10 **Abstract.** Soil water isotope datasets are useful for understanding connections between the hydrosphere,
11 atmosphere, biosphere, and geosphere. However, they have been underproduced because of technical challenges
12 associated with collecting those datasets. Here, we present the full testing and automation of the Soil Water Isotope
13 Storage System (SWISS). The unique innovation of the SWISS is that we are able to automatically collect water
14 vapor from the critical zone at a regular time interval and then store that water vapor until it can be measured back in
15 a laboratory setting. Through a series of quality assurance and quality control tests, we rigorously tested that the
16 SWISS is resistant to both atmospheric intrusion and leaking in both laboratory and field settings. We assessed the
17 accuracy and precision of the SWISS through a series of experiments where water vapor of known composition was
18 introduced into the flasks, stored for 14 days, and then measured. From these experiments, after applying an offset
19 correction, we assess the precision of the SWISS at 0.9‰ and 3.7‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively. We deployed
20 three SWISS units to three different field sites to demonstrate that the SWISS stores water vapor reliably enough
21 that we are able to differentiate dynamics both between the sites as well within a single soil column. Overall, we
22 demonstrate that the SWISS is able to faithfully retain the stable isotope composition of soil water vapor for long
23 enough to allow researchers to address a wide range of ecohydrologic questions.

24 **1 Introduction**

25 Understanding soil water dynamics across a range of environments and soil properties is critical to food
26 and water security (e.g. Mahindawansa et al., 2018; Quade et al., 2019; Rothfuss et al., 2021); understanding
27 biogeochemical cycles, such as the the nitrogen and phosphorus cycles (e.g. Hinckley et al., 2014; Harms and
28 Ludwig, 2016); and understanding connections between the hydrosphere, biosphere, geosphere and atmosphere (e.g.
29 Vereeken et al., 2022). One approach that can be used to understand water use and movement in the critical zone is
30 the stable isotope geochemistry of soil water (e.g. Sprenger et al., 2016; Bowen et al., 2019). Variations in the stable
31 isotope ratios of oxygen and hydrogen of soil water ($\delta^{18}\text{O}$, $\delta^2\text{H}$) track physical processes like infiltration, root uptake

32 and evaporation. In particular, stable water isotopes are useful for disentangling complex mixtures of water from
33 multiple sources (e.g. Dawson and Ehleringer, 1991; Brooks et al., 2010; Soderberg et al., 2012; Good et al., 2015;
34 Bowen et al., 2018; Gomez-Navarro et al., 2019; Sprenger and Allen 2020). Despite the long-recognized utility of
35 measuring soil water isotopes for understanding a range of processes (e.g. Zimmerman et al., 1966; Peterson & Fry.,
36 1987), soil water isotope datasets have been under-produced as compared to groundwater and meteoric water
37 isotope datasets (Bowen et al., 2019).

38 The primary barrier to producing soil water isotope datasets has been the arduous nature of collecting
39 samples. Traditionally, soil water samples are taken by digging a pit, and collecting a mass of soil to bring back to
40 the lab for subsequent water extraction, disrupting the soil profile each time a sample is collected. To circumvent
41 issues related to this style of sampling, the ecohydrology community has developed a variety of in situ water
42 sampling methods over the last 10 years (e.g. Rothfuss et al., 2013; Volkmann and Weiler, 2014; Gaj et al., 2015;
43 Oerter et al., 2016; Beyer et al., 2020). These methods have helped to shed light on a range of ecohydrologic
44 questions from evaporation and water use dynamics in managed soils (e.g. Oerter et al., 2017; Quade et al., 2019) to
45 better understanding where plants and trees source their water (e.g. Beyer et al., 2020).

46 The expansion in situ sampling methods allows for a greater understanding of ecohydrologic dynamics
47 temporally, but with current methods these studies are often done in close proximity to the institutions performing
48 the studies because of logistical constraints. The spatial constraints limit what we can learn about soil hydrology in
49 remote and traditionally understudied landscapes. Beyond the ecohydrology community, the creation of high
50 temporal resolution soil water isotope data sets is useful to a broader set of stakeholders. For example, long-term
51 temporal records of soil water can be used to better understand geologic proxy development (e.g. stable isotope
52 records from pedogenic carbonate, br-GDGTs, etc.). These projects, however, commonly have environmental
53 constraints like soil type or local climate state that may not be located near institutions performing those studies,
54 creating the need for a system that is capable of collecting water vapor from remote settings in an automated way.

55 In this contribution, we report on the further development and testing of a field deployable system first
56 introduced in Havranek et al., (2020). This system is now capable of independently sampling soil water vapor in
57 situ, storing that water vapor for a period of time until the samples can be brought back to a laboratory to be
58 measured. In our case, we used a Picarro L-2130i water isotope analyzer (Picarro, Inc. Santa Clara, CA) to measure
59 both water concentration and the oxygen and hydrogen isotope ratios of the soil water vapor. The combination of the
60 autonomous sampler and the CRDS instrument offers a flexible and reliable solution to obtain data that is otherwise
61 difficult to collect from soil profiles. Here, we present the testing and optimization of the Soil Water Isotope Storage
62 System (SWISS). First, we present a quality assurance and quality control (QA/QC) procedure that we strongly
63 recommend any future user to complete prior to deploying this kind of system for either a field or lab experiment.
64 Second, we demonstrate the viability of this system under field-conditions through two field suitability experiments.
65 Lastly, we sampled three different field sites to show that the automation schema works on a monthly timescale and
66 that the system preserves soil water vapor isotopes signals with sufficient precision to distinguish between three
67 different field settings and vertical profile differences.

68 **2 Background**

69 In recent years, a number of technical innovations have made it easier to sample and measure soil water for
70 stable isotope analysis. Advances in laser-based instrumentation (e.g. cavity ring-down spectroscopy, CRDS) have
71 made high throughput, high precision measurements of both water concentration and water stable isotopes possible.
72 Field deployments with laser-based instruments are technically possible and have been conducted successfully (e.g.
73 Oerter et al., 2017; Quade et al., 2019; Künhammer et al., 2021), but require uninterrupted AC power, adequate
74 shelter as well as safe and stable operating environments for best results. These prerequisites are not often available
75 at most field sites, especially in more remote locations and for longer sampling time frames.

76 Second, the testing and adoption of vapor permeable tubing provides a way to sample soil water vapor with
77 minimal disturbance to the soil profile (e.g. Rothfuss et al., 2013; Quade et al., 2018; Oerter and Bowen, 2019;
78 Beyer et al., 2020; Kubert et al., 2020). This method works by flushing dry nitrogen (or dry air) through the vapor
79 permeable membrane (Accurell PP V8/2HF, 3M, Germany), creating a water vapor gradient from inside the probe
80 to the soil, thus inducing water vapor movement across the membrane. Water vapor is then entrained in the dry
81 nitrogen and flushed to either a CRDS system or into a storage container. The adoption of vapor permeable tubing
82 has been a large step forward for the ecohydrology community, and opened the possibility of creating long-term soil
83 water stable isotope records, particularly when paired with measurement in the field by spectroscopic instruments.
84 While this application is a major advancement, it has many practical limitations for remote field sites, therefore, we
85 aimed to develop a system, termed the SWISS, that is capable of independently collecting samples and can then
86 store those samples for a period of time before being returned to the lab for analysis.

87

88 **2.1 Soil Water Isotope Storage System details and previous work**

89 The Soil Water Isotope Storage System (SWISS) uses three basic components for water vapor storage of
90 multiple samples: glass flasks, stainless steel tubing and a flask selector valve (Fig. 1, Supplementary Table 1). The
91 ability of the SWISS to reliably store water vapor for up to 30 days was demonstrated previously using a series of
92 lab experiments (Havranek et al., 2020). This proof of concept demonstrated that the flasks retain original water
93 isotope values, but the laboratory system was not field deployable or have customizable automation. Here, we
94 present a fully autonomous, field-ready system that has been thoroughly tested under both laboratory conditions and
95 field conditions, including development and testing of a solar-powered, battery backed automation system that
96 enables pre-scheduled water vapor sampling without manual intervention in remote field locations.

97

98 **2.2 Field Sites:**

99 **2.2.1 Site Set-Up**

100 In figure 1 we show the field-setup employed at all of our field sites. At each site we dug two holes. One
101 hole is instrumented with soil moisture and temperature data loggers at 25 cm, 50 cm, 75 cm, and 100 cm depths, as
102 well as the water vapor permeable probes at 25 cm, 50 cm and 75 cm depths (Fig 1A). All probes were deployed >9
103 months before the first samples were collected to allow the soil to settle and return to natural conditions as much as
104 possible. During probe deployment we took care to retain the original soil horizon sequence and horizon depths as
105

106

107 **Figure 1. A)** The sampling flow path. To sample soil water, dry nitrogen is regulated at a specific rate using a mass flow
 108 controller, and then directed to one of the three sampling depths, or the soil bypass loop using a set of solenoid valves.
 109 Both the mass flow controller and solenoid valves are housed inside the SWISS. Once directed to the correct sampling
 110 depth, dry nitrogen is carried to the vapor permeable probes via gas impermeable tubing that is buried approximately 15
 111 cm depth. After passing through the vapor permeable probe, the entrained soil water vapor is carried back to the SWISS
 112 where it is directed to the correct flask using a Valco multiselector valve. **B)** Photos of a built-out SWISS and the layout of
 113 a field site. Each of the system components (i.e. solar panel, battery, N₂ tank, SWISS, PVC tube) are labeled, in addition
 114 to the location of the instrumented hole in which all of the probes are buried. The hole which houses the SWISS, power,
 115 and N₂ tank is approximately 1.5 m wide.

116
117 much as possible. The second hole is where the SWISS unit, dry nitrogen tank, and associated components to power
118 the SWISS are stored (Fig 1B). The water vapor probes, which connect to the SWISS with Bev-A-Line impermeable
119 tubing, are run through a PVC pipe buried at approximately 15 cm depth. We chose to run the impermeable tubing
120 to the SWISS underground to limit the effect of diurnal temperature variability on the impermeable tubing, so as to
121 limit condensation as water travels from the relatively warm soil to the SWISS.

122

123 **2.2.2 Site description**

124 We deployed the SWISS at three field locations: Oglala National Grassland, Nebraska, USA; Briggsdale,
125 Colorado, USA; and Seibert, Colorado, USA.

126 The Oglala National Grassland site (Lat: 42.9600/Long: -103.5979/elev: 1117 m) is located in
127 northwestern Nebraska, USA in a cold semi-arid climate. The soil at this site is described as an aridisol with a silt-
128 loam texture. It is part of the Olney series (Natural Resources Conservation Service, 2022).

129 The Briggsdale site (Lat: 40.5947/Long: -104.3190/elev: 1480 m) is located in northeastern Colorado, USA
130 in a cold semi-arid climate. The soil at this site is described as an alfisol with a loamy sand - sandy loam texture. It is
131 part of the Olnest series (Natural Resources Conservation Service, 2022).

132 The Seibert site (Lat: 39.1187/Long: -102.9250/Elev: 1479 m) is located in eastern Colorado, USA in a
133 cold semi-arid climate. The soil at this site has been described as an alfisol, that has a sand loam texture in the top 50
134 cm of the profile, and a silt loam texture between 50 - 100 cm. It is part of the Stoneham series (Natural Resources
135 Conservation Service, 2022).

136 **3 Materials**

137 **3.1 SWISS Hardware components**

138 In each SWISS there are 15 custom made ~650 ml flasks. These flasks are designed similarly to those used
139 for other water vapor applications. For example, a similar flask is currently used in an unmanned aerial vehicle to
140 collect atmospheric water vapor samples for stable isotope analysis (Rozmiarek et al., 2021). The flasks have one
141 long inlet tube that extends into the flask almost to the base, and one shorter outlet tube so that vapor exiting the
142 flask is well mixed and representative of the whole flask (Fig. 1A). The large flask volume is advantageous because
143 there is a low glass surface area to volume ratio, and therefore we are able to reliably measure vapor from the flasks
144 on a CRDS instrument without interacting with vapor bound to the flask walls. The 15 glass flasks are connected to
145 a 16-port, multi-selector Valco valve. We chose to use a Valco valve because these have previously been shown to
146 sufficiently seal off sample volumes for subsequent stable isotope analysis (Theis et al., 2004). The valve and flasks
147 are connected by 1/8 inch stainless steel tubing and stainless steel 1/4 inch to 1/8 inch union Swagelok fittings; we use
148 PTFE ferrules on the glass flasks with the Swagelok fittings. The first port of the valco valve is 1/8th inch stainless
149 steel tubing that serves as a flask bypass loop, which enables flushing of either dry air or water vapor through the
150 system without interacting with a flask. All components are contained in a 61 cm x 61 cm x 61 cm Pelican case with

151 foam. This case is insulated, and provides enough protection to allow reliable transport of the SWISS by vehicle to
152 field sites.

153

154 **3.2 Soil Probes**

155 There are three components for the collection and interpretation of soil water vapor: vapor permeable
156 probes, soil temperature loggers, and soil moisture sensors (Fig 1B, Supp. Table 1). Here, we use a vapor permeable
157 membrane (ACCURELL PP V8/2HF, 3M, Germany) that was first tested by Rothfuss et al., (2013). We opted to
158 use this tubing because it has been shown to deliver reliable data over time (i.e. Rothfuss et al., 2015), and is easy to
159 use and customize to individual needs. We previously observed that variability in the length of the vapor permeable
160 tubing can lead to systematic offsets in the stable isotope composition of measured waters (Havranek et al., 2020).
161 Therefore, we were careful to construct all probes such that the length of the Accurrell vapor permeable tubing was
162 10 cm long, and the impermeable Bev-A-Line IV connected on each side of the vapor permeable tubing was 2 m
163 long. We also constructed the vapor permeable probes to be used in the lab setting for standards in an identical
164 fashion. Soil temperature loggers (Onset HOBO MX2201), used for applying a temperature correction to all soil
165 water vapor data, were buried at the same depths as the vapor permeable probes. Soil moisture sensors (Onset S-
166 SMD-M005) were also buried at the same depths as the vapor permeable probes.

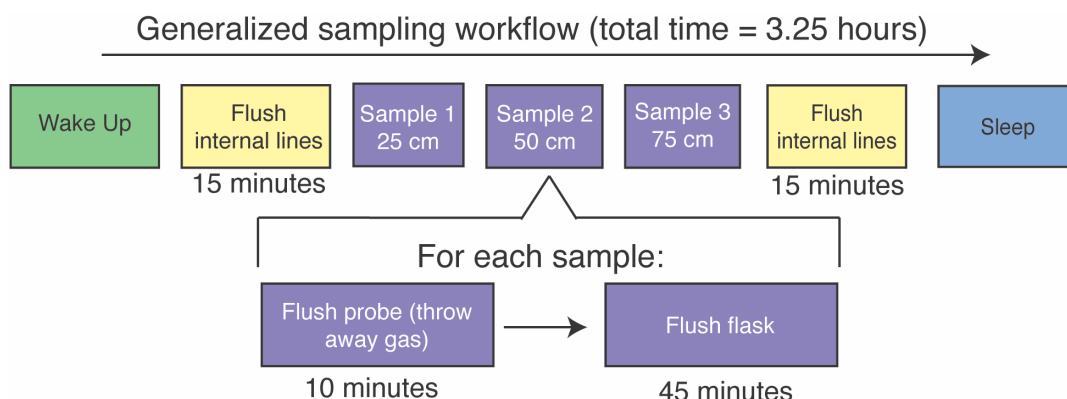

167

168 **3.3 Automation components, code style, and remote setting power**

169 The philosophy behind the automation of the SWISS was to make it as easy to reproduce as possible, and
170 as flexible as possible to meet different users' sampling needs. We therefore use widely available hardware
171 components and electronics parts; for each product there are numerous alternatives which should be equally viable
172 and could be swapped to better meet each user's needs. In an effort to make our system as accessible and
173 customizable as possible for the scientific community, all automation code is completely open source and will
174 continue to be refined for future applications and hardware improvements. We note that all code is provided as is
175 and should be tested carefully for use in other experiments.

176 The overall sampling scheme used in this paper is described in figure 2 and table 1. Our experimental goal
177 was to create a time series of soil water vapor data from three discrete sampling depths (25 cm, 50 cm, 75 cm). Prior
178 to sampling any soil water vapor, we flushed away any water vapor present in the lines within the SWISS prior to
179 flushing the sample loops. Then, at the start of sampling for each depth, we also flushed the water vapor probe to
180 remove condensation or 'old' water vapor. The gas from both of those steps was expelled via the flask bypass loop.
181 Each soil depth was then sampled for 45 minutes by flushing through the next flask designated in the sequence.

182 Supplement Figure SI 1 shows the components of the automation system. To automate and program the
183 sampling scheme, we used: (1) a microcontroller to run the automation script; (2) a coin-cell battery powered real
184 time clock so that the microcontroller was always capable of keeping track of time through power losses, and
185 therefore maintain the sampling schedule; (3) an RS-232 to TTL converter for serial communication with the Valco
186 valve; (4) solenoid valves that were used to control which depth was being sampled and the associated VDC power
187 relay; (5) a mass flow controller used to control the rate at which dry nitrogen (1 ppm H₂O) is flushed through the

188

191 Table 1. Description of soil water sampling steps

192

193 probes; and (6) a power relay used to power the Valco valve and mass flow controller. All parts are described in
 194 detail in Supplemental Table 2.

195 In a remote setting, the SWISS units are powered using the combination of a 12V deep-cycle battery and a
 196 12VDC, 100W solar panel that is used to charge the battery. The solar panel is mounted to a piece of plywood that
 197 covers the hole where the SWISS is deployed (note, the hole is uncovered in Fig. 1B for illustrative purposes). We
 198 opted for this setup because the underground storage of all parts of the system creates a discreet field site that
 199 attracts minimal attention from other land users. In the field, we used a 12VDC-120VAC power inverter to provide
 200 simple plug and play power for the Valco valve and mass flow controller. This simple combination was suitable for
 201 summertime in the Western U.S. where there are a great number of sunny hours, and the solar panel was able to
 202 easily charge the 12V battery. This setup may need to be adjusted based on location and desired sampling time. Like
 203 the automation system, there are many commercial options available for products, and they can be easily adjusted
 204 for users' needs; example parts are described in detail in Supplemental Table 2. We also note that in areas where it is
 205 possible to plug into a power grid, the deep cycle battery, solar panel and power inverter can be removed.

206

207 **4 Methods**

208 **4.1 QA/QC: Testing the SWISS under lab conditions**

209 The highest order concern for the SWISS is that it remains leak-free because any leaks introduce potential
210 for fractionation or mixing of atmosphere that would alter the stable isotope ratio of the water vapor in the flask. So,
211 we developed a three-part quality assurance and quality control (QA/QC) procedure that must be completed for each
212 new SWISS prior to the first deployment. The first step detects any significant leaks using helium detection
213 methods; the second step is to perform a dry air test to detect medium scale leaks; and the third step is to perform a
214 water vapor test to detect slow leaks. Below, we quickly summarize each of these QA/QC steps. Full procedural
215 descriptions are available in supplementary material and the data processing code is available via github.

216

217 **4.1.1 Step 1: using helium to detect large scale leaks**

218 After initial assembly of the SWISS plumbing, we filled the flasks with helium and used a helium leak
219 detector to find large leaks. Typically, the kinds of leaks we were able to detect with this method were due to
220 cracking of the inlet or outlet on the glass flask that occurred while tightening the swagelok fittings. Another easy
221 alternative is to complete a short dry air test (described below) that requires on the order of 12-24 hours.

222

223 **4.1.2 Step 2: dry air tests detect medium scale leaks**

224 Once we felt sure that there were no major leaks in our systems, we completed a dry air test. The goal of
225 this test was to catch any second order, medium-scale leaks. Typically, this test found swagelok fittings that had
226 been under tightened. The advantage of this kind of test is that it is easy and quick to complete. This test started with
227 a dry air fill. A *dry air fill* consists of flushing flasks with air that is filtered through drierite (which has a water
228 vapor mole fraction of less than 500 ppm), at 2 L/min for 5 minutes. With a flask volume of 650 ml, this means the
229 volume of the flask is turned over 15 times. Flasks were then sealed and left to sit for seven days.

230 At the end of the seven-day period we measured each flask using the *dead-end pull sample introduction*
231 (note, italicized terms are specific methods, and are explained in greater detail in supplementary material) method on
232 a Picarro L2130-*i* Isotope and Gas Concentration Analyzer. For this sample introduction method, the inlet to the
233 valco valve was sealed with a ¼" swagelok cap and there was no introduction of a carrier gas. As a result, air was
234 removed from the flask based on the flow rate of the Picarro CRDS (typically 27 - 31 ml/min).

235 We found that in a low-humidity environment, we needed a week to really see leaks, but this timescale
236 would likely be shorter in more humid locations. Additionally, this test could be modified based on available
237 equipment (for example, if an instrument is available to measure trace atmospheric gases, that could be used
238 instead). To ensure that SWISS units continue to operate as expected, this test should be done between field
239 deployments on every SWISS unit.

240 We repeated dry air tests until the majority (typically at least 13/15) flasks had a water vapor mole fraction
241 value of less than 500 ppm at the end of the seven day experiment. Water vapor values from the CRDS have not
242 been independently calibrated, but relative variations are believed to be reliable.

243

244 **4.1.3 Step 3: Water vapor tests detect small scale leaks**

245 The purpose of this experiment was to mimic storage of water vapor at concentrations similar to what we
246 might expect in a soil, and for durations similar to those of our field experiments. Additionally, these tests were used
247 to demonstrate that flasks that were filled early in the sampling sequence did not lead by the time the samples were
248 returned to the lab for measurement. For this experiment, flasks were filled with water vapor of known isotopic
249 composition and known concentration, sealed for 14 days, and then we measured the water vapor concentration and
250 isotope values.

251 Prior to putting any water vapor into the flasks (either in the field or in the lab), we completed a dry air fill
252 (as defined above) that served to purge the flasks of any prior water vapor that might exchange with the new sample.

253 To supply water vapor to the flasks, we used the vapor permeable tubing immersed in water. Across three
254 different measurement sessions, we used three different waters that are used as tertiary standards in the INSTAAR
255 SIL lab to complete these experiments: a light water made from melting and filtering Rocky Mountain snow (-
256 25.5‰ and -187.5‰ VSMOW, for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively), an intermediate water that is deionized (DI) water
257 from the University of Colorado Boulder Campus (~16.2‰ and -120.7‰ VSMOW for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively)
258 and a heavy water that is filtered water sourced from Florida, USA (~-0.8‰ and -2.8‰ VSMOW for $\delta^{18}\text{O}$ and $\delta^2\text{H}$,
259 respectively). All secondary lab standards are characterized relative to international primary standards obtained from
260 the International Atomic Energy Agency and are reported relative to the V-SMOW/SLAP standard isotope scale.
261 We flushed the flasks at a rate of 150 ml/min for 30 minutes, and measured the $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values and mole
262 fraction of water vapor as each flask was filled. To calculate the input value, we averaged $\delta^{18}\text{O}$ and $\delta^2\text{H}$ over the last
263 three minutes of the filling period.

264 At the end of the 14-day storage period, we measured each flask to evaluate if the isotope composition had
265 significantly changed over the storage period. To mitigate memory effects between flasks, we ran dry air via the
266 flask bypass loop (port 1 of every Valco valve) for 5 minutes between each flask measurement. During this 5 minute
267 window, we used a heat gun to manually warm each flask. The purpose of the heating was to help create a longer,
268 more stable window of measurement time. While the temperature of the flask was not strictly controlled or
269 regulated, they were all warm to the touch.

270 Once the flask was warmed and the impermeable tubing dried, water vapor was introduced to the CRDS
271 using one of two methods: 1) the dead-end pull method described above, or 2) a *dry air carrier gas sample*
272 *introduction* method. The dead-end pull method is preferable when the water vapor mole fraction inside the flask is
273 low (<17,000 ppm). But, the major downside of the dead-end pull method is that condensation forms in the stainless
274 steel tubing that connects the flasks to the Valco valve, as well as the Valco valve itself, far more commonly as
275 compared to the *dry air carrier gas method*. During the dry air carrier gas method, dry air is continuously flowing
276 through the flask at a rate of 27-31 ml/min for the entire 12 minute measurement period. Additionally, to reach a
277 water vapor mole fraction of approximately 25,000 ppm (the optimal humidity range for the CRDS), we diluted the
278 water vapor with dry air at a rate of 10 ml/min. Without dilution, the concentration out of the flasks is as high as
279 35,000 - 40,000 ppm, which leads to saturation issues on a Picarro L2130-*i*. Providing a carrier gas prevents
280 condensation from forming in the Valco valve and tubing, and prevents fractionation that may occur because of

281 changing pressure within the flask. The dry air carrier gas method is our preferred method for sample introduction in
282 most cases.

283 For each flask we looked at signal stability individually, and for approximately 90% of the flasks we found
284 that after excluding the first three minutes of measurement of each flask, the subsequent three minutes were the most
285 stable and consistent. For some flasks, using either a later portion of the measurement period, or slightly earlier
286 offered a more stable signal.

287 During these experiments, instrument drift and stability were monitored using a suite of four waters of
288 known composition that were introduced to the CRDS using a flash evaporator system, described in detail by
289 Rozmiarek and others (2021). Additionally, instrument stability was assessed by measuring water vapor of known
290 composition that was produced using the vapor probes, in a fashion that is identical to how the flasks were flushed.

291

292 **4.2 Field suitability and Field application experiments:**

293 **4.2.1 Field suitability experiment #1: Long term field leak test**

294 As a complement to the QA/QC we did under lab conditions, we also completed long term dry air tests at
295 our field sites. The purpose of these experiments was to demonstrate that even under field conditions the flasks are
296 still resistant to atmospheric intrusion. Furthermore, this leak test was used to demonstrate that the flasks filled last
297 during the sampling sequence had not taken on an atmospheric isotope composition prior to sampling.

298 Like all field deployments, we started with a dry air fill, and then one SWISS was deployed to each of our
299 three field sites. No soil water was collected during these deployments. The duration between filling the flasks with
300 dry air to measuring the flasks was anywhere between 34 - 52 days.

301

302 **4.2.2. Field suitability experiment #2: Mock field tests**

303 To demonstrate that the automation code and sampling scheme we propose worked as expected on short,
304 observable timescales, we set up an experiment to simulate field deployment of one SWISS unit (Meringue) near the
305 University of Colorado Boulder. This test used the automation components and remote power setup described in the
306 materials section. During this field-simulation experiment, our goal was to collect three discrete samples each
307 sampling period, to simulate collection of samples from three depths at each field site. Importantly, we wanted to
308 demonstrate that the sampling scheme does not introduce significant memory effects between samples.

309 Over the course of 25 hours, all 15 flasks were filled with three different vapors. Two were water vapors,
310 created from the light water and intermediate water as described above in the water vapor test section. The third was
311 water vapor from the ambient atmosphere. For this experiment we filled three flasks per cycle with each one of the
312 waters (e.g. Flask 2 = light, Flask 3 = intermediate, Flask 4 = Atmosphere).

313 For seven days, the SWISS unit was stored in a simulated field setting, while the water vapor remained in
314 the flasks. At the end of the seven days, flasks with a higher water vapor mole fraction (light and intermediate water
315 vapor samples) were measured using the carrier gas sample introduction method, whereas those with a low water
316 vapor mole fraction (atmosphere) were measured using the dead end pull sample introduction method. We used
317 equations 2A and 2B from Rothfuss et al., (2013) to convert from water vapor to liquid values. Then, using tertiary

318 standards, data were corrected into the VSMOW data frame. Finally, the SWISS unit offset correction (detailed
319 below) was applied.

320

321 4.2.3 Full field deployment experiment: One month period

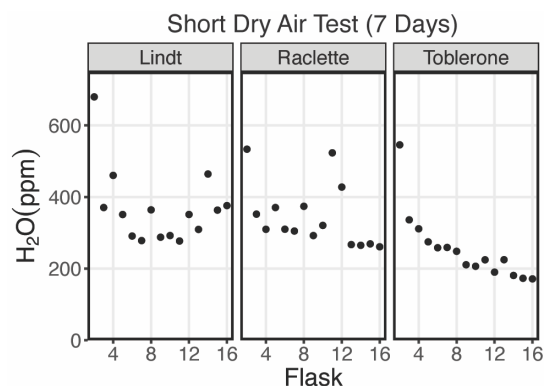

322 We deployed one SWISS unit each to the three field sites described. We sampled at three depths (25 cm, 50
323 cm, and 75cm) on each sampling day, following the protocol in figure 2. We sampled at each depth every 5 days
324 (protocol length = 25 days total). At the end of a 28 day period, the SWISS units were returned to the lab, and
325 measured. The measurement protocol and data reduction protocol follows the procedures described in the water
326 vapor QA/QC test section above. The data correction scheme follows as in the section above.

327 5 Results

328 5.1 QA/QC Results

329 5.1.1 Dry air test

330 Figure 3 shows the results of a seven-day dry air test for three SWISS units (marked by the box name) (SI
331 Table 3). For all three SWISS units, at least 13/15 of the flasks maintained a water vapor mole fraction value of less
332 than 500 ppm over the seven day period. In two of the three SWISS units (Lindt and Raclette), the water vapor mole
333 fraction for flasks was randomly distributed around approximately 350 ppm. In Toblerone there was a systematic
334 decrease in water vapor mole fraction from flask 2 through flask 16, matching the order in which the flasks were
335 filled with dry air initially. In both Lindt and Toblerone, flask 2 had the highest water vapor mole fraction of all the
336 flasks.

337

338 **Figure 3. Results of a dry air test from three different SWISS units named: Lindt, Raclette and Toblerone. The majority**
339 **of the flasks maintain a water vapor mixing ratio of less than 500 ppm.**

340

341 5.1.2. Water vapor test

342 In panels a and b of figures 4 and 5, we show the results of 11 different water vapor tests performed across
343 three analytical sessions using 6 different SWISS units. This dataset includes water vapor tests using three different
344 water vapors (light, intermediate and heavy) and uses both the dead-end pull and dry-air carrier gas methods to
345 introduce water vapor to the CRDS. Across these three sessions, we measured 164 flasks while filling them with

346 water vapor and at the end of the two week hold period. After correcting for instrument drift, we calculated the
347 difference between the starting and end values to assess drift in water vapor isotope values due to leaking or other
348 measurement bias.

349 Ideally, we expect a normal distribution centered about 0 within the uncertainty limits of the water vapor
350 probes (Oerter et al., 2016). For $\delta^{18}\text{O}$, the mean difference between the start and end values for the flasks is 1.1‰
351 with a standard deviation of 0.72‰ (outliers removed). There is a consistent positive offset, with a few clear outliers
352 (Fig. 4A). We do not observe a consistent difference between water vapor sample introduction methods (Supp. Fig.
353 2). After removing outliers ($< Q1 - 1.5 * IQR$ or $> Q3 + 1.5 * IQR$, $n = 15$) from the dataset, we compared the kernel
354 density estimate shape to a normal distribution calculated from the mean and standard deviation of the dataset to
355 assess dataset normality (Fig. 4B). A normal distribution slightly overestimates the center of the data, but captures
356 the overall shape fairly well. Therefore, we used the median offset (1.0‰) to correct our water vapor isotope values,
357 and used the interquartile range of the dataset (outliers removed) to estimate uncertainty of the SWISS as $\pm 0.9\%$.
358 In figure 5C, for simplicity, we just present the results from 45 flasks (three SWISS units), with the 1.0‰ offset
359 correction applied. After correction, data are randomly distributed about 0, and are within the uncertainty range of \pm
360 0.9‰ (Supp. Table 4).

361 For $\delta^2\text{H}$, the mean difference between the start and end values is 2.63‰ with a standard deviation of 2.85‰
362 (outliers removed). Similarly to $\delta^{18}\text{O}$, we ideally expected a normal distribution of differences centered around 0. As
363 with $\delta^{18}\text{O}$, there was a consistent positive offset with some outliers (i.e. $< Q1 - 1.5 * IQR$ or $> Q3 + 1.5 * IQR$) (Fig.
364 5A). After removing outliers ($n = 26$) from the dataset, we compared the kernel density estimate to a normal
365 distribution calculated from the mean and standard deviation of the dataset to assess dataset normality (Fig. 5B). As
366 for $\delta^{18}\text{O}$, the center of the dataset is overestimated by the mean, but the overall peak shape is roughly captured. We
367 therefore use the median value of 2.3‰ as an offset correction, and estimate uncertainty at $\pm 3.7\%$ for $\delta^2\text{H}$ from the
368 interquartile range. In figure 5C, we present the results from 45 flasks (three SWISS units), with the 2.3‰ offset
369 correction applied. Data are randomly distributed about 0, and are within the uncertainty range of $\pm 3.7\%$ (Supp.
370 Table 4).

371

372 **5.2 Field suitability and field deployment experiment results**

373 **5.2.1. Dry air test**

374 Figure 6A shows the result of placing SWISS units that were flushed with dry air out into field conditions
375 over the course of 34 - 52 days (SI Table 3). We chose these time intervals because they bracket the typical length of
376 a deployment, which helped us determine how quickly flasks should be measured after bringing a SWISS back to
377 the lab. At the timescale of 34 - 43 days, 13 of the 15 flasks typically maintained a water vapor mole fraction of less
378 than 1000 ppm. At the timescale of 52 days, eight of the 15 flasks had a water vapor mole fraction between 1000 -
379 2500 ppm, and the remaining seven flasks had a water vapor mole fraction of less than 1000 ppm. Given that these
380 tests were completed with different SWISS units, these data also include some of the inter-unit variability.

381

382

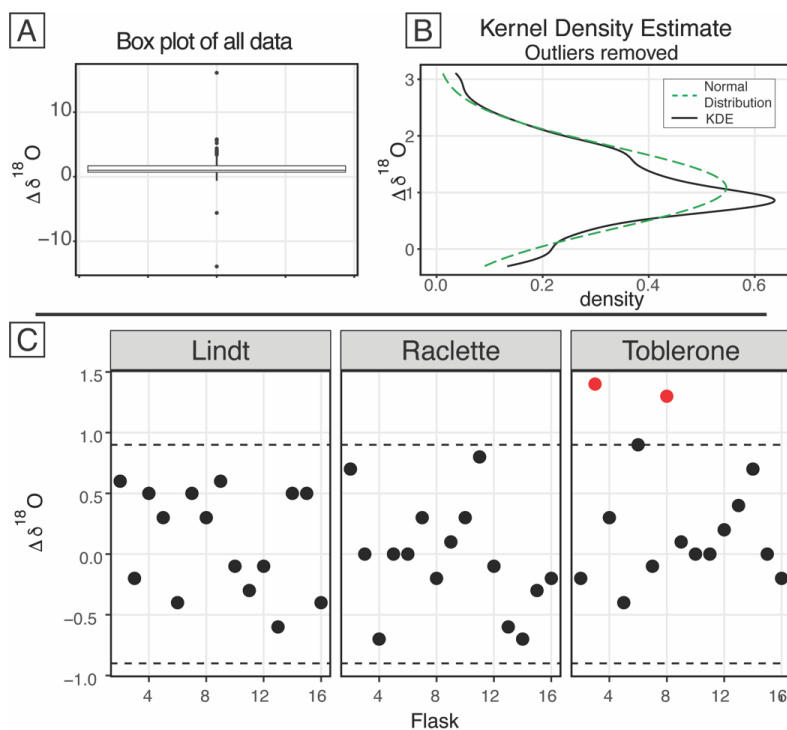

Figure 4. Results of the water vapor tests. A) Boxplot of the difference between the starting $\delta^{18}\text{O}$ value and the final $\delta^{18}\text{O}$ value of all 164 flasks. B) After removing the outliers from the dataset, the kernel density estimate (black line) and the normal distribution calculated from the dataset (dashed green) are shown. C) After applying the offset correction of 1.0‰, the difference between the starting $\delta^{18}\text{O}$ value and the final $\delta^{18}\text{O}$ value for three boxes from the August 2022 session are shown. An uncertainty of $\pm 0.9\text{‰}$ is marked with a dashed line, and data points that fall outside that uncertainty are colored red.

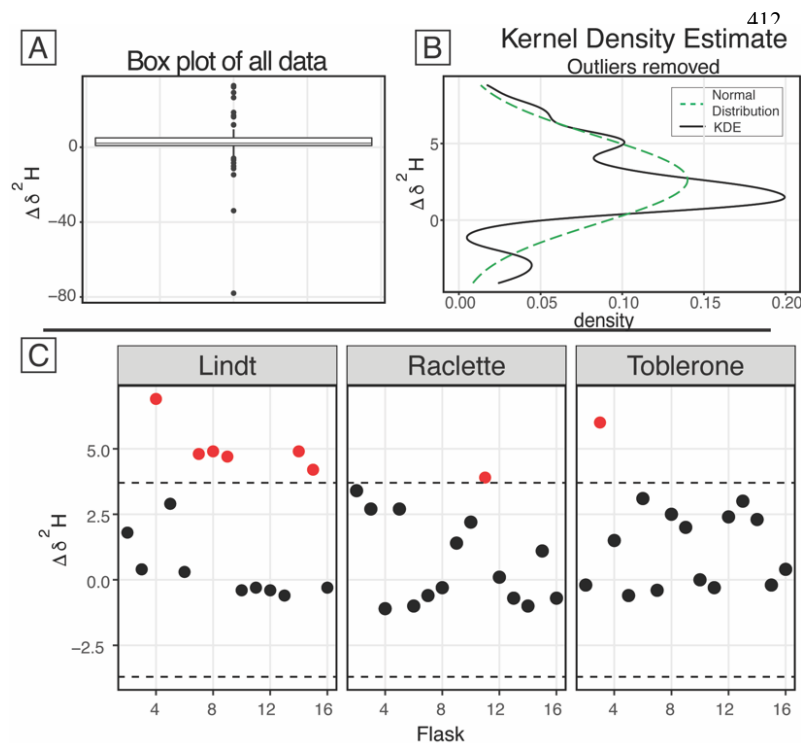

Figure 5. Results of the water vapor tests A) Boxplot of the difference between the starting $\delta^2\text{H}$ value and the final $\delta^2\text{H}$ value of all 164 flasks. B) After removing the outliers from the dataset, the kernel density estimate (black line) and the normal distribution calculated from the dataset (dashed green) are shown. C) The difference between the starting $\delta^2\text{H}$ value and the final $\delta^2\text{H}$ value for three boxes from the August 2022 session are shown after applying the offset correction of 2.3‰. An uncertainty of $\pm 3.7\text{‰}$ is marked with a dashed line, and data points that fall outside that uncertainty are colored red.

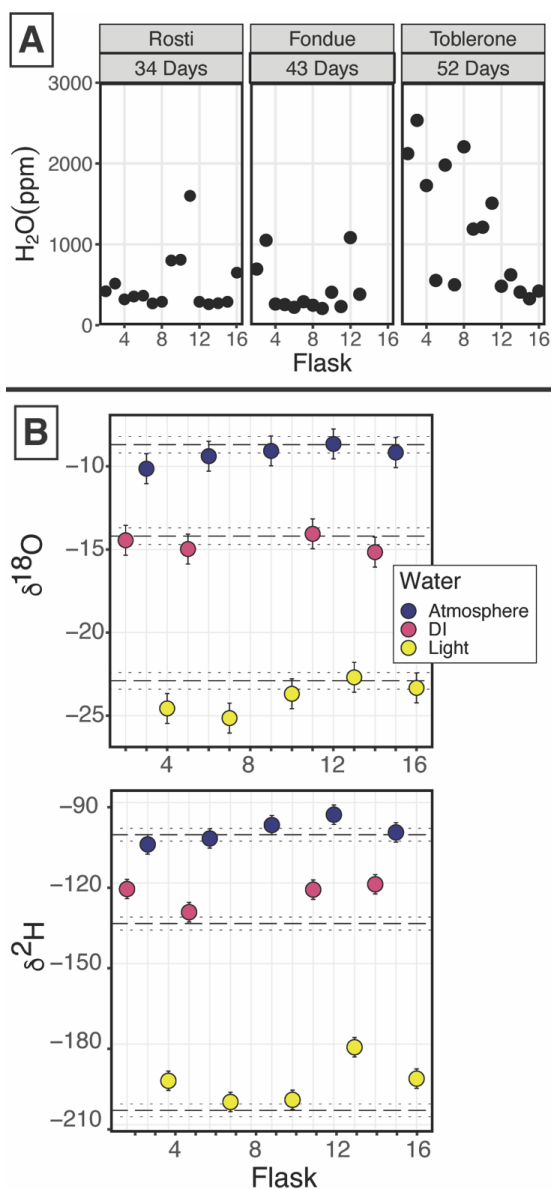

Figure 6. A) Results from three different field-based long dry air tests. B) Results from the automation field suitability tests using the SWISS unit named Meringue. Flasks that sampled atmosphere are shown in blue, flasks that sampled deionized water (DI) are shown in pink, and flasks that sampled the light water are shown in yellow. The top plot shows the $\delta^{18}\text{O}$ results, and the bottom plot shows the $\delta^2\text{H}$ results.

 494
 495
 496
 497

498 **5.2.2. Automation test**

499 Figure 6B shows the result of using the automation code to collect and store water vapor of known
 500 composition for seven days (Table 2). In both plots, the known values of the water are shown as a long-dash line.
 501 Uncertainty on those measurements is estimated at 0.5‰ and 2.4‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$ respectively (Oerter et al.,
 502 2016), shown as the dotted lines. We estimated the isotope value of the atmosphere at the time of sampling with data
 503 from the CRDS in the lab. The corrected isotope value of each flask is shown, with uncertainty associated with the
 504 SWISS units estimated at 0.9‰ and 3.7‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively.

505 Seven of the nine flasks filled with water vapor overlap within uncertainty of the known $\delta^{18}\text{O}$ value for
 506 those standards (top plot, Fig. 6B), and four of the five flasks filled with atmospheric vapor overlap within
 507 uncertainty of our estimated $\delta^{18}\text{O}$ value. Flasks that fall outside of the bounds of uncertainty tend to have lower $\delta^{18}\text{O}$
 508 values than the expected value. For $\delta^2\text{H}$, (bottom plot, Fig. 6B) only three of the nine flasks filled with water vapor
 509 overlap within uncertainty of the known value of those standards, while four of the five flasks filled with
 510 atmospheric vapor overlap within uncertainty of the estimated $\delta^2\text{H}$ value. Flasks that fall outside of the bounds of
 511 uncertainty typically have higher $\delta^2\text{H}$ values than the expected value.

512

513 **Table 2. Results of the Automation test**

514

515 **5.2.3 Field deployment**

516 Figure 7 shows the results from three field deployments in Oglala National Grassland, Nebraska;
 517 Briggsdale, Colorado; and Seibert, Colorado (table 3).

518

519

520 **Figure 7. Results from all three field deployments to Oglala National Grassland, NE, Briggsdale, CO and Seibert, CO.**
 521 **Note, the y-axis scale for all three plots is different.**
 522

523 There are 15 samples from Oglala National Grassland (Fig. 7); five from 25 cm depth, five from 50 cm
 524 depth and five from 75 cm depth. Samples were taken approximately every five days from 2022-06-25 to 2022-07-
 525 14. Four of the five samples from 25 cm overlap within uncertainty in $\delta^{18}\text{O}$ value, and all five samples overlap with
 526 uncertainty in $\delta^2\text{H}$ value. There is a significant decrease in the $\delta^{18}\text{O}$ value at 25 cm between 2022-06-25 and 2022-
 527 06-29. There is no similar shift in $\delta^2\text{H}$ value over the same time period. The first three samples from 50 cm overlap
 528 in both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values, then the final two samples drift to higher isotope values. All five samples from 75 cm
 529 overlap in $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values. Similar to the samples from 50 cm, there is a trend towards higher $\delta^2\text{H}$ values for
 530 the last three samples. Overall, $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values from 25 cm are significantly higher than the values from 50 and
 531 75 cm depth. Generally, samples from 50 cm depth have lower $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values than samples from 75 cm depth.

532 There are 10 samples from Briggsdale, CO (Fig. 7); five samples are from a vapor probe buried at 50 cm
 533 depth and five samples are from a vapor probe buried at 75 cm depth. Data from 25 cm at Briggsdale, CO were
 534 excluded because the water vapor mole fraction from all of the flasks with samples at this depth had extremely low
 535 water vapor mole fractions (<13,000 ppm), and so those data may either represent atmosphere or soil gas from an
 536 extremely dry soil. Samples were taken every five days between 2022-07-17 and 2022-08-06. All samples overlap
 537 within uncertainty in both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values, however samples from 50 cm are clearly offset to higher values for
 538 both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ as compared to samples from 75 cm.

539 There are 8 samples from Seibert, CO (Fig. 7); four samples are from a vapor probe buried at 25 cm depth
 540 and four samples are from a vapor probe buried at 50 cm depth. Samples collected from 75 cm depth at Seibert, CO
 541 were discarded because there were significant problems with condensation while measuring these flasks, and so all
 542 data were considered spurious. Samples were collected every five days between 2022-06-19 and 2022-07-04. At 25
 543 cm depth, $\delta^{18}\text{O}$ values of three of the four samples overlap within uncertainty; the 25 cm sample from 2022-06-29
 544 that does not overlap has a higher $\delta^{18}\text{O}$ value than the other three samples. At 25 cm depth, $\delta^2\text{H}$ values overlap

545 within uncertainty for all four samples. At 50 cm depth, there is a steady decrease in $\delta^{18}\text{O}$ value over the sampling
546 period, while $\delta^2\text{H}$ values for all four samples remain steady.

547

548 **6 Discussion**

549 **6.1 QA/QC and field suitability tests**

550 **6.1.1 Dry Air tests**

551 For the seven day dry air tests, the flasks were able to maintain a water vapor mole fraction typically less
552 than 400 ppm, and all flasks maintain a water vapor mole fraction of less than 700 ppm (Fig. 4). In Colorado, the
553 ambient atmosphere during the summertime typically sits at a water vapor mole fraction between 10,000 - 20,000
554 ppm, and in winter the water vapor mole fraction can drop as low as 4000 ppm. If the flasks allowed in a significant
555 amount of atmosphere, the flasks would have had much higher water vapor molar fractions. This suggests that the
556 system is resistant to atmospheric intrusion.

557 There seems to be a systemic bias towards a high water vapor mole fraction for the first flask that is
558 measured (flask 2). There are two potential analytical sources of this. First, its possible that during the filling phase,
559 not all of the atmospheric vapor has been flushed out of the system before starting the fill process. Similarly, it is
560 possible that not all of the atmospheric water vapor was flushed from the line that connects to the CRDS prior to the
561 start of the measurements.

562

563 **6.1.2 Water vapor tests**

564 The in-lab water vapor tests served three functions: 1) they allowed us to test the best method for
565 measuring soil water vapor at fairly high water vapor mole fractions that might be representative of field conditions
566 (i.e. > 25,000 ppm), 2) to test if there is any systemic bias introduced through the building materials or measurement
567 schema, and, 3) test whether soil water vapor samples can yield reliable stable isotope values.

568 We completed 11 water vapor tests using 6 SWISS units and three analytical sessions, resulting in 164
569 measurements of water vapor. Across the three analytical sessions, three waters with different isotopic compositions
570 were used to produce water vapor (1 heavy, 1 intermediate, and 1 light). If there was alteration of original values due
571 to leaky flasks, we might expect the $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values to converge on the $\delta^{18}\text{O}$ and $\delta^2\text{H}$ value of the atmosphere.
572 For example, we might expect water vapor from the light water test to have the most significant change in isotope
573 value, towards that of the ambient atmosphere.

574 Figures 4 and 5 demonstrate that there is a consistent offset in both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ of the water vapor from
575 the start of storage to the end for all three analytical sessions. After removing outliers from the dataset, there remains
576 a consistent bias across all SWISS boxes and analytical sessions (Figs 5B, 6B). The consistency across >135 flasks,
577 different starting water vapor isotope values, sample introduction methods, and multiple analytical sessions suggests
578 that this difference is a function of the storage and measurement. Additionally, the normality of the distribution
579

Table 3. Results from the three field deployments of SWISS.

580

581

582 suggests that there is a systematic bias that we can reliably correct for. We chose to use the median value as an offset
583 correction over the mean of the normal distribution, because the median is not biased by higher isotope difference
584 values that are a complex combination of systematic bias and slow leaking. The calculated average offset is 1.0‰
585 and 2.6‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively.

586 Based on the results of the water vapor tests, we estimate the uncertainty of the SWISS at 0.9‰ and 3.7‰
587 for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively using the interquartile range (IQR) of the water vapor test results after removing
588 outliers from the dataset. We prefer the IQR over the calculated standard deviation of the normal distribution,
589 because IQR is not biased by outlier values. In figures 5C and 6C, we show the results of 3 water vapor tests from
590 the August 2022 analytical session, with an offset correction applied. 43 of the 45 measured flasks faithfully retained
591 the starting $\delta^{18}\text{O}$ value of the water vapor, and 37 of the 45 measured flasks faithfully retained the starting $\delta^2\text{H}$ value
592 of the water vapor. Additionally, after the offset correction was applied, most flasks also fall within the uncertainty
593 of the water vapor permeable probes ($\delta^{18}\text{O} = 0.5\%$ and $\delta^2\text{H} = 2.4\%$).

594 Supplemental figure 3 shows a kernel density estimate plot of the results from two water vapor test
595 sessions, with the offset correction applied. During the March 2022 session, flasks were measured using the dead-
596 end pull sample introduction method and during the August 2022 session, flasks were measured using the dry air
597 carrier gas sample introduction method. There is no significant difference in the measured difference between the
598 two sample introduction methods. We prefer the dry air carrier gas method, because it is far simpler to control the
599 water vapor mixing ratio, and optimize the concentration to be around 25,000 ppm, which is the concentration at
600 which the Picarro L2130-i is most reliable. The dry air carrier gas method also makes it far easier to control for and
601 monitor for condensation in the stainless steel tubing and vapor impermeable tubing, which can bias a measurement.

602

603 **6.1.3 Field suitability tests**

604 In Figure 7A, we observe that the flasks typically maintained a low water vapor mole fraction (< 1000
605 ppm) under field conditions, and at timescales relevant to 4-6 week field deployments (34 - 43 days). The 34 day
606 test was done during June 2022, and therefore tests the SWISS under warm summertime conditions. The 43 day test
607 was done in October 2021, which included nights where temperatures fell below 0°C, and therefore tests the
608 suitability of the SWISS to maintain integrity under freezing conditions. We observe that the SWISS did
609 considerably worse at maintaining a low water vapor mole fraction over a 52 day time period during similar
610 summertime conditions as compared to the 34 - 43 day time period. Over the 52 days, seven flasks maintained a
611 water vapor mole fraction less than 1000 ppm and the remaining 8 had a water vapor mole fraction between 1000 -
612 2500 ppm. Though the SWISS performed considerably worse after 52 days than it did from 34 - 43 days, it is
613 important to note that the atmospheric water vapor mole fraction during the storage time period was likely 15,000 -
614 20,000 ppm, and so the measured values demonstrate that the SWISS are still quite resistant to atmospheric intrusion
615 at that timescale.

616 In figure 7B, the data show that the flasks faithfully preserved the $\delta^{18}\text{O}$ value of both water vapor produced
617 using the vapor permeable probe and the atmosphere over a seven day period. One flask was removed from the
618 dataset (flask eight), because there was noticeable condensation in the impermeable tubing during the measurement

619 phase, with an increase of $> 5\%$ for $\delta^{18}\text{O}$ during the measurement period. Notably, the two flasks whose $\delta^{18}\text{O}$
620 oxygen isotope values do not overlap within uncertainty are more negative than expected, rather than drifting
621 towards atmospheric values or values expected with kinetic fractionation. It is possible that those samples were also
622 affected by condensation at the start of the experiment; during condensation, we expect that ^{18}O will preferentially
623 go into the liquid phase, and that the water vapor that enters the flask will have a lower than expected $\delta^{18}\text{O}$ value.

624 Surprisingly, only 3 flasks filled with either DI or light water vapor overlap within uncertainty of the
625 known $\delta^2\text{H}$ values, while four of the five flasks overlap within uncertainty of the estimated atmosphere isotope
626 value. The flasks tend to drift towards the value of the atmosphere, but retain the overall data pattern from the
627 oxygen isotope values.

628

629 **6.1.4 Lessons learned and recommendations from the QA/QC and field suitability tests:**

630 The dry air test is a time-efficient method for identifying flasks that are leaky and will not preserve the
631 sampled water vapor value, therefore we recommend these tests as a required step prior to field deployment of future
632 SWISS units. For example, supplemental figure 4 shows that it is possible to drastically reduce the water vapor mole
633 fraction in a flask filled with dry air between tests by tightening and/or replacing problematic fittings (both those
634 attached to the glass flasks and those on the valco valve) and in some cases the glass flask itself. This shows we can
635 reduce the leakiness of the flasks. The dry air test is also an easy baseline test that also allowed us to test building
636 materials. For example, in supplemental figure 5, we tested using PTFE swagelok fittings with $\frac{1}{8}$ " PTFE tubing
637 rather than stainless steel. These materials would be advantageous because they are much easier to install and are
638 significantly lighter. We found that these fittings and tubing *may be* sufficient to store water for up to a single week,
639 but on longer timescales (e.g. 27 days) we observed greater exchange and leaking than the stainless steel. We
640 encourage any future user using this modification to rigorously test these fittings on a timescale appropriate for their
641 application.

642 From the water vapor tests, we get a sense of the accuracy and precision of the SWISS. The calculated
643 uncertainty of the flasks (0.9‰ and 3.7‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively) is somewhat larger than the uncertainty
644 associated just with the use of the water vapor probes (0.5‰ and 2.4 ‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively, Oerter et al.,
645 2016), but is sufficient for many critical zone applications, given the magnitude of seasonal variability that can be
646 observed in natural systems (e.g. Oerter et al., 2017; Quade et al., 2019).

647 We opted to use a large flask volume because it allows us to measure a sample for long enough on a CRDS
648 that we get reliable data, without interacting with vapor bound to the flask walls. The drawback of this, however, is
649 that we must sample soil water vapor for a relatively long period of time (45 minutes). In supplemental figure 6, we
650 show that the sampling regime, and particularly the length of time we pump dry air through the tubing, does not
651 significantly alter the soil moisture content of the soil. Additionally, we demonstrate that the sampling regime we
652 use does not introduce significant memory effects.

653 Based on the results of the long, field dry air test, we recommend that the water vapor storage time doesn't
654 exceed 40 days for reliable results, or that the user undertake multiple dry air tests with lower concentration
655 benchmarks if deployments may exceed 40 days.

656 Overall, the quality control and quality assurance as well as the field suitability tests demonstrate that the
657 SWISS are able to faithfully retain the isotope value of water vapor collected using water vapor permeable probes.
658 Like many other systems that measure dual isotopes, each system (i.e. $\delta^{18}\text{O}$ and $\delta^2\text{H}$) must be evaluated separately.
659 In general, we interpret oxygen isotope data with a higher degree of confidence than the hydrogen isotope data. As
660 the automation test revealed however, even when the absolute $\delta^2\text{H}$ value is not correct, the general pattern can reveal
661 information about soil water dynamics. One particular challenge with the vapor permeable probes, that others have
662 noted, is condensation in any portion of the system (e.g. Quade et al., 2019; Kühnhammer et al., 2019). As much as
663 possible, it is helpful to have the impermeable tubing at warmer temperatures than the soil or water it is sampling. In
664 many situations it may be worthwhile to warm the transfer tubing, but this should be done in a way that does not
665 alter the thermal structure of the soil, and in remote settings, can operate safely independently. Additionally, taking
666 care to ensure that the SWISS is evenly and lightly warmed in the lab setting helps to prevent condensation from
667 forming in the stainless steel tubing and Valco valve.

668

669 **6.2 Field Deployments**

670 In Figure 7 we show the results of three field deployments completed during summer 2022 (table 3). At the Oglala
671 National Grassland site, we used the SWISS named Lindt to collect samples. During the August 2022 water vapor
672 test on Lindt, all of the oxygen isotope values fall within uncertainty of the system, and nine of the fifteen flasks fall
673 within uncertainty of the system. Therefore, we interpret the $\delta^{18}\text{O}$ values with a higher amount of confidence and the
674 $\delta^2\text{H}$ values with a lower amount of confidence (Figs. 4C and 5C). We note that most of the $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values
675 follow the same trends, and fall on the global meteoric water line (Figs. 7 and 8A). In general, soil water from 25 cm
676 had higher $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values than soil water from both 50 and 75 cm (Fig. 8A). Given that 4 of the 5 samples
677 from 25 cm overlap with the GMWL and have a d-excess that overlaps within error of 10‰, the soil water from that
678 depth may reflect summer precipitation with higher $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values. Soil water from 75 cm had intermediate
679 $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values for most of the study period, and soil water from 50 cm depth had the lowest $\delta^{18}\text{O}$ and $\delta^2\text{H}$
680 values for most of the study period, which may reflect a more mean-annual or winter precipitation biased value. The
681 d-excess value of soil water collected from 75 cm is centered around a global meteoric water line value of 10‰ (Fig.
682 8B). Based on data available from the National Weather Service (Chadron, NE), there were likely significant
683 precipitation events on 2022-06-25 and 2022-07-08 at the field site. There is a significant shift to lower $\delta^{18}\text{O}$ values
684 at a sampling depth of 25 cm between 2022-06-25 and 2022-06-29, as well as a marked increase in the d-excess
685 value (Fig. 8A). We interpret this shift as infiltration of precipitation with lower $\delta^{18}\text{O}$ values, and is supported by a
686 return of d-excess values to ~10‰ (Fig. 8A). The National Weather Service reported 0.84 inches of rain at Chadron
687 Municipal Airport, approximately 50 km from the study site on 2022-07-08, which likely was associated with at
688 least some precipitation at our field site. Following the significant rain event on 2022-07-08, we observe a marked
689 increase in the stable isotope value of water vapor from a sampling depth of 50 cm, towards values that are much
690 closer to those at 25 cm depth. This indicates that after a large precipitation event, there is mixing and the creation of
691 a far more uniform soil water isotope profile to a depth of 50 cm, but at the depth of 75 cm, the oxygen isotope data
692 remain fairly uniform across the sampling period.

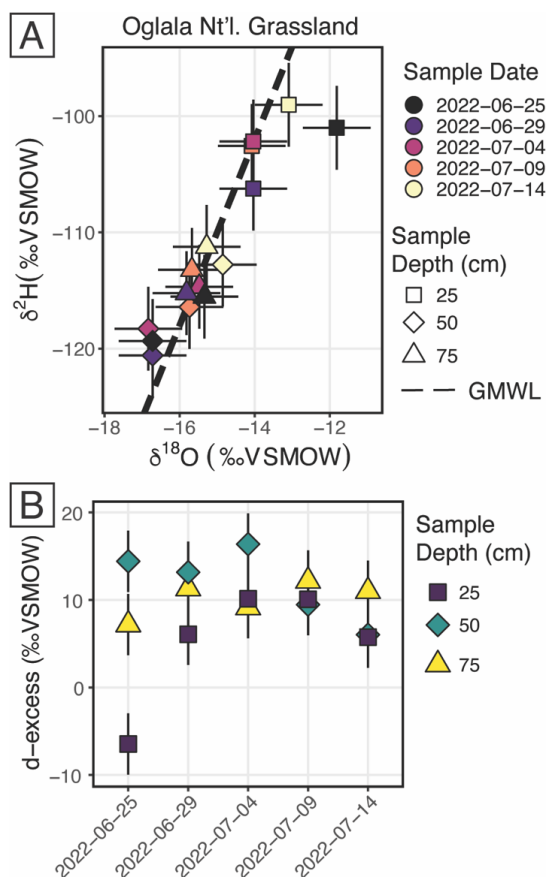

Figure 8. Results from the Oglala National Grassland, NE field site. A) $\delta^2\text{H}$ vs. $\delta^{18}\text{O}$, where the dashed line is the global meteoric water line. The shape of the depth sampled matches figure 7, and the color of the points is the date on which the soil water was sampled B) A plot of d-excess. Note, both the color and shape match figure 7.

730

731

732

At Briggsdale, CO we used the SWISS named Raclette to collect soil water vapor samples. Data from 25 cm depth at Briggsdale, CO were discarded because the water vapor mole fraction was much lower than would be expected given the soil temperature (i.e. < 15,000 ppm). The gravimetric water concentration at that soil depth at the time of sampling was approximately 4% through the sampling period. Given the low water concentration, it is possible that there was simply not enough water vapor to sufficiently sample. Based on the results of the August 2022 water vapor test done on Raclette where all flasks fell within uncertainty of the SWISS system for both $\delta^{18}\text{O}$ and $\delta^2\text{H}$, except for flask 11 (Figs. 4C and 5C), which corresponds to the 25 cm depth sample from 2022-07-27, we interpret all of the data with a higher level of confidence. This sample was already removed from the dataset because of low water vapor mole fraction associated with the very dry soil. The soil water $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values from a sampling depth of 50 cm and 75 cm overlap within uncertainty, but the soil water $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values from 50 cm have a higher isotopic value than the samples from 75 cm. All of the data from within each sampling depth group (i.e. 50 cm and 75 cm) overlap within uncertainty, conforming to the expectation that soil water from these sampling depths should be fairly invariant (e.g. Oerter et al., 2017). There were precipitation events at the study site on 2022-

733 07-24, 2022-07-28 and 2022-07-31. It is possible that the slight negative shift in both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ on 2022-08-01
734 reflects infiltration of precipitation to those depths, but this is not certain given that all of the measurements from
735 within a sampling depth overlap within uncertainty.

736 At Seibert, CO we used the SWISS named Toblerone to collect soil water vapor samples. Data from 75 cm
737 depth at Seibert, CO were discarded because of evidence of condensation during the measurement of the flasks
738 associated with that sampling depth. Based on the results of the August 2022 water vapor test done on Toblerone,
739 we interpret all of the data with a high degree of confidence, except for Flask 3, which is the 50 cm sample from
740 2022-06-19 (Figs. 4C and 5C). Unlike data from the other two field sites, soil water from 25 cm and 50 cm overlap
741 within uncertainty. There were two precipitation events at the field site during the sampling period on 2022-06-25
742 and 2022-07-01, but both events were quite small (<0.02 inches, CoAgMet). There is no significant influence of the
743 precipitation events on the $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values. The $>1.0\text{‰}$ increase in $\delta^{18}\text{O}$ values on 2022-06-29 is surprising
744 given that there is not a comparable magnitude increase in $\delta^2\text{H}$ value, and that the values measured from 2022-07-04
745 more closely match the $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values from the two earlier sampling days. There are two potential
746 explanations for this data. First, that is a real signal from an evaporation driven increase in the $\delta^{18}\text{O}$ value, and the
747 reset to a lighter $\delta^{18}\text{O}$ value on 2022-07-04 is due to the infiltration of precipitation. This explanation is corroborated
748 by a low d-excess value associated with this measurement (Fig. SI 9). The second possible explanation is that the 25
749 cm sample from 2022-06-29 is influenced by condensation at the time of sampling. Dew point at the field site on
750 2022-06-29 significantly decreased as compared to the other sampling days to a monthly minimum of 20.6°C . It is
751 possible that environmental conditions encouraged the formation of condensation in the impermeable tubing at the
752 time of sampling. There were no obvious signs of condensation during the time of measurement in the lab. These
753 results highlight the utility of having broad contextual environmental data to aid in the interpretation of soil water
754 isotope data.

755 All together, these three soil water isotope datasets demonstrate two main findings. First, data from these
756 samples show that the differences between field sites is easily resolvable using the SWISS. For example, at 50 cm
757 depth the oxygen isotopes range between -14.4 to -16.3‰ , -9.9 to -10.3‰ , and -7.4 to -9.3‰ for the Oglala,
758 Briggsdale and Seibert sites, respectively. These differences likely reflect differences in the stable isotope
759 composition of precipitation and evaporation dynamics. Second, the sample data retrieved from a SWISS are
760 sufficiently precise to be able to meaningfully resolve vertical profile soil water isotope data. For example, at the
761 Oglala National Grassland field site, soil water from 25 cm clearly has higher $\delta^{18}\text{O}$ and $\delta^2\text{H}$ values as compared to
762 soil water from a depth of 50 and 75 cm.

763

764 **6.3 Future improvements**

765 One significant SWISS unit hardware improvement that could be made would be to install a heating
766 implement to the flasks. One source of uncertainty on the current system is the potential effect of uneven heating of
767 the flasks prior to measurement. This could be improved in subsequent iterations of the SWISS with the addition of
768 heat tape or blankets that can deliver controlled and consistent amounts of heat. This improvement could also help

769 limit the amount of manual intervention needed during measurement, and could improve automation of flask
770 measurement.

771 In addition, we have made a few improvements to the automation system that were not implemented for the
772 data presented in this contribution, but will be part of future deployments. First, we will track conditions inside the
773 SWISS with a temperature and relative humidity sensor inside the case. Second, we plan to eliminate the power
774 inverter by powering both the Valco valve and mass flow controller with VDC using a power step up controller.
775 Lastly, we will add an IoT cellular router to be able to remotely monitor and control the SWISS units.

776 Finally, there are two future considerations for field deployments. The first is finding a way to safely and
777 automatically heat the impermeable tubing that connects the water vapor probes and the SWISS in a way that
778 doesn't change the inherent thermal structure of the soil, and is safe for unmonitored use. Additionally, we plan to
779 test SWISS unit resilience during air travel so that these units can be used at field sites that are not within driving
780 distance of a research facility.

781 **Conclusions**

782 We presented the evolution of the soil water isotope storage system (SWISS) from a prototype to a fully
783 built out and tested system. We also presented a quality control and quality assurance procedure that can be used to
784 ensure the reliable storage of soil water vapor over long time periods (up to 40 days). In addition, these quality
785 control and quality assurance tests shed light on the accuracy and precision of the SWISS. After applying an offset
786 correction, we determine the overall precision of the SWISS to be 0.9‰ and 3.7‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively. In
787 a field setting, flasks reliably resist atmospheric intrusion. Additionally, the proposed sampling schema does not
788 introduce significant memory effects. Lastly, we demonstrate that the precision of the SWISS still allows us to
789 distinguish between field sites and between soil water dynamics within a single soil column. Taken as a whole, these
790 data show that the SWISS can be used as a tool to answer many emerging ecohydrological questions, and will
791 enhance researchers' ability to collect soil water isotope datasets from more remote and traditionally understudied
792 field sites.

793 **Acknowledgements**

794 We thank the numerous field assistants who helped to make the field work presented in this paper possible,
795 including Spencer Burns, Anne Fetrow, Sarah Brookins, Juliana Olsen-Valdez, and Haley Brumberger. We
796 acknowledge that both field work and laboratory work for this study was done on the traditional territories and
797 ancestral homelands of the Arapahoe, Ute and Cheyenne peoples. This work was supported by startup funding from
798 CU Boulder and NSF funding from grant EAR-2023385 awarded to K. Snell. Additionally, this work was supported
799 by the University of Colorado Boulder Beverly Sears Research Grant and the Clay Minerals Society Graduate
800 Student Research Grant both awarded to R. Havranek. CUBES-SIL is a CU Boulder Core Facility associated with
801 RRID: SCR_019300.
