ABSTRACT

Understanding where normal faults are is critical to an accurate assessment of seismic hazard, the successful exploration for and production of natural (including low-carbon) resources, and for the safe subsurface storage of CO₂. Our current knowledge of normal fault systems is largely derived from seismic reflection data imaging intra-continental rifts and continental margins. However, exploitation of these data is limited by interpretation biases, data coverage and resolution, restricting our understanding of fault systems. Applying supervised deep learning to one of the largest offshore 3-D seismic reflection data sets from the northern North Sea allows us to image the complexity of the rift-related fault system. The derived fault score volume allows us to extract almost 8000 individual normal faults of different geometries, which together form an intricate network characterised by a multitude of splays, junctions and intersections. Combining tools from deep learning, computer vision and network analysis allows us to map and analyse the fault system in great detail and a fraction of the time required by conventional interpretation methods. As such, this study shows how we can efficiently identify and analyse fault systems in increasingly large 3-D seismic data sets.

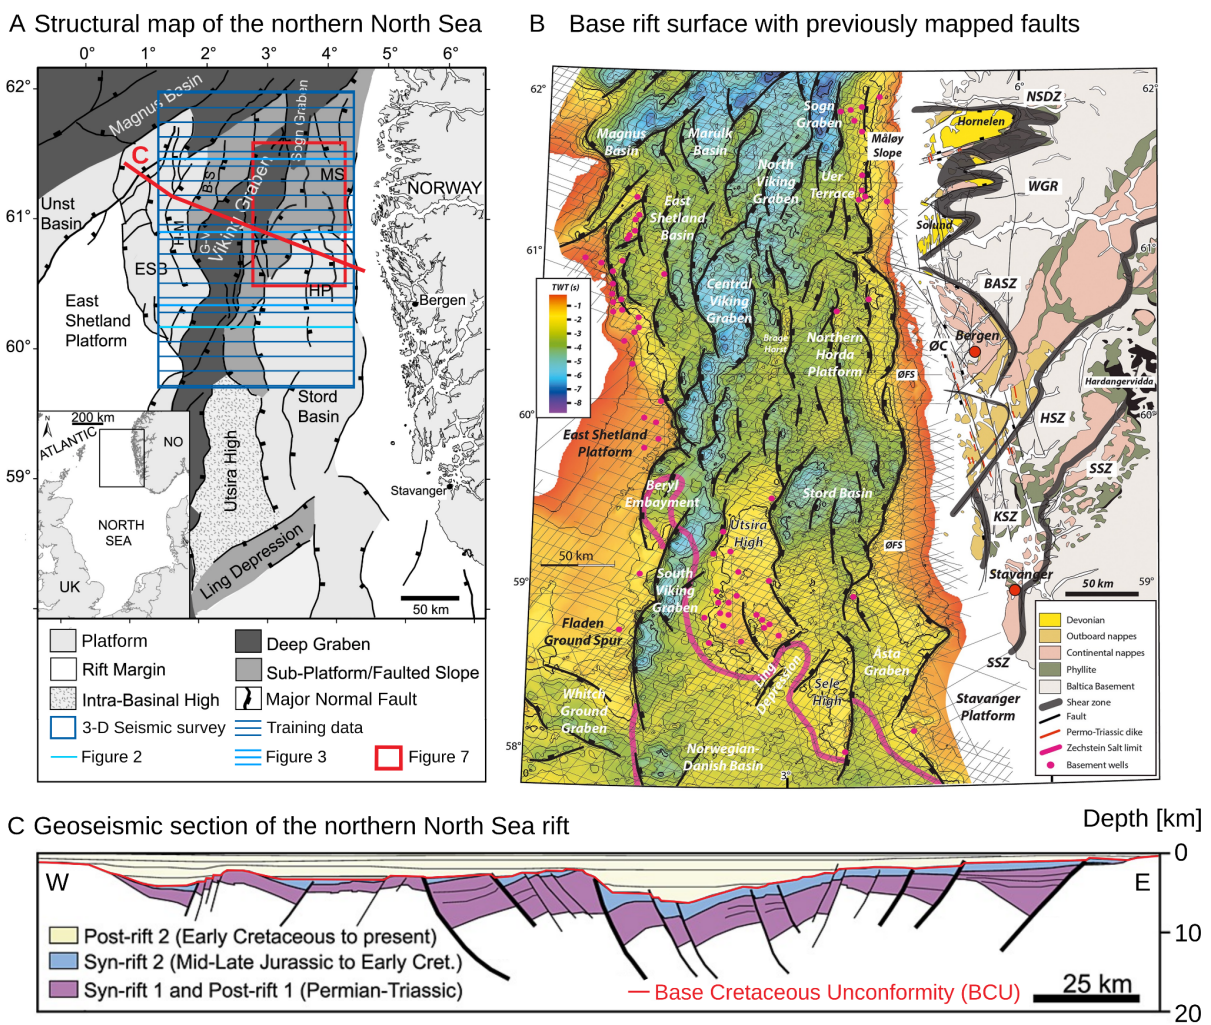

37 1. INTRODUCTION

38 Understanding the geometry and growth of normal fault systems is critical when assessing
39 seismic hazard, when identifying suitable sites for subsurface CO₂ storage and when exploring for
40 natural resources (traditional and low-carbon). For example, whereas probabilistic seismic hazard
41 analyses based on seismic event catalogues are extremely useful when trying to forecast earthquake
42 likelihood and location, high-resolution fault mapping, preferably in 3-D, can help us constrain the
43 slip tendency of faults, where seismic catalogues are discontinuous and/or incomplete (e.g. Morris et
44 al., 1996; Moeck et al., 2009; Yukutake et al., 2015). Moreover, faults can facilitate (or impede) fluid
45 and gas migration to the Earth's surface, thus determining their geometry and connectivity, as well as
46 their hydraulic properties is key for assessing their role in the long-term subsurface storage of CO₂
47 (Bissell et al., 2011; Kampman et al., 2014). In both of these examples, we need robust predictions of
48 3-D fault geometry over large areas and across a wide range of scales (100s m to 100 km).

49 Accurately mapping fault systems in 2-D and 3-D seismic reflection data typically requires
50 expertise and time (e.g. Bond, 2015). While we can map fault systems in great detail over small areas
51 using 3-D seismic reflection data (e.g. Lohr et al., 2008; Wrona et al., 2017; Claringbould et al.,
52 2020), we lack an understanding of the character of 3-D fault populations at the scale of entire rift
53 systems, as regional studies are often limited to only sparse, 2-D seismic sections (e.g. Clerc et al.,
54 2015; Fazlikhani et al., 2017; Phillips et al., 2019). 3-D numerical models are now capable of
55 simulating fault networks at the rift scale; however, there are few observational data sets of the same
56 scale to test the predictions of these models and, therefore, help refine them (e.g. Naliboff et al., 2020;
57 Pan et al., 2021).

58 Supervised deep learning allows us to map faults in seismic reflection data (e.g. Wu et al.,
59 2019; Mosser et al., 2020; Wrona et al., 2021a), but up until now many of these studies have laid the
60 foundation by focusing on detecting faults rather than studying the geometry of these faults. In this
61 study, by applying supervised deep learning to newly-acquired broadband 3-D seismic reflection data

62 imaging much of the northern North Sea rift (161 km wide in E-W, 266 km long area in N-S, 0-20 km
 63 deep), we map the fault network associated with a continental rift basin at an unprecedented level of
 64 detail. Using manually labelled data (<0.1% of data volume), we train a deep convolutional neural
 65 network (U-Net) to predict faults in our data set. The predicted score ranges from 0 (no fault) to 1
 66 (fault). Based on this score across the entire 3-D seismic volume we employ a second workflow to
 67 extract the normal fault system as a network (a set of nodes and edges) allowing us to investigate the
 68 architecture and growth of this extremely complex system consisting of thousands of intersecting
 69 faults.

70

82 respectively. C Regional interpretation of the structure of the northern North Sea after Færseth (1996).

83 2. GEOLOGICAL SETTING

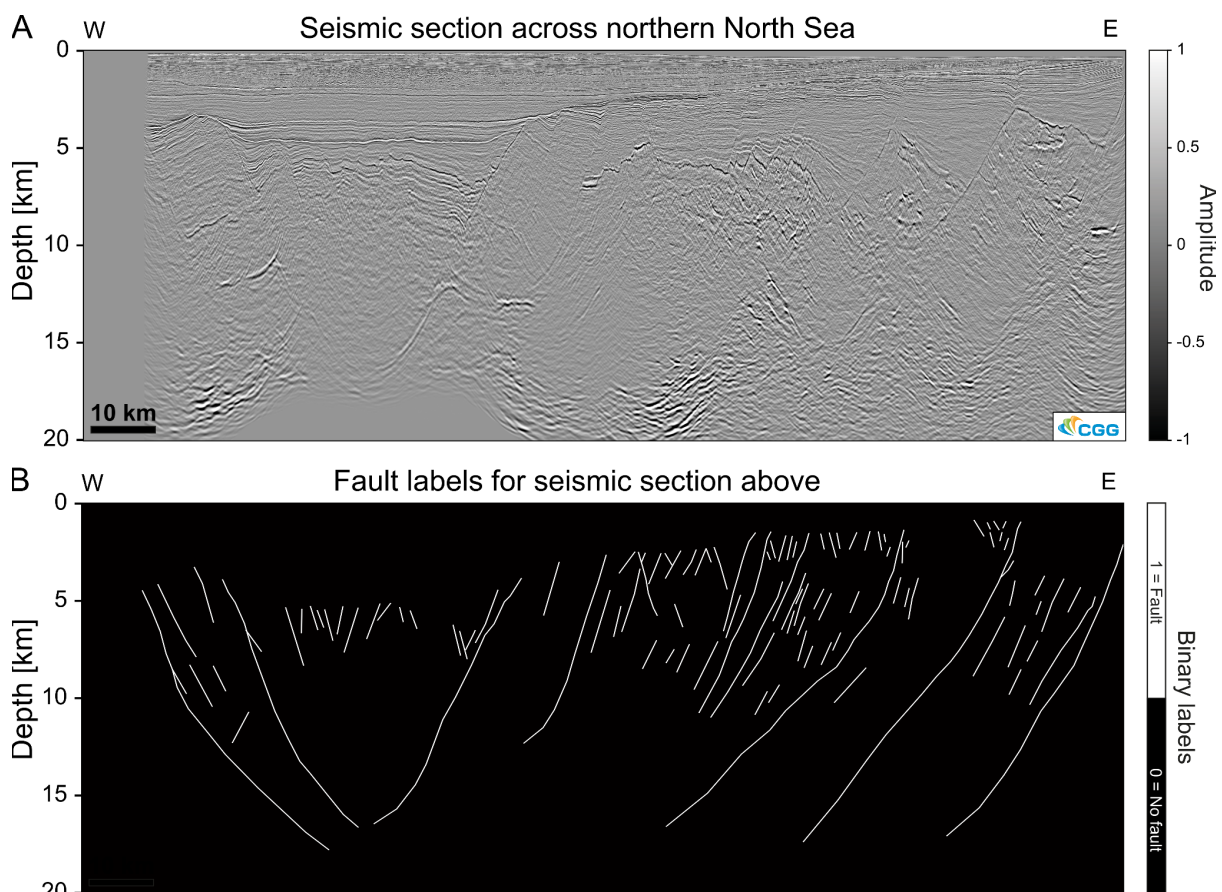

84 The study area is located in the northern North Sea (Fig. 1), where continental crust consists of
85 10–30-km-thick crystalline basement overlain by as much as 12 km of sedimentary strata deposited
86 during, after, and possibly even before periods of rifting in the late Permian–Early Triassic (rift phase
87 1) and Middle Jurassic–Early Cretaceous (rift phase 2) (e.g. Whipp et al., 2014; Bell et al., 2014;
88 Maystrenko et al., 2017). The extension direction of these two phases has long been debated. Whereas
89 most studies agree that the late Permian–Early Triassic rifting was driven by E-W extension (e.g.
90 Færseth et al., 1997; Torsvik et al., 1997), Middle Jurassic–Early Cretaceous rifting has been
91 associated with both E-W (e.g. Bartholomew et al., 1993; Brun and Tron, 1993) and NW-SE
92 extension (e.g. Færseth, 1996; Doré et al., 1997; Færseth et al., 1997) (Fig. 1B). This debate is further
93 complicated by the fact that some of the largest normal faults on the Horda Platform developed during
94 rift phase 1, but were subsequently reactivated during rift phase 2 (e.g. Whipp et al., 2014; Bell et al.,
95 2014). The crystalline basement underlying the sedimentary strata formed by terrane accretion during
96 the Sveconorwegian (1140–900 Ma) and Caledonian (460–400 Ma) orogenies (Bingen et al., 2008).
97 Several studies argue that this structural template, in particular the ductile shear zones, controlled the
98 location, strike, and overall pattern of rift-related faulting in the overlying sedimentary successions
99 being reactivated as normal faults, or by limiting the along-strike propagation of faults (e.g.
100 Fazlikhani et al., 2017; Phillips et al., 2019; Osagiede et al., 2020; Wiest et al., 2020).

101 3. DATA & METHODS

102 3.1. 3-D seismic reflection data

103 In this study, we use one of the largest offshore 3-D seismic data sets ever acquired, which
104 images a large part of the northern North Sea rift across an area of 35,410 km², and with excellent
105 depth-imaging down to 22 km (i.e., the middle-to-lower crust) (Figs. 1, 2A, 3). The data set was

106 acquired using eight, up to 8-km-long streamers that were towed ~ 40 m below the water surface. The
107 broadseis technology used for recording covers a wide range of frequencies (2.5-155 Hz), providing
108 high-resolution depth imaging. The data were binned at 12.5×18.75 m, with a vertical sample rate of
109 4 ms. The data was 3-D true amplitude prestack depth-migrated. The seismic volume was zero-phase
110 processed with SEG normal polarity; i.e., a positive reflection (white) corresponds to an acoustic
111 impedance (density \times velocity) increase with depth. More details on data acquisition and pre-
112 processing steps are provided by Wrona et al., (2019, 2021a).

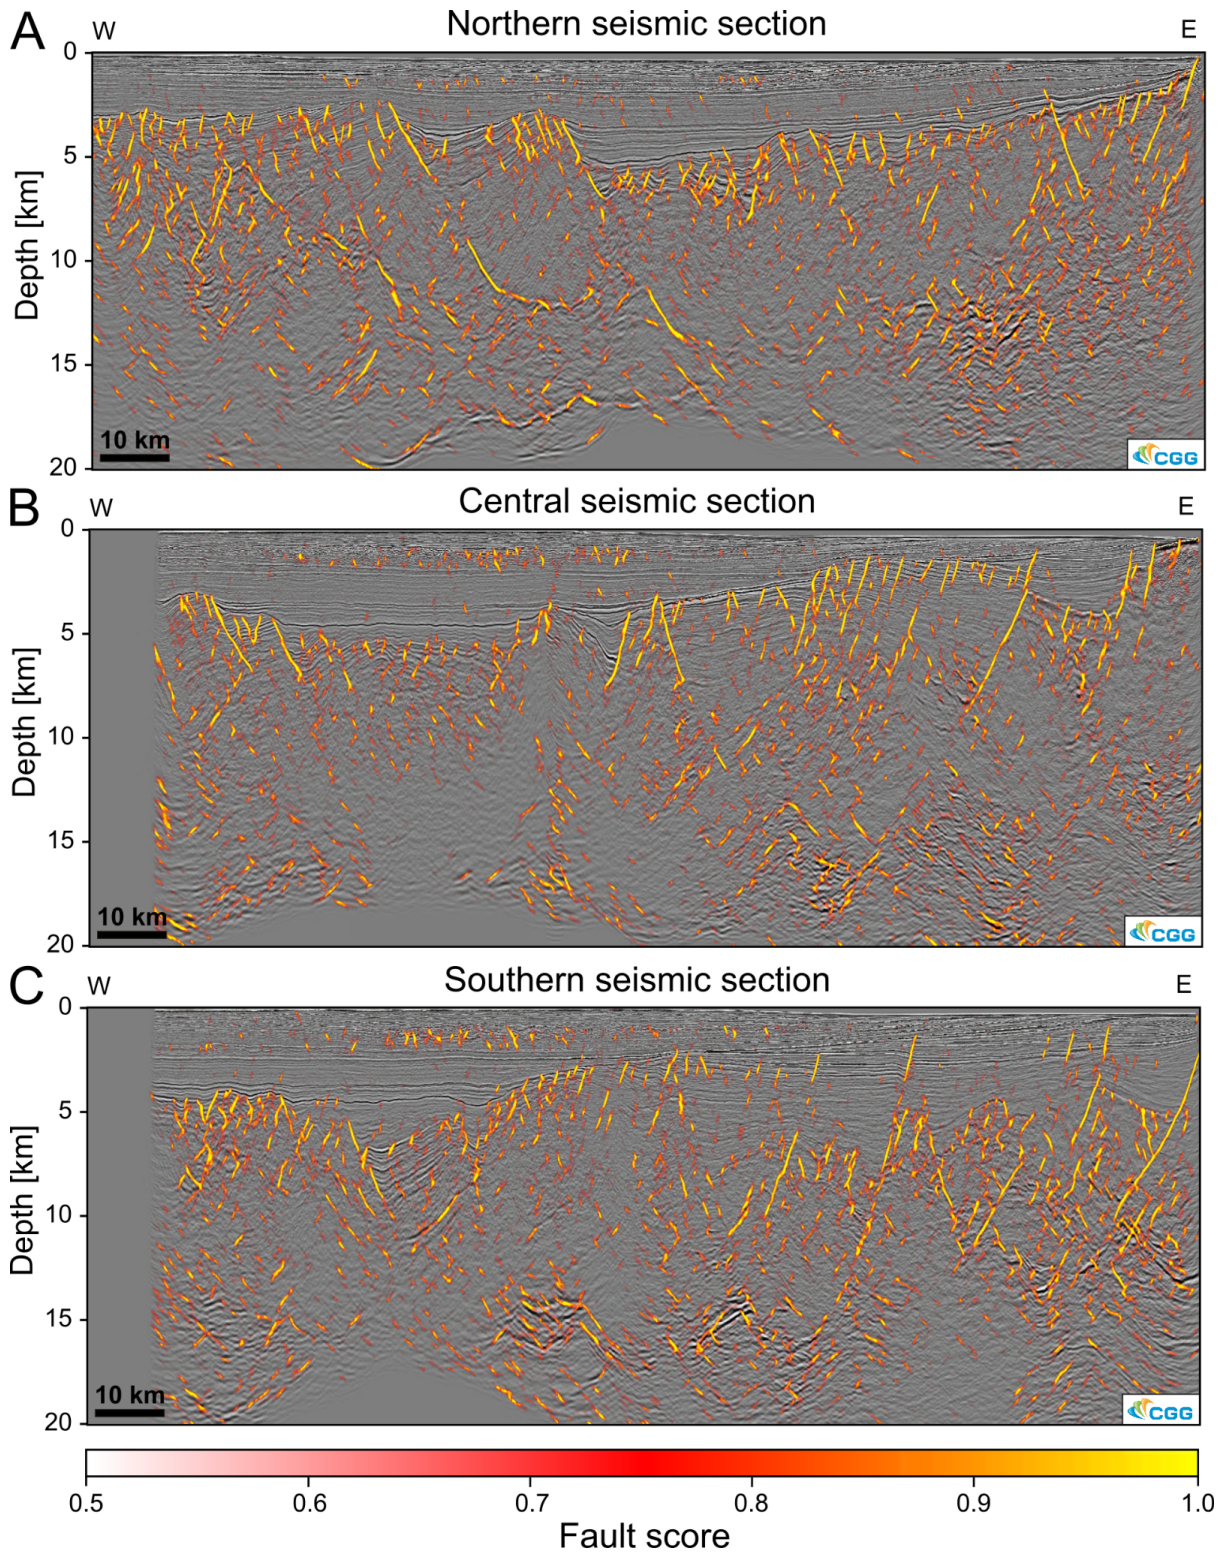

113 **Figure 2:** **A** Example seismic section across the northern North Sea. Amplitudes are scaled for
114 machine learning **B** Example of fault interpretation of the section used to train a deep convolutional
115 neural network for fault prediction.
116

117 3.2. Deep learning

118 Deep learning describes a set of algorithms and models, which learn to perform a specific task
119 (e.g. fault interpretation) on a given data set without explicit feature engineering (e.g. the calculation
120 and calibration of seismic attributes, such as coherence or variance). Deep learning allows the

121 derivation of a fault score volume that highlights normal faults within a 3-D seismic volume. This
122 approach requires that a large number of examples of faults and unfaulted strata are labelled in the
123 training seismic data. We extract 80,000 such examples (2-D squares of 128×128 pixels) from 22
124 interpreted seismic sections oriented perpendicular to the N-trending rift (Figs. 1A, 2). Note that these
125 seismic sections only constitute <0.1% of the entire 3-D seismic volume. Next, we split these
126 examples into three groups; one set for training (80%), one for validation (10%), and one for testing
127 (10%). We use the first of these to train a deep convolutional neural network (U-Net) designed to
128 perform image segmentation tasks (Ronneberger et al., 2015). Using the validation set, we track the
129 accuracy and loss of the model during training and stop once the validation loss does not decrease
130 further, [resulting in a final binary accuracy of 0.83 and F1-score of 0.76 \(see Wrona et al., 2021a\)](#).
131 Finally, we apply the model to the entire 3-D seismic volume to derive a fault score volume (Figs. 3,
132 4), an attribute, which ranges from 0 (no fault) to 1 (fault). All details of the workflow and the code
133 are provided by Wrona et al. (2021b, 2021a).

 140

Figure 3: Examples of seismic sections extracted from fault score volume of the 3-D seismic data set. Note that these sections were not part of the training data, but are actually 6.25 km away from the closest interpreted seismic section (see Fig. 1A). To show the correspondence between seismic data and fault score, we needed to define a cutoff value (0.5) below which the fault score becomes transparent and the seismic data becomes visible.

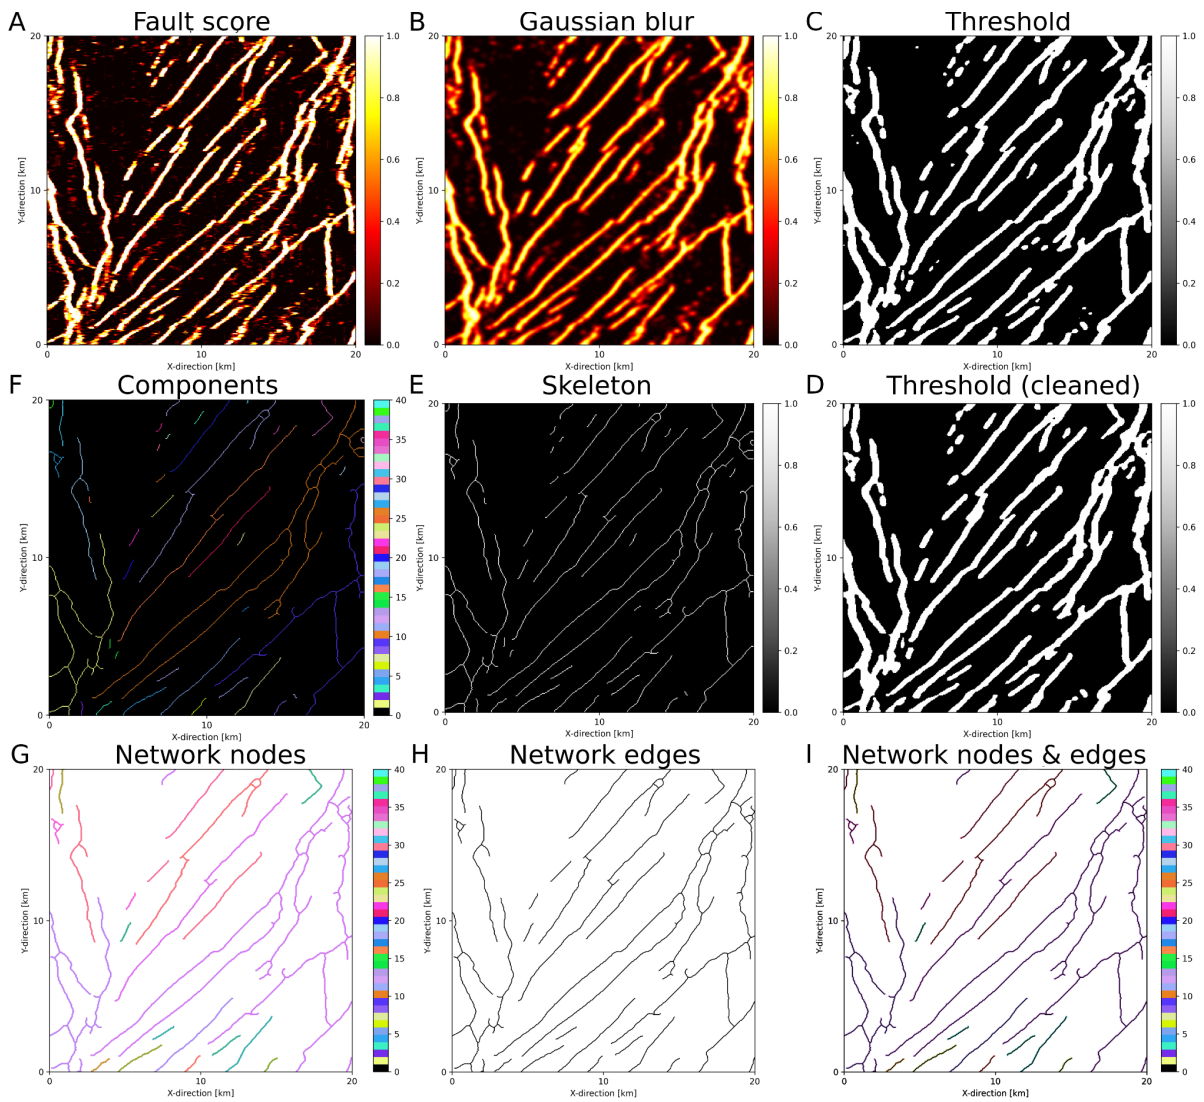

141
 142 **Figure 4:** Surface capturing tectonic faults extracted from fault likelihood volume. The surface was
 143 extracted 500 m below the Base Cretaceous Unconformity, where we observe a large number of
 144 faults, which were either formed or reactivated in the second rift phase. White rectangle shows the

145 area used for validation (Fig. 8) and the red rectangle indicates the area where we demonstrate our
 146 fault network extraction workflow (Fig. 6). Note that this figure shows to whole range of values of the
 147 fault score [0,1].

162 **Figure 7:** **A** Fault network extracted from BCU (Fig. 4D). Note the large areas with the same colours resulting from multiple faults being grouped into one
163 connected component **B** Fault network after removal of noise (i.e. small components). **C** Fault network after splitting junctions previously connecting
164 splaying and intersecting faults. Note that large connected components are split up and individual faults are highlighted by different colours.

165 3.3. Automated fault network extraction and analysis

166 Extracting a fault network from the 3-D volume allows us to perform a comprehensive
167 geometric analysis of the fault system using our fault analysis toolbox - fatbox (Wrona et al., 2022).
168 The basic idea is to describe a fault system in 2-D as a network (or graph), i.e. sets of nodes and edges
169 (Fig. 5). Each node marks a location along the fault and each edge connects two nodes. All nodes
170 connected to one another by edges are labelled as a (connected) component.

171 Our fault extraction workflow consists of these eight steps: (1) extract horizon, (2) Gaussian
172 blur filter, (3) thresholding, (4) cleaning, (5) skeletonization, (6) connect components, (7) add nodes
173 to graph, (8) add edges to graph and (9) split junctions. While applying it to our North Sea target
174 region, we first attempt to capture as many faults as possible by extracting the fault score along a
175 horizon 500 m below Base Cretaceous Unconformity (BCU) (Fig. 1C). Here we observe a large
176 number of faults, which were either formed in the second rift phase, or formed in the first rift phase
177 and reactivated in the second rift phase (Figs. 4, 6A). Second, we apply a Gaussian blur filter to
178 increase lateral fault continuity (Fig. 6B), which allows us to extract long, geologically plausible
179 faults. Using a small filter ($\sigma=2$) results in local smoothing without connecting distant faults with one
180 another. Third, we apply a threshold of 0.35 to separate the faults from the background in the fault
181 likelihood (Fig. 6C). This threshold is a tradeoff, which balances capturing as many faults as possible
182 (lower values) and identifying clearly resolvable faults (high values). Four, we further restrict this
183 threshold and essentially filter these points by removing areas smaller than 25 pixels (Fig. 6D). Five,
184 we collapse the faults to one-pixel wide lines using skeletonization (Guo and Hall, 1992) (Fig. 6E).
185 Six, we label adjacent pixels in the image as connected components (Wu et al., 2009) (Fig. 6F). Each
186 component consists of pixels which are connected to each other. These components represent the
187 faults in the network. At this point, we can build our graph using these connected components of the
188 image (Fig. 6F). Each pixel belonging to a component becomes a node whereas edges are created
189 between neighbouring nodes (Fig 6G-I). This process results in a number of faults with splays,
190 junctions or intersections being grouped into one connected component (Fig. 7A). To correct this, we
191 split up junctions (nodes with three edges) based on the similarity of strike, i.e. aligned branches

192 remain connected (Fig. 7B,C). This final network is compared to the Base Late Jurassic horizon
193 mapped by Tillmans et al., (2021) (Fig. 8). Additionally, we perform the exact same workflow on ten
194 slices through the fault score volume (1-10 km depth) to capture 3-D fault geometries with depth (Fig.
195 9).

196 After extracting the fault system, we calculate a series of typical fault properties using our fault
197 analysis toolbox - fatbox (Wrona et al., 2022) (Fig. 10). First, we calculate the fault length as the sum
198 of the edge lengths of each component (Fig. 10B). Second, we calculate the strike along the fault from
199 neighbouring nodes (Fig. 10C). If we were to calculate the overall fault strike, we would overlook
200 along-strike variations in strike. If we were to calculate the strike as the orientation of each edge, we
201 would only obtain values of 0, 45 or 90°, because the nodes are closely spaced. Instead, we calculate
202 the strike from the 3rd degree neighbouring nodes (i.e. neighbours of neighbours of neighbours). This
203 assures a robust, high resolution fault strike calculation. Combining the fault length and strike, we can
204 generate a length-weighted Rose diagram (Fig. 10C). Finally, we calculate the fault density as the
205 fault length per area (Fig. 10D).

206 3.4. Comparison to conventional seismic interpretation

207 We can ask ourselves, “how good are our results compared to a state-of-the-art fault
208 interpretation from the same data set using conventional fault mapping techniques?” (Fig. 8). Tillmans
209 et al., (2021) map the Base Late Jurassic (base of syn-rift sediments associated with rift phase 2) on
210 the eastern flank of the North Viking Graben (see Figs. 1A, 4 for location) using a combination of
211 manual picking and auto-tracking on the same seismic dataset. This horizon is calibrated with 40
212 exploration wells, which provide direct constraints on the depth of the surface. Tillmans et al. (2021)
213 highlight the fault system by computing the variance attribute (Chopra and Marfurt, 2007) along the
214 horizon (Fig. 7A). On top of the horizon, we plot the fault network mapped from the fault score
215 extracted 500 m below the easily-mappable Base Cretaceous Unconformity (BCU) (Fig. 8B). This
216 visual comparison shows that while we are missing a few faults in the southwest of the map, we are
217 able to identify and accurately represent most of the faults identified by Tillmans et al. (2021). The
218 missing faults are either overlooked by our model (i.e. false negatives) or result from the difference in

219 the horizons that we compare: Base Cretaceous Unconformity (our study) versus Base Late Jurassic
220 (Tillmans et al., 2021).

252 4. OBSERVATIONS

253 Our fault extraction allows us to map a complex network consisting of 7983 individual faults
254 across an approximately 161 km-wide and 266 km-long area, covering 35,410 km² of the northern
255 North Sea rift (Fig. 7C).

256 4.1. Fault length

257 Faults vary in length by 3 orders of magnitude - from 50 m to 75.9 km, with some of the
258 longest faults (>30 km) extending from the Stord Basin and Bjørgvin Arch in the south to the Uer and
259 Lomre Terrace in the north (Fig. 10B). In cross-section, these faults have up to several kilometres of
260 displacement and bound rotated half-graben (e.g. Whipp et al., 2014; Bell et al., 2014) (Fig. 3B,C).
261 While we observe some long (up to 20 km) faults in the Viking Graben and Tampen Spur, most faults
262 (>90%) are closely spaced (< 5 km) and relatively short (<10 km long) (Fig. 10B).

263 4.2. Fault strikes

264 In map view, we observe a complex network consisting of a large number of variably trending
265 faults that display a broad range of intersection styles (e.g., oblique, perpendicular). These faults show
266 a large range of strikes, varying from NW-SE to NE-SW (Figs. 9, 10C). The length-weighted rose
267 plot shows that most faults strike NW-SE (light blue) or NNE-SSW (light orange), with a large
268 number showing intervening strike directions (Fig. 10C). This general divide occurs between
269 predominantly NW-SE-striking faults along the eastern part of the rift and NE-SW-striking faults in
270 the central and northwestern part of the rift. This divide becomes most evident when comparing faults
271 on the Lomre Terrace (NE-SW) to the adjacent Bjørgvin Arch (NW-SE), at least at the structural level
272 of the Base Cretaceous Unconformity (Fig. 10C).

273 4.3. Fault density

274 In map view, we observe large variations in fault density 500 below the BCU (Fig. 10D). While
275 dense networks of intersecting faults result in high density areas (e.g. Lomre Terrace, Bjørgvin Arch)
276 we observe low densities in the Viking and Sogn Graben, where faults occur at greater depths (e.g.
277 Fig. 9C).

278 4.4. Vertical continuity

279 The faults extracted at different depths are variable in their vertical continuity (i.e., fault height;
280 Fig. 8). Whereas some faults, in particular in the Stord Basin, the Tampen Spur, and the Magnus
281 Basin show parallel fault traces from 1 to 10 km depth (Fig. 9A), we also observe a large number of
282 faults that occur only at shallower (1-5 km) or at greater depths (6-10 km) (Fig. 9B, C). Upon closer
283 inspection, we observe that the faults, which occur continuously between 1-10 km depth, e.g. in the
284 eastern Stord Basin and the Bjørgvin Arch, are typically large-displacement normal faults with tens of
285 kilometres spacing (e.g. Fig. 3B, C), whereas the other faults, which only occur between 6-10 km
286 depth (e.g. northwestern Stord Basin), are usually shorter and more closely spaced (a few kilometres)
287 (e.g. Fig. 9C).

288

289

290 5. DISCUSSION

291 5.1. Advantages of deep learning based fault interpretation

292 When comparing our results to conventional interpretation methods, we can ask ourselves
293 “what value does deep learning add?”. Here, we highlight the advantages of the supervised deep
294 learning-based fault interpretation workflow which we present in this study. First, we can predict
295 faults in a seismic section in a fraction of the time (5 seconds) required by expert interpreters (~10
296 minutes). These differences accumulate, in particular when interpreting such a large data set with
297 >22000 inlines. A conventional fault interpretation of such a large data set can take several months,
298 whereas a trained convolutional neural network can identify faults across the entire volume within a
299 day on a single GPU (GeForce GTX 1080 Ti). Note that this comparison does not include the time
300 required to label the training data (~2 days), train the initial model (~4 hours), fine-tune and select the
301 final model (days-months). Second, after identifying faults in seismic reflection data, they also need to
302 be mapped before we can perform the relevant fault analysis. Here we map the fault network using a
303 series of tools from computer vision and network analysis compiled in our fault analysis toolbox -
304 fatbox (Wrona et al., 2022) (Figs. 6, 7). Our automated workflow extracts the fault network in less
305 than five minutes compared to the several weeks to months that would have been required to

306 manually map the faults in this large data set. Furthermore, once extracted, we can immediately
307 conduct a number of typical fault analyses using predefined functions implemented in fatbox (Wrona
308 et al., 2022) (e.g. Fig. 10).

309 Third, conventional fault interpretations are often binary (fault vs. no fault), but deep learning delivers
310 a score ranging from 0 (no fault) to 1 (fault). Although this score is no true fault probability (see
311 discussion by Mosser and Naeini, 2022), the fault score nevertheless correlates with the visibility of
312 faults (i.e. faults, which are well-resolved by the data, are associated with higher fault scores). This
313 allows users to qualitatively select the faults that they want to analyze using a threshold (as done
314 herein).. This selection is particularly useful for assessing the sealing potential of certain layers for
315 CO₂ storage and for predicting fluid flow during geothermal exploration. Fourth, seismic interpreters
316 typically focus on the largest faults, whereas our model performs the same prediction across the entire
317 data set irrespective of the size of the faults encountered. Fifth, given the same data, labels, model and
318 training, our model and results are fully reproducible, which is not the case for conventional fault
319 interpretations, where the interpreter has to make a myriad of decisions in the process of mapping a
320 fault network.

321 5.2. Complex fault system in the northern North Sea

322 Our study shows how to reveal the complex geometry of normal fault systems in 3-D seismic
323 reflection data using a combination of deep learning and automated fault extraction. We were able to
324 map an intricate network consisting of almost 8000 individual faults that cover an area approximately
325 161 km wide and 266 km long (e.g. Figs. 4, 6, 10). This fault network shows large variations in fault
326 length, strike and density, with extremely complex splays, junctions and intersections between these
327 faults (Figs. 7-11). As such, our work goes far beyond typical seismic interpretations in previous case
328 studies, which covered only a fraction of the rift (e.g. Duffy et al., 2015; Deng et al., 2017; Tillmans
329 et al., 2021), or regional studies that mapped <100 of the largest faults using primarily sparse, 2-D
330 seismic sections (e.g. Fig. 1B; Fazlikhani et al., 2017; Phillips et al., 2019).

331 5.3. Uncertainties during fault mapping

332 While there are several advantages to our approach, it is worth remembering the uncertainties
333 associated with mapping faults in seismic reflection data. First, seismic reflection data can only image
334 faults with displacement above the seismic resolution (and level of noise) of the data set. The seismic
335 resolution of our data set decreases from 15 m (vertical) and 30 m (lateral) around 3 km depth down
336 to 180 m (vertical) around 20 km depth (see Wrona et al., 2019; Tillman et al., 2021). Second, the
337 labels we use to train our model are derived from 22 interpreted seismic sections, which, like any
338 seismic interpretation, contains the expertise and biases of the interpreter (e.g. Bond et al., 2007, Bond
339 2015). Third, our current model has not been trained and is thus unable to distinguish between
340 different fault types (normal, reverse, strike-slip). We labelled all major faults in the training data,
341 which are predominantly normal faults (probably >99%). A handful of these normal faults may show
342 evidence of minor inversion, but they all remain in net-extension, i.e. the hanging wall has moved
343 down relative to the footwall. While strike-slip faults are notoriously difficult to resolve in seismic
344 reflection data, as they show little to no vertical offset of reflectors, normal and reverse faults show
345 differing offsets, which neural networks could learn to recognize by correlating reflectors across the
346 fault. Machine learning models could thus be able to distinguish fault types based on their seismic
347 signature in the future. Fourth, the convolutional neural network that we trained achieves an accuracy
348 of 83%, implying that 17% of the data is misclassified (see Wrona et al., 2021). A closer inspection
349 reveals that 36% are false positives (i.e. faults that were overlooked) and 5% are false negatives (i.e.
350 faults that were misinterpreted) (see Wrona et al., 2021). Despite these limitations, the robustness of
351 our approach is evident when considering along-strike fault continuity across a large number of
352 different seismic lines (Fig. 10, 11).

353 5.4. Future research on automated fault mapping

354 Based on our work, we can identify three related areas for future research. First, conventional
355 neural networks predict a fault score from 0 to 1, which seems to correspond to the visibility of the
356 fault in the dataset. Bayesian neural networks, on the other hand, allow the prediction of true fault
357 probabilities (e.g. Mosser et al., 2020). Predicting fault probabilities in regional seismic data sets

358 could significantly accelerate the screening for and risk assessment of potential CO₂ storage sites (see
359 Wrona and Pan, 2021). Second, we currently map faults on seismic in- and crosslines, which may
360 contain redundant information regarding the faults. In the future, it may be advantageous to maximize
361 the diversity of the training set (i.e. different fault types or levels of noise) using uncertainty estimates
362 and active learning. -Third, in addition to predicting where faults occur, we can explore the prediction
363 of other fault properties, such as displacement, fault zone permeability or even the time when they
364 were active. This would significantly allow us to study the spatial and temporal evolution of fault
365 systems in high resolution at a regional scale. ~~Third~~Fourth, while our fault extraction workflow
366 currently focuses on mapping fault networks in a series of 2-D slices or horizons, we really need
367 freely-available methods to generate 3-D fault surfaces, which allow for complex fault splays,
368 junctions and intersections, as they could be applied to large 3-D seismic data sets, but also to
369 analogue and numerical models. ~~observed here.~~

370 6. CONCLUSIONS

371 This study shows that the combination of deep learning and network analysis applied to 3-D
372 seismic reflection data allows us, for the first time, to map almost 8000 normal faults across the entire
373 northern North Sea rift. These faults form an intricate network with complex relationships (e.g.
374 splays, junctions, intersections) including large variations in fault length (50 m to 75.9 km) and strikes
375 (NW-SE to NE-SW). As such, this work goes far beyond previous seismic studies by providing high
376 resolution fault maps at a regional scale in a fraction of the time required by conventional
377 interpretation methods.

378 ACKNOWLEDGEMENTS

379 We would like to thank The Norwegian Academy of Science and Letters (VISTA), The
380 University of Bergen and The Initiative and Networking Fund of the Helmholtz Association through
381 the project “Advanced Earth System Modelling Capacity (ESM), The Geo.X Network and Deutsche
382 Forschungsgemeinschaft (Projektnummer 460760884) for supporting this research. I. Pan
383 acknowledges the NUAcT fellowship for partially supporting the work. We are grateful to CGG, in

384 particular Stein Åsheim and Jaswinder Mann, for the permission to present this data and publish this
385 work. We thank Schlumberger for providing the software Petrel 2019© and Leo Zijerveld for IT
386 support.
