
1438 atmospheric intrusion. Additionally, the proposed sampling schema does not introduce  
1439 significant memory effects. Lastly, we demonstrate that the ~~current~~ precision of the SWISS still  
1440 allows us to distinguish between field sites and between soil water dynamics within a single soil  
1441 column. Taken as a whole, these data show that the SWISS can be used as a tool to answer many  
1442 emerging ecohydrological questions, and will enhance researchers' ability to collect soil water  
1443 isotope datasets from more remote and traditionally understudied field sites.

## 1444 Acknowledgements

1445 We thank the numerous field assistants who helped to make the field work presented in  
1446 this paper possible, including Spencer Burns, Anne Fetrow, Sarah Brookins, Juliana Olsen-  
1447 Valdez, and Haley Brumberger. We acknowledge that both field work and laboratory work for  
1448 this study ~~was~~ere done on the traditional territories and ancestral homelands of the Arapahoe,  
1449 Ute and Cheyenne peoples. This work was supported by startup funding from CU Boulder and  
1450 NSF funding from grant EAR-2023385 awarded to K. Snell. Additionally, this work was  
1451 supported by the University of Colorado Boulder Beverly Sears Research Grant and the Clay  
1452 Minerals Society Graduate Student Research Grant both awarded to R. Havranek. CUBES-SIL  
1453 is a CU Boulder Core Facility associated with RRID: SCR\_019300.
