15 16 **Abstract**

17 Continental rifts evolve by linkage and interaction of adjacent individual segments. As rift
18 segments propagate, they can cause notable re-orientation of the local stress field so that
19 stress orientations deviate from the regional trend. In return, this stress re-orientation can
20 feed back on progressive deformation and may ultimately deflect propagating rift segments
21 in an unexpected way. Here, we employ numerical and analog experiments of continental
22 rifting to investigate the interaction between stress re-orientation and segment linkage. Both
23 model types employ crustal-scale two-layer setups where pre-existing linear heterogeneities
24 are introduced by mechanical weak seeds. We test various seed configurations to investigate
25 the effect of i) two competing rift segments that propagate unilaterally, ii) linkage of two
26 opposingly propagating rift segments, and iii) the combination of these configurations on
27 stress re-orientation and rift linkage. Both the analog and numerical models show counter-

28 intuitive rift deflection of two sub-parallel propagating rift segments competing for linkage
29 with an opposingly propagating segment. The deflection pattern can be explained by means
30 of stress analysis in numerical experiments where stress re-orientation occurs locally and
31 propagates across the model domain as rift segments propagate. Major stress re-orientations
32 may occur locally, which means that faults and rift segment trends do not necessarily align
33 perpendicularly to far-field extension directions. Our results show that strain localization and
34 stress re-orientation are closely linked, mutually influence each other and may be an important
35 factor for rift deflection among competing rift segments as observed in nature.

36

37 **1. Introduction**

38 Continental rifting involves brittle faulting and the formation of subsiding rift basins. In places
39 where individual rift segments are in proximity, they may interact and link when segments
40 propagate and the rift system matures (Morley et al., 1990; Nelson et al., 1992; Rosendahl,
41 1987). The propagation and linkage of formerly isolated rift segments resembles the
42 propagation and interaction of extension fractures on a micro-scale (e.g., Childs et al., 1995;
43 Willemse, 1997; Willemse et al., 1996; Fig. 1a). Indeed, analytical solutions and models have
44 been used to describe crack growth and to predict its direction (e.g., Macdonald and Fox,
45 1983; Mills, 1981). Such cracks occur in a variety of materials over a vast order of magnitude
46 in length scale from micro-scale cracks in glass to km-scale ridge interaction structures in
47 oceanic crust (Pollard and Aydin, 1984; Fig. 1a).

48

49 Propagation and interaction of individual rift segments occur in continental rift systems at
50 various styles and scales (Fig. 1b) and have been intensively studied over the years. The East
51 African Rift System (EARS) constitutes a narrow rift with an Eastern and Western branch that
52 propagate southward and northward, respectively (EARS; e.g., Ebinger et al., 2000; Morley
53 et al., 1990; Nelson et al., 1992; Bonini et al., 2005; Bosworth, 1985; Brune et al., 2017; Corti

54 et al., 2019; Glerum et al., 2020; Heilman et al., 2019; Koehn et al., 2008; Kolawole et al.,
 55 2018) comprising different sub-parallel deformed regions (inset Fig. 1c). On smaller scale,
 56 interaction of segmented grabens has been studied for example in in the Canyonlands National
 57 Park, Utah, a part of the Basin and Range wide rift (Allken et al., 2013; Trudgill, 2002; Schultz-
 58 Ela and Walsh, 2002), where various styles of graben interaction are attributed to the
 59 underlying strata (e.g., salt layer) or pre-existing weaknesses (Fig. 1d).

60

61
62

63 **Figure 1:** Similar linkage structures occurring at a vast range of spatial scales. a) Propagation and linkage of segments at
64 different scale from micro cracks in glass to linkage of oceanic ridge segments. Redrawn after Pollard and Aydin, (1984). b)
65 Rift-interaction types investigated in this study. c) Rukwa Rift and Malawi rift along the Western Branch of the East African
66 Rift System (EARS; inset). The two basins link obliquely via the Karonga Basin and form an i-type interaction zone. Rift axis
67 redrawn after Kolawole et al., (2021). WB: Western Branch; EB: Eastern Branch of the EARS. d) Rift-related linked graben
68 structures in the Canyonlands National Park, USA. Red rectangles mark areas with distinct interaction geometries (v-, i-, and
69 y-geometries; see b) and text for detail). Redrawn after Allken et al., (2013).

70

71 Structural inheritance is thought to control nucleation and strain distribution along newly
72 formed normal faults, as weak fabrics can precondition and weaken a heterogenous upper
73 crust (e.g., Collanega et al., 2018; Heilman et al., 2019; Kolawole et al., 2018; Morley, 2010;
74 Morley, 1999; Kolawole et al., 2021; Morley et al., 2004). Pre-existing weak fabrics may appear
75 as large shear zones (Daly et al., 1989), suture zones along adjacent basement terranes (Corti,
76 2012; Corti et al., 2007) or upper crustal fabrics. Resulting rift structures may form as initially
77 isolated segments that propagate along strike, interact and evolve into continuous zones of
78 deformation as they link (Nelson et al., 1992). Rift segments link through previously un-rifted
79 interaction zones resulting in a characteristic geometry that persists during later rift stages
80 (Nelson et al., 1992).

81

82 Recent strain accommodation in the Rukwa-North Malawi segment of the western branch of
83 the EARS (Fig. 1c) shows dominant dip-slip faulting parallel to the border faults (Kolawole et
84 al., 2018; Morley, 2010) driven by the reactivation of pre-existing basement fabrics (Heilman
85 et al., 2019). There, the concentration of seismicity in the SE and NW of the Rukwa and
86 Northern Malawi Rift, respectively suggest subsequent propagation and linkage of the rift
87 segments with a flip in the boundary fault polarity near the interaction zone (Heilman et al.,
88 2019 and references therein).

89

90 Pre-existing structures as well as fault interaction across multiple scales disturb the regional
91 stress orientation (Morley, 2010; Oliva et al., 2022). In return, stress re-orientations within
92 and adjacent to rift segments influence the style of progressive deformation. Ultimately, stress
93 re-orientation may even favor pure dip-slip behavior even for extensional faults with an
94 oblique orientation to the regional extension (e.g., Morley, 2010; Corti et al., 2013; Morley,
95 2017; Philippon et al., 2015). This interplay between pre-existing structures and local re-
96 orientation of the regional stress field affects how propagating rift segments interact. Under
97 favorable conditions, it may even cause deflection of propagating rift segments (Nelson et al.,
98 1992).

99

100 Rift propagation and segment interaction has been investigated by analog modelling studies
101 that examined linkage of two segments across a transfer zone (e.g., Zwaan et al., 2016;
102 Zwaan and Schreurs, 2017; Corti, 2012; Acocella et al., 1999; Bellahsen and Daniel, 2005).
103 Bellahsen and Daniel (2005) studied the control of existing faults on new fault growth under
104 multiphase extension. They suggested that pre-existing faults may disturb the local stress field
105 and impede linkage of newly forming faults which also occurs in natural examples of
106 multiphase extension (Duffy et al., 2015). Such stress deflections due to the vicinity of pre-
107 existing faults have been reported and studied in natural settings such as the North Malay
108 Basin, Thailand, (Tingay et al., 2006; Tingay et al., 2010). While analog experiments are an
109 effective tool to simulate mechanical (brittle and ductile) deformation processes, accessing
110 information about stresses is challenging. In contrast, numerical modelling experiments
111 provide direct access to element-wise stress tensors that can be interpreted in terms of stress
112 regimes and orientations under extension (Brune and Autin, 2013; Duclaux et al., 2020).
113 Despite the impact of stress distribution on faulting and rift segment interaction, only recently
114 numerical studies made use of it to gain further insights into rift evolution and continental
115 break-up (e.g., Glerum et al., 2020; Mondy et al., 2018). However, these studies mostly focus

116 on larger-scale deformation to evaluate stresses over the entire time span of rifting up to
117 continental break-up.

118

119 Here we use crustal-scale analog and numerical models to investigate rift propagation and
120 strain localization in early rifting stages when rift segments interact. Both types of models
121 document enigmatic rift segment deflection when two sub-parallel rift segments propagate
122 approximately in the same direction and compete for linkage with an opposingly propagating
123 segment. To understand the reason for rift segment deflection, we analyze the stress
124 distribution in early rifting stages and its interplay with strain localization that initiates above
125 pre-existing structures. Our experiments show that relatively simple rift segment interactions
126 can cause locally complex stress patterns that deviate from the regional stress field. Such
127 stress re-orientations occur in transient stages and can change over time and with progressive
128 deformation due to changes in material strengths.

129

130 2. Analog model

131 The presented analog modelling experiment shows unexpected features such as rift deflection.
132 It motivates our numerical study, and we use the analog model as a reference for examining
133 strain and stress distribution in numerical experiments.

134

135 2.1. Analog model setup

136 For the analog reference model, we use a simplified two-layer crustal scale setup with a brittle
137 and a viscous material to simulate upper crustal brittle faulting and lower crustal viscous
138 deformation, respectively. The base of the model consists of a set of alternating plexiglass
139 and foam bars which are compressed prior to the model preparation by two mobile sidewalls
140 (Fig. 2a). During the experiment the computer-controlled sidewalls extend and provide a
141 symmetric velocity gradient as the model base expands and the model vertically thins. For
142 monitoring the surface deformation evolution, we use a stereoscopic camera setup to take
143 top view photos and stereo image pairs every 60 s for quantitative deformation analysis by
144 means of 3D stereo Digital Image Correlation (Adam et al., 2005). The model was scanned
145 every 20 min in a medical XRCT scanner for gaining insights on internal model evolution.

146

147
148

149 **Figure 2:** Analog modelling setup. a) Top view of the experimental apparatus with two mobile side walls that extend
150 orthogonally. The entire model comprises an area of 80 x 30 cm and three viscous seeds are placed on top of the viscous layer
151 before sieving in the brittle sand layer. The central model part where propagating rift segments interact contains no seeds.

152 *b) Zoom in of the seed configuration into the analyzed model area (i.e., 30 x 30 cm). The two competing seed segments form*
153 *an intermediate angle of 50°. The model center contains an area with a radius of 10 cm where weak seeds are absent. c)*
154 *Sketch of the model cross section. The model setup consists of a brittle sand layer representing the upper brittle crust on top*
155 *of a viscous mixture of PDMS and corundum sand imitating the lower ductile crust.*

156

157 **2.2. Model geometry, rheological layering, and material properties**

158 For simulating upper crustal deformation, we use dry quartz sand with a bulk density of 1560
159 kg m^{-3} and an internal friction coefficient of 0.72 (Schmid et al., 2020a). For the lower viscous
160 model part, we use a quasi-Newtonian PDMS/corundum sand mixture (weight ratio 1:1) with
161 bulk density of 1600 kg m^{-3} and a viscosity of $\sim 1 \times 10^5 \text{ Pa s}$ (Zwaan et al., 2018). Hence, the
162 brittle-viscous setup has a density gradient that avoids density instabilities and spontaneous
163 upwelling of the viscous layer. The model features viscous rods placed on top of the viscous
164 model layer before sieving in the quartz sand (Fig. 2). These rods act as mechanically weak
165 seeds and localize faulting in the upper brittle model domain. The used seed configuration
166 includes three individual seed segments. The model includes a y-seed configuration with one
167 seed segment perpendicular to the extension direction on one side (hereafter called frontal
168 segment) whereas on the opposing side of the model center two obliquely placed seeds
169 (hereafter called rear segments) form an intermediate angle of 50° (Fig. 2; see also Fig. 1b,d).
170 The three seed segments hypothetically merge at the model center. However, we exclude
171 weak seeds in an area with a radius $r = 10 \text{ cm}$ around the model center to allow free
172 interaction of the propagating rift structures (Fig. 2b). The analog model comprises an initial
173 area of 80 cm by 30 cm and has a total thickness of 6 cm (each layer 3 cm) which represents
174 a 30 km thick continental crust. In accordance with the numerical setup, the effectively
175 analyzed model area is restricted to 30 x 30 cm. The mobile sidewalls move with an extension
176 velocity of 5 mm h^{-1} each (totaling in 10 mm h^{-1}), which results in a maximum extension of
177 40 mm at the final model stage after 4h.

178

179 **2.3. Analog model results**

180 In the analog model three different rift segments initiate above the weak seeds and propagate
181 toward each other. Thereby, the two rear segments compete for linkage with the frontal
182 segment. After 30 min (i.e., 5 mm extension; Fig. 3(i)), brittle deformation localizes along two
183 rift boundary faults forming the frontal rift segment. Rifting in the rear segments localizes first
184 along right-dipping rift boundary faults and after 60 min (i.e., 10 mm extension; Fig. 3(ii))
185 both rear segments develop a set of two conjugate rift boundary faults (Fig. 3a,b (ii)).
186 Interestingly, instead of advancing straight forward, the fault tips deflect and propagate away
187 from each other (Fig. 3b,d (ii)). This is partially due to the rift propagation over the area where
188 no seeds are present where rifting perpendicular to the extension direction is favored.
189 However, after 120 min (i.e., 20 mm extension; Fig. 3 (iii)) rift tips deflect and turn away from
190 one another. Rift tips deflect from an initially oblique orientation and rotate into an inverted
191 oblique direction (with respect to the extension direction). The frontal and the rear left rift
192 segment propagate further and, as they approach one another, form an en-echelon basin that
193 convergently overlaps with the frontal rift segment (Morley et al., 1990; Fig. 3b,d (iii)). After
194 180 min (i.e., 30 mm extension; Fig. 3(iv)), intra-rift faults develop in the frontal and left rear
195 rift segments. Note that strain rate is successively localized in the two fully linked rift segments
196 whereas the right rear segment experiences minor strain rate values (Fig. 3d (iv)). At the final
197 model stage (i.e., after 240 min and 40 mm extension; Fig. 3 (v)), the right rear segment
198 propagated minimally with a rift tip turned away from the linked segments (Fig. 3b,d (v)). The
199 fully linked frontal and left rear segments continuously accommodated displacement resulting
200 in deeper rift structures compared to the abandoned right rear segment (Fig. 3c,e (v)).

Distinct time steps (i.e., after 30 min and after every hour) show the model evolution. a) CT volumes of the investigated model domain at distinct time steps. White dashed lines indicate the brittle-viscous interface. b) Top views and line drawings indicating observable normal faults at the model surface. Red arrows indicate rift tips that deflect and turn away from one another. c) Topography from digital elevation models of the model surface. d) Strain rates obtained from 3D stereo DIC. Black dashed lines indicate positions of 3 transects through the CT volume. e) Rift transects A-A', B-B', and C-C'. White dashed lines indicate the brittle-viscous interface.

211

212 3. Numerical modelling

213 We perform a series of numerical models to investigate rift linkage interaction and to analyze
214 occurring surface stresses. Similar to the analog experiment, the numerical model consists of
215 a two-layer crustal setup with laterally homogenous material layers where boundary-
216 orthogonal extension with constant velocity is applied.

217 **3.1. Numerical model setup**

218 We use the open source, finite-element code ASPECT to solve the extended Boussinesq
219 equations of momentum, mass, and energy in combination with advection equations for each
220 compositional field (Gassmöller et al., 2018; Glerum et al., 2018; Heister et al., 2017;
221 Kronbichler et al., 2012; Rose et al., 2017; Glerum et al., 2020). Since the numerical models
222 are motivated by the analog model, the two setups are designed in a similar way. To this aim,
223 we employ a numerical setup where the rheologies of upper and lower crust are brittle and
224 ductile, respectively, and independent of temperature just like in the analog model. However,
225 the numerical models operate on the true scales of the continental crust over tens of
226 kilometers and millions of years, while the analog model is a scaled, cm-sized representation
227 that evolves on hour-scale. Additionally, the numerical setup applies maximum extension
228 velocities at the side walls and extension velocities at the base that linearly increase from the
229 center towards the model boundaries. In contrast, maximum extension velocities at the side
230 walls in the analog model are achieved via compression of a basal foam plexiglass setup (prior
231 to the model run) that extends homogeneously during the model run.

232
233 The presented numerical experiments cover a rectangular cuboid domain of 150 km width
234 and length in the horizontal x- and y-direction, respectively, and 30 km in depth along the
235 vertical z-axis (Fig. 4a). The entire model domain is divided into 1.53 million hexahedral,
236 second-order elements. For the upper 15 km of the model, we use a cell resolution of 750 m,
237 with an additional refinement at the uppermost km which yields near-surface elements with a
238 resolution of 375 m. The grid resolution for the lower 15 km of the model is 1500 m. At the
239 left and right model sides, we apply a symmetrically distributed outflow velocity of $\frac{1}{2} V_x = 5$
240 mm yr^{-1} , resulting in a total extension velocity of 10 mm yr^{-1} (Fig. 4a,b). After a total model
241 time of 4 My, the model has therefore experienced a total extension of 40 km. While V_x is
242 prescribed at the left and right model sides, V_y and V_z are left free. We compensate material

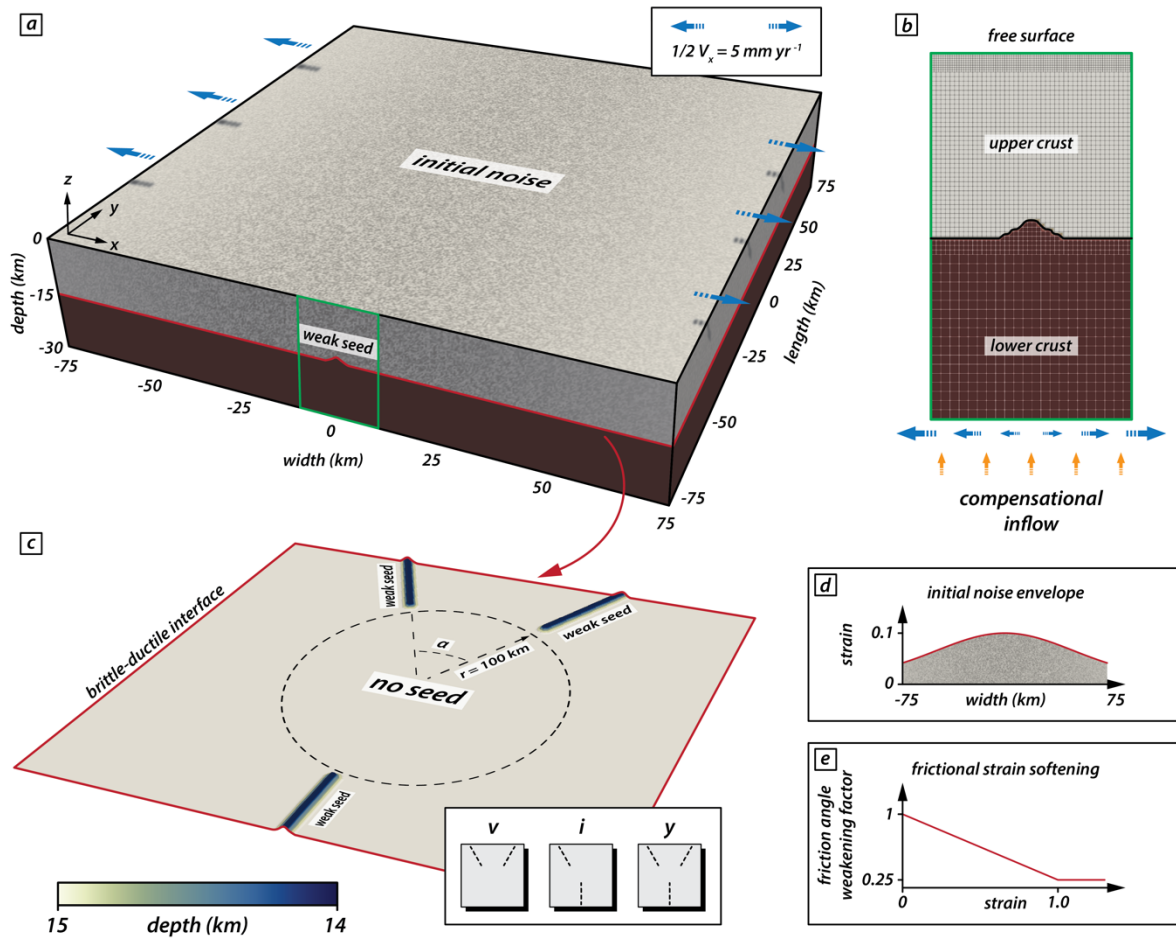

243 loss through the side boundaries by compensational inflow at the model base (Fig. 4b). The
244 front and back lateral boundaries allow for free slip and the top of the model features a free
245 surface boundary condition (Rose et al., 2017).

246

247 The model includes two rheological layers represented by compositional fields, namely a 15
248 km thick visco-plastic upper crust with a density of 2700 kg m^{-3} and a 15 km thick iso-viscous
249 lower crust with a density of 2900 kg m^{-3} and a constant viscosity of $1 \cdot 10^{20} \text{ Pa s}$. For the upper
250 crust, the viscous viscosity is fixed to $2 \cdot 10^{28} \text{ Pa s}$, such that plastic deformation is always
251 enabled. We introduce initial and dynamic mechanical weaknesses in the upper crust in two
252 ways. (i) Mechanically weak seeds: At distinct positions near the brittle-ductile interface, the
253 upper model layer is locally 10% thinned and the lower model layer elevates like the viscous
254 weak seeds in the analog model setup. These mechanical seeds weaken the upper crustal
255 strength and localize brittle faulting. Our experiments include three different seed
256 configurations: v, i, and y (Fig. 4c; see also Fig. 1b-d), where seeds within a central model
257 area (i.e., $r = 100 \text{ km}$) are absent. For each configuration, the rear seeds form an intermediate
258 angle of 10° , 30° , or 50° . (ii) Friction softening: For each element, an initial plastic strain value
259 of 0 (resulting in strong material) to 0.1 (weaker) is randomly assigned and reduces the
260 maximum friction angle of 26.56° by a maximum of 10%. This reflects the structural
261 heterogeneity of natural settings and allows for more randomized strain patterns in the central
262 model domain where the mechanical seeds are absent. The initial plastic strain noise is
263 distributed over the entire model width with an amplitude following a Gaussian curve parallel
264 to the extension direction that is repeated along the model length (y-direction, Fig. 4d). During
265 continuous extension, the effective friction angle linearly reduces to 25% of the maximum
266 friction angle (i.e., to 6.64°) for plastic strain between 0 and 1 while it remains constant at
267 6.64° for plastic strains > 1 (Fig. 4e). This corresponds to a reduction of the effective friction

268 coefficient from 0.5 to 0.12. The cohesion of the upper crust remains constant at $5 \cdot 10^6$ Pa for
 269 all conducted experiments.

Figure 4: Numerical model setup for iso-viscous models. a) The model domain comprises a volume of 150 x 150 x 30 km. Blue arrows indicate the applied boundary-orthogonal extension. The green rectangle indicates the position of the zoom-in in b). The red line indicates the initial depth of the brittle-ductile interface (as defined by the interface between the two rheological layers) indicated in c). b) Initial conditions and mesh refinement (arrows not to scale). c) Position and configuration of the mechanical weak seeds at the brittle-ductile interface. The setup comprises an area with radius $r = 100 \text{ km}$ where no weak seeds are present. Three different seed configurations refer to y -, i -, and v -models (see text for details). d) Initial amplitude of strain along the x -axis. The Gaussian distribution is constant along the y -axis; also see grey shade in a). Note that while the strain amplitude follows a Gaussian distribution, the location of the initial strain is random. e) Linear weakening with strain applied to the friction angle.

283 **3.2. Model limitations**

284 Just like the analog model (Sec. 2), our crustal scale two-layer numerical setup does not
285 comprise a lithospheric mantle layer and no asthenosphere. Further, the iso-viscous setup
286 does not account for a temperature-dependent viscosity. However, we focus on an early rifting
287 phase where the influence of the deforming mantle lithosphere can be neglected. The crustal-
288 scale setup strongly limits the computational effort for calculating deformation in 3D (Allken
289 et al., 2011, 2012; Katzman et al., 1995; Zwaan et al., 2016) and hence, our simplifications
290 allow for a higher model resolution; a necessity to depict early stages of rifting and the
291 coalescence of brittle deformation. Several alternative model runs have been performed
292 including a temperature- and pressure-dependent viscosity. Those tests reproduced first-order
293 features (i.e., strain rates, rift geometry and stress distribution) of the presented models in
294 this study, which further justified the choice of a simplified iso-viscous setup. Note that we
295 apply frictional softening as a function of strain within each cell. For simplicity, we do not
296 include normalization accounting for cell size (Lavie et al., 2000) nor viscoplastic
297 regularization techniques (Duretz et al., 2019; Jacquy and Cacace, 2020). Moreover, our
298 model does not include the influence of melting or magma intrusions nor sedimentation and
299 erosion.

300

301 **3.3. Post-processing**

302 Numerical models pose the advantage that they grant direct access to stress tensors of each
303 individual cell. We exploit this opportunity by investigating surface stresses to deduce the
304 stress regime and the effect of different seed configurations on stress distribution. ASPECT
305 provides post processors that calculate the magnitude and orientation of the maximum
306 horizontal stresses and the Regime Stress Ratio (RSR) (Glerum et al., 2020). This stress
307 regime characterization is calculated according to the scheme of the World Stress Map
308 (Zoback, 1992). The RSR value maps possible stress regimes to an interval between 0 and 3.

309 For isotropic and homogenous materials, the standard rules of Andersonian faulting are
310 applied (Anderson, 1905). For RSR values < 1 , faulting occurs in an extensional stress regime
311 whereas for RSR values > 2 compressive stress regimes generate thrust faults. Strike-slip
312 faults occur for values $1 \geq \text{RSR} \geq 2$. We extract data of maximum horizontal compressive
313 stress together with the stress regime and investigate them in areas where the strain rate
314 exceeds a threshold of 10^{-16} s^{-1} and deformation occurs. For visualization, surface stresses
315 from an originally unstructured grid are resampled on an equidistant grid.

316

317 **3.4. General model evolution of the reference model**

318 In this section we describe the numerical modelling results focusing particularly on the general
319 evolution of our reference model with a y-seed configuration and an intermediate seed angle
320 of 50° (Figure 5). At the early stage (i.e., after 0.5 million years), three distinct rift segments
321 develop above the initial seed positions bounded by a pair of conjugate rift boundary faults
322 (Fig. 5a (i)). This early stage is characterized by a symmetric evolution of the two competing
323 rear segments, which results in a symmetric subsidence inside of the graben structures (Fig.
324 5b (i)). For each rift segment, faulting activity is localized along the rift boundary faults. In
325 the central model domain, however, strain rates depict a more distributed deformation pattern
326 with multiple minor faults (Fig. 5c (i)). Note that the two rear segments propagate and show
327 curved fault segments that initially deflect and turn away from each other resulting in rift
328 segments with a curved geometry expressed in the topography (Fig. 5b (i)), similar to the rift
329 evolution in the analog model. Once they overlap with the propagating frontal segment, faults
330 symmetrically curve inwards and towards the frontal segment. The change from localized
331 strain rates above the seeds to distributed strain rate patterns in the central model domain is
332 best seen in transects (Fig. 5d (i)).

333

334 After the first million years, deformation has prominently localized along the left of the two
335 rear segments and along the frontal segment (Fig. 5a,c, (ii)). While deformation in the frontal
336 segment is localized along the rift boundary faults, inward migration occurred in the left rear
337 segment with developing intra-rift faults and only the left-dipping rift boundary fault active.
338 Similarly, the right rear segment shows faulting along the right-dipping rift boundary fault but
339 activity along intra-rift faults is lacking. In the central model domain, formerly distributed
340 deformation localized between the frontal and left rear rift segment (Fig. 5d (ii)). While strain
341 rates indicate a shift from a symmetric to an asymmetric deformation phase, topography is
342 still symmetric which implies that the shift is imminent and has not affected the topography
343 after the first million years (Fig. 5b (ii)).

344

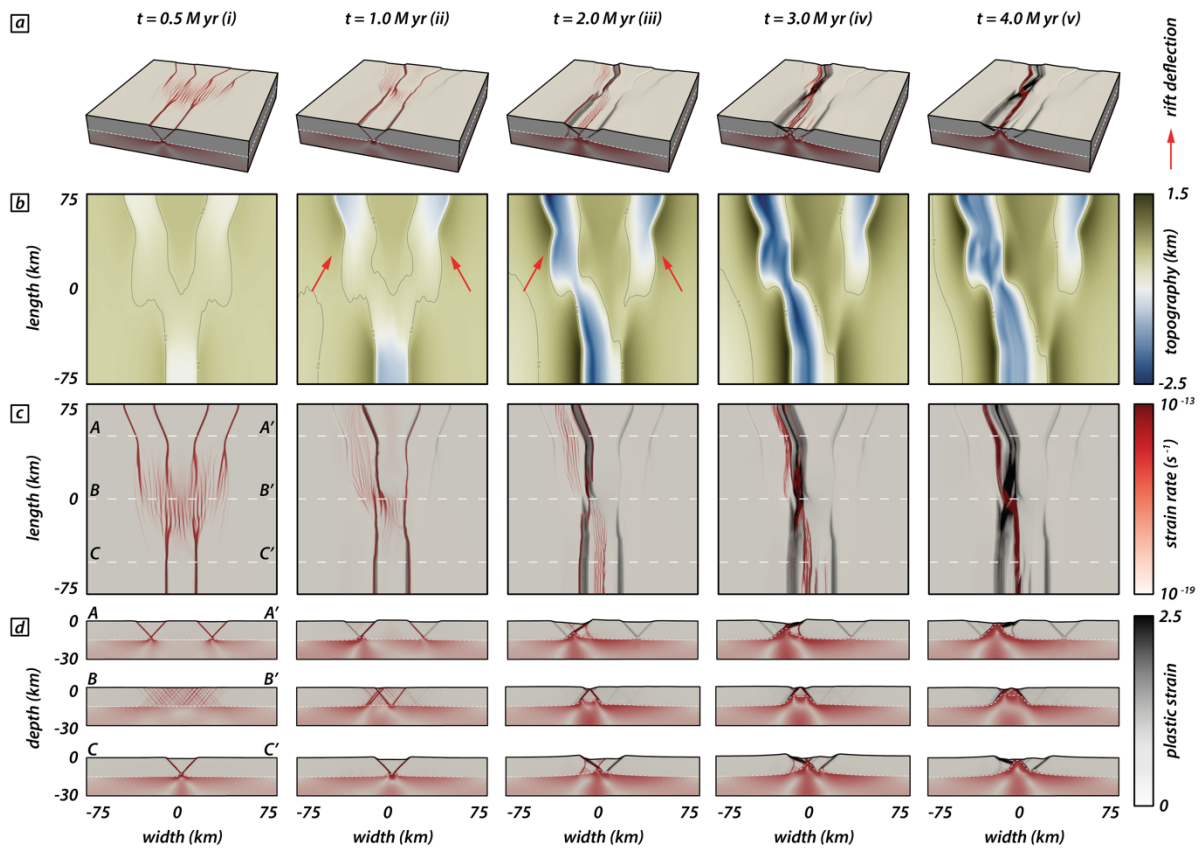

345 After two million years, deformation is entirely localized along the frontal and left rear
346 segment. Only the right-dipping rift boundary fault of the frontal segment is active and inward
347 migration led to a set of pervasive intra-rift faults (Fig. 5a,c (iii)). The left rear segment depicts
348 a similar deformation pattern as in the previous step, but strain mainly accumulates along the
349 left-dipping rift boundary fault causing an asymmetric graben geometry (Fig. 5d (iii)). Note
350 that, after two million years, fault activity along the right rear segment completely ceased with
351 no further strain accumulation visible (Fig. 5a,c,d (iii)). The topography reflects this completed
352 switch from a symmetric to an asymmetric deformation stage with enhanced subsidence along
353 the frontal and left rear segments and their linkage throughout the central model domain (Fig.
354 5b (iii)).

355

356 With ongoing extension, deformation subsequently localizes along the axial rift zone that links
357 the frontal and left rear segments (Fig. 5a,c,d (iv,v)) and faulting activity along rift boundary
358 faults ceases. The linked structure reaches maximum depth inside of the rift after three million
359 years. After four million years, however, the basin experiences minor uplift due to increase

360 upward motion of the underlying viscous material (Fig. 5d (iv,v)). Note that the basin depth
 361 of the right rear rift segment remains stable after two million years and does not experience
 362 further subsidence nor uplift.

363

364

365

366 **Figure 5:** Modelling results of the reference model documenting cessation of fault activity along the right rear segment while
 367 the left rear and frontal segments link. Distinct time steps show the model evolution. a) Model box showing logarithmic strain
 368 rates (red) and plastic strain (black) in the brittle and viscous model domain. White dashed lines indicate the brittle-viscous
 369 interface. b) Top views showing the model topography. Red arrows indicate rift tips that deflect and turn away from one
 370 another. Black lines refer to the zero-elevation height. c) Top views of the model showing strain rates (red) and corresponding
 371 plastic strain (black) at distinct model run times. White dashed lines correspond to the three rift transects A-A', B-B', and C-C'
 372 in subfigure d). d) Rift-axis perpendicular transects A-A', B-B', and C-C' parallel to the extension direction.

373

374 **3.5. Early localization patterns for v-, i-, and y-seeds**

375 To investigate the influence of different seed configurations, we compare v- (Fig. 6a-c), i-
 376 (Fig. 6d-f), and y-seed (Fig. 6g-i) configurations for different intermediate angles (i.e., 10°,
 377 30°, and 50°) at an early stage after 0.5 million years. y- and i-seed configurations provide a

378 setup where rift structures opposingly propagate towards the model center where rift linkage
379 eventually occurs. In contrast, rift structures in the v-seed configuration propagate
380 approximately in the same direction, which has a consequence on the overall strain rate
381 distribution.

382

383 The early stage in v-seed experiments (Fig. 6a-c) is characterized by a zone of localized and
384 distributed deformation in the rear and frontal part of the experiments, respectively. The
385 transition from localized to distributed deformation occurs where the two competing rift
386 segments deflect and rotate away from one another. Note that the fault deflection successively
387 decreases towards the left and right model sides, where faults strike perpendicular to the
388 extension direction. This is consistent with observations for experiments with a y-seed
389 configuration. However, there the two competing rear segments rotate back and eventually
390 bend towards the propagating frontal segment (Fig. 6g-i).

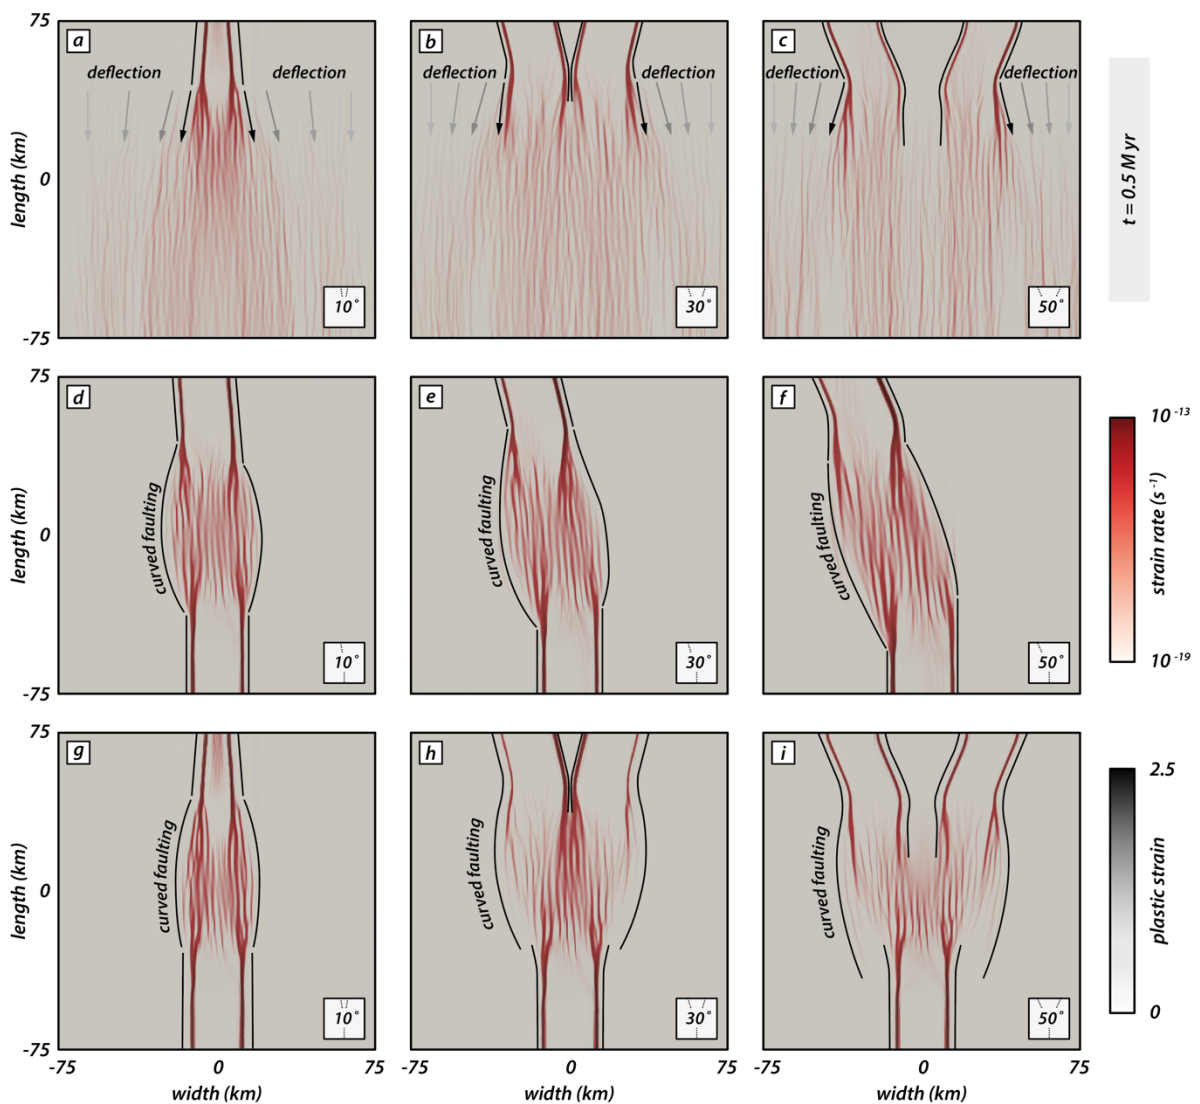

391

392 For experiment with a i-seed configuration (Fig. 6d-f) two opposingly propagating rift branches
393 form. Since the right rear segment is absent, both opposingly propagating rift segments link
394 in the model center where deformation is distributed onto intra-rift faults. The overall strain
395 rate field is localized, and no strain rate deflection occurs.

396

397 Models with a y-seed configuration (Fig. 6g-i) depict a strain rate pattern where deformation
398 is localized along rift boundary faults at the model margins where seeds are present and a
399 distributed en-echelon strain rate pattern in the model center. Note that for the model with
400 an intermediate angle of 10° the two competing rear segments are close enough resulting in
401 a zone where strain is localized along only one rift boundary fault per rift segment (i.e.,
402 outward-dipping faults with respect to the model box) that overlap and form a central graben
403 with minor intra-rift faults. For larger intermediate angles, two individual rift segments

404 (bounded by two rift boundary faults) form that propagate towards the model center. While
 405 the strain rate pattern due to the competing rear segments is identical for experiments with
 406 a y- and v-seed configuration, the additional frontal segment in experiments with a y-seed
 407 configuration causes localization of strain rates in a single rift branch bounded by two rift
 408 boundary faults. This contrasts with the v-seed configuration where strain rates in the frontal
 409 model domain occur distributed over the entire model domain (Fig. 6a-c).
 410

411
412

413 **Figure 6:** Types of rift segment linkages depending on the seed configuration at an early phase after 0.5 million years. Model
 414 top views show strain rates (logarithmic) and plastic strain in red and black colors, respectively. a-c) v-seed configuration for
 415 intermediate angles of 10°, 30°, and 50°. d-f) i-seed configuration for intermediate angles of 10°, 30°, and 50°. g-i) y-seed
 416 configuration for intermediate angles of 10°, 30°, and 50° (reference model). Black lines confine deformed areas. For models

417 *with a v-seed configuration (a-c), competing rift segments deflect away from each other resulting in a fan-shaped geometry.*
418 *Note that fault strike successively re-orientates into an orientation perpendicular to the extension direction towards the left and*
419 *right model sides. Curved faulting occurs in models with an i- and y-seed configuration (d-j) where rift segments interact.*

420

421 **3.6. Final rift geometry and localization patterns for v-, i-, and y-seeds**

422 The final model stage after four million years best illustrates differences in rift geometry
423 between the models with different seed geometry and an intermediate angle (Fig. 7). Rift
424 deflection is well visible in v-seed models (Fig. 7 a-c) and most prominent in experiments with
425 a larger intermediate angle (Fig. 7b,c). Above the seeds, two short individual rift segments
426 form bounded by a pair of conjugate rift boundary faults. However, as the rifts propagate
427 towards the model center, strain is mainly accommodated along the boundary faults that dip
428 towards the model center. Hence, the larger part of the model subsides uniformly and builds
429 a broad rift zone confined by two large boundary faults. When the two rift segments
430 propagate, they deflect and turn away from one another resulting in a gradually wider rift.
431 For intermediate angles of 30° and 50°, both competing rift segments show active faulting
432 along intra-rift faults in the rear model part, but a zone of continuous faulting activity has
433 developed along the right side of the rift.

434

435 Models with an i-seed configuration show a continuous and straight rift geometry for all
436 intermediate angles (fig. 7d-f). For an intermediate angle of 10°, the rift structure is nearly
437 orthogonal with respect to the extension direction. Note that most plastic strain is
438 accommodated along the left-dipping rift boundary fault (Fig. 7d). For larger intermediate
439 angles, the rift subsequently experiences more segmentation with small left stepping
440 segments towards the rear model part (Fig. 7e,f). Strain accommodation occurs mainly on the
441 right-dipping rift boundary fault for the frontal model part and switches to the left-dipping
442 boundary fault in the rear model part.

443

444

445 **Figure 7:** Influence of seed configuration on the final rift geometry after 4 million years. Strain rates (logarithmic) and plastic
 446 strain are indicated by red and black colors, respectively. a-c) v-seed configuration for intermediate angles of 10°, 30°, and
 447 50°. d-f) i-seed configuration for intermediate angles of 10°, 30°, and 50°. g-i) y-seed configuration for intermediate angles
 448 of 10°, 30°, and 50° (reference model).

449

450 The most prominent difference occurs in models with a y-seed configuration and various
 451 intermediate angles. For an intermediate angle of 10°, the final rift geometry resembles that
 452 of a continuous straight rift segment (Fig. 7g). Both competing rear seeds are close enough
 453 such that they build one rift system rather than two distinct branches. For y-seed models with
 454 a larger intermediate angle (Fig. 7h,i), two individual rear rift segments form and compete for
 455 linkage with the frontal rift segment. Plastic strain well illustrates the asymmetric strain

456 accommodation focused along the left-dipping rift boundary fault of the left rear segment,
457 whereas the right rear segment only experienced minor strain accommodation (Fig. 7h,i). In
458 both cases, high strain rates are localized in the axial rift zone and witness activity along the
459 linked frontal and left rear segments.

460

461 Note that all experiments with an intermediate angle of 10° (Fig. 7a,d,g) form continuous
462 straight rift segments, regardless of the seed configuration. Additionally, the final rift geometry
463 for y- and v-seed configurations for an intermediate angle of 10° is similar with a gently wider
464 rift in the frontal model part (Fig. 7a,g). In contrast, for i-seed configurations the rift width is
465 similar along the entire length with a minor lateral offset (Fig. 7d). Strain rates are localized
466 in the axial rift zone throughout the entire model length forking into two close zones in the
467 rear end where the competing seeds are located.

468

469 **3.7. S_{Hmax} evolution with progressive deformation**

470 In this section we present the distribution and orientation of the maximal horizontal
471 compressive stress component S_{Hmax} with progressive rift evolution and segment linkage. We
472 focus on models with v-, i-, and y-seed configurations and an intermediate angle of 50° (Fig.
473 8; see also supplementary Figures S1-S3) distinguishing between model zones with pre-
474 existing structures (i.e., weak seeds) and a central zone where material strength is isotropic.

475

476 Our models depict two distinct phases within the first two million years: early strain
477 accommodation over a wider model domain followed by strain localization and linkage of
478 propagating rift segments (see also supplementary Figures S4-S6). Consequently, we focus
479 on S_{Hmax} in the first two million years of deformation and its effect on rift propagation. Figure
480 8 shows the orientation of S_{Hmax} and the stress regime based on the common color scheme of
481 the World Stress Map (Heidbach et al., 2018). Note that S_{Hmax} orientation and the stress regime

482 alone do not suffice to discriminate between locations where stresses exceed crustal strength
483 and faulting occurs. Strain rate values provide further necessary information, and we use a
484 threshold of 10^{-16} s^{-1} that splits the model into locations of active deformation (i.e., $\geq 10^{-16} \text{ s}^{-1}$)
485 and tectonically inactive domains (i.e., $< 10^{-16} \text{ s}^{-1}$).
486

487

488

489 **Figure 8:** Interplay of rift localization and surface stresses. Top views show the distribution of the maximum horizontal
490 compressive stress component S_{Hmax} (not scaled to the magnitude) in models with an intermediate angle of 50° at early
491 deformation stages (i.e., until 2 million years). a-e) v-seed configuration. f-j) i-seed configuration. k-o) y-seed configuration.
492 Black colors refer to topographic elevation and red colors mark zones where strain rates exceed a threshold of $10^{-16} s^{-1}$. Color
493 coding for the stress regime marks normal, strike-slip, and thrust faulting in red, green, and blue, respectively, using the
494 common color scheme of the World Stress Map (Heidbach et al., 2018). Black arrows highlight stress deflection of S_{max} . Rose
495 diagrams show the distribution of S_{Hmax} orientation in zones where active faulting occurs (i.e., strain rate $\geq 10^{-16} s^{-1}$). Large
496 grey arrows for the y-seed configuration mark the change from a symmetric to an asymmetric S_{Hmax} distribution.

497

498 **3.7.1. Effect of S_{Hmax} re-orientation on rift propagation of competing rift** 499 **segments (v-seed models)**

500 Early stages in our numerical experiments are characterized by rift deflection and curved fault
501 traces in the model center where rift segments interact (see Fig. 6). Hereafter, we refer to
502 that phenomenon as arcuate faulting. Arcuate faulting mainly occurs in experiments with
503 larger intermediate angles ($>10^\circ$) in early stages (Fig. 6), especially if two competing rift
504 segments are present (v-, and y-seed configurations). Moreover, we have shown that
505 deflection of propagating rifts occurs when deformation is symmetrically distributed along
506 both competing rift branches. This is clearly visible for the v-seed configuration (Fig. 8a-e).
507 Assuming orthogonal extension and isotropic material properties, S_{Hmax} is expected to align
508 perpendicular to the extension direction producing pure dip-slip normal faults (Anderson,
509 1905). However, the model shows an immediate S_{Hmax} re-orientation at early deformation
510 stages (i.e., after 0.4 million years; Fig. 8a) from a N-S to a E-W orientation in the vicinity of
511 the underlying weak seeds such that dip slip faults are favored over oblique-slip faults with a
512 strike-slip component. With progressive extension (Fig. 8b-e), S_{Hmax} re-orientations
513 successively propagate into the isotropic zone without pre-existing structures, concomitant
514 with the rift propagation. Consequently, the position of the front where stress rotation occurs
515 propagates over time resulting in the deflection of the propagating rift arms away from each
516 other.

517

518 There is a distinct difference between stress deflection along weak structures and E-W
519 deflections of S_{Hmax} in zones where strain rates are below the set threshold of $10^{-16} s^{-1}$. The v-
520 seed configuration shows localized strain accumulation along one rift boundary fault per
521 segment (i.e., the outer one) resulting in a rift zone with a broad graben system that subsides
522 (Fig. 8e). S_{Hmax} re-orientation inside of the graben is in parts identical to the E-W orientation
523 of S_{Hmax} outside of the graben. While local S_{Hmax} rotations may be explained by small
524 differences in the maximum and intermediate principal stress components, such E-W stress
525 re-orientation in our model occurs systematically and suggest that this feature reflects the
526 influence of the strength anisotropy (Morley, 2010). The initial S_{Hmax} deflection near weak
527 structures locally favors dip-slip faulting but also has regional influence on the overall stress
528 regime.

529

530 **3.7.2. S_{Hmax} evolution in sub-parallel rift segments (i-seed models)**

531 During the early stage (i.e., after 0.4 million years, Fig. 8f), the distribution of S_{Hmax} resembles
532 the distribution from the v-seed configuration described in the previous section. Stress
533 deflection mainly occurs in zones where a weak fabric is present. S_{Hmax} values in the central
534 zone rotate by a small amount and reflect arcuate faulting (see Fig. 6). Since the two rift
535 segments propagate in opposing directions, linkage is efficient and localizes in a short time
536 (Fig. 8f-j). S_{Hmax} values deflect accordingly along propagating faults, which affects the entire
537 model domain. This deflection does not occur symmetrically on both sides of each rift segment.
538 Rather, it shows two distinct zones: 1) E-W orientations outside the rift deflect into a parallel
539 orientation near the rift boarder or 2) N-S orientations outside of the rift deflect into E-W
540 orientations near faults (Fig. 8j).

541

542 We find that S_{Hmax} orientations deflect gradually from E-W to N-S along abandoned rift
543 boundary faults where activity ceased (Fig. 8h-j; upper left and lower right model domain). In

544 contrast, S_{Hmax} re-orientations from N-S to nearly E-W towards active rift boundary faults are
545 followed by a rapid flip back to N-S along the faults (Fig. 8h-j; lower left and upper right model
546 domain). The two types of re-orientation seem to correspond with two types of deformed
547 zones. Where deformation is strongly localized along rift boundary faults, jumps in the S_{Hmax}
548 orientation occur. In contrast, zones where inward migration of fault activity activates intra-
549 rift faults, S_{Hmax} re-orientation occurs gradually.

550

551 **3.7.3. Rift arm competition and deflection (y-seed models)**

552 A prominent feature in our models with two competing rift segments is the deflection of rift
553 branches and arcuate strain rate patterns (Fig. 8a-e) in the model with a v-seed configuration.
554 Moreover, the i-seed configuration demonstrates a gradual S_{Hmax} re-orientation over a broader
555 pre-weakened zone due to formerly active boundary faults. One could therefore expect that
556 both features should occur in the model with y-seed configuration (Fig. 8k-o).

557

558 Indeed, early stages (i.e., after 0.4 million years; Fig. 8k) are characterized by a symmetric
559 stress field with re-oriented S_{Hmax} values near the two rear rift segments. However, in contrast
560 to the v-seed configuration, S_{Hmax} re-orientation also occurs near the frontal pre-existing weak
561 fabric along developing rift boundary faults. In the isotropic zone, S_{Hmax} values dominantly
562 show a N-S direction. The general N-S orientation reflects the regional stress field due to an
563 E-W extension as predicted by Anderson (1905) in isotropic areas, into which rift segments
564 have yet to propagate. With ongoing extension, all three rift segments propagate into the
565 isotropic zone and cause a re-orientation of S_{Hmax} (Fig. 8l). Note that after 0.8 million years
566 the stress re-orientation occurs symmetrically. This contrasts with the i-seed configuration
567 where S_{Hmax} values deflect into either an E-W orientation along active rift boundary faults or
568 gradually turn into a fault parallel direction over a broader weakened zone (see subsection
569 3.7.2.). The early symmetric stress distribution in the y-seed configuration model is

570 unarguably due to the symmetric seed configuration (see also Fig. 8a-e). At this stage, dip-
571 slip faulting along the competing sub-parallel rift segments is favored over oblique slip faults
572 as in models with a v-seed configuration. It is only after 1.2 million years, when fault activity
573 along the right rear segment ceases that deformation localizes along the left rear and frontal
574 segments and linkage intensifies (Fig. 8m). Successively, localization and linkage occur
575 coevally with a switch from a symmetric to an asymmetric stress distribution and resembles
576 more the stress distribution in the i-seed configuration model (Fig. 8f-j). The model state after
577 1.2 million years (Fig. 8m) also marks the switch from a symmetric to an asymmetric stress
578 distribution that was formerly dominated by the competing rear rift segments with dip-slip
579 faulting favored along the two competing rift segments (see also v-seed configuration; Fig. 8
580 a-e). After 1.2 million years the system is dominated by the linkage of two obliquely oriented
581 segments (i.e., i-seed configuration). Note that after 1.2 million years dip-slip faulting mostly
582 occurs along the competing rift segment that links with the opposingly propagating segment
583 whereas dominantly oblique slip faults occur along the abandoned rift segment where activity
584 ceases.

585

586 The symmetry switch is also visible in rose diagrams of stress orientations within the active
587 faulting zone (i.e., strain rate $\geq 10^{-16} \text{ s}^{-1}$). A dominantly N-S oriented S_{Hmax} distribution changes
588 to a bimodal distribution with a second E-W orientation (Fig. 8l-n). Similarly, bimodal S_{Hmax}
589 distribution is also visible in the experiment with an i-seed configuration but occurs earlier.
590 Since the experiment with an i-seed configuration is never in the state of an early symmetric
591 stress distribution linkage is facilitated and occurs earlier (Fig.8g-i).

592

593 **4. Discussion**

594 Despite the relatively simple setup of our experiments, the interaction of individual weak seeds
595 generates a complex evolution of linkage patterns. In the following we discuss the effect of

596 pre-existing structures on S_{Hmax} re-orientations and how, in return, stress re-orientation
597 influences rift propagation and rift segment linkage.

598

599 **4.1. Effect of pre-existing structures on rift segment propagation,** 600 **interaction, and S_{Hmax}**

601 Previous modelling studies demonstrated that pre-existing weaknesses may cause local re-
602 orientations of S_{Hmax} resulting in extensional faults with an oblique orientation to the regional
603 extension direction which exhibit pure dip-slip behavior (e.g., Morley, 2010; Corti et al., 2013;
604 Morley, 2017; Philippon et al., 2015). This contrasts the expected (assuming Andersonian
605 faulting theory) occurrence of faults with an oblique slip component above pre-existing
606 structures that are obliquely oriented with respect to the extension direction (Tron and Brun,
607 1991; Withjack and Jamison, 1986). Our S_{Hmax} analysis documents two types of stress re-
608 orientation, either gradually or by a jump along faults (Fig. 8i). A potential explanation for the
609 two types of stress deflection is that cessation of boundary fault activity (and subsequent
610 faulting activity along intra-rift faults) creates a broad zone of reduced crustal strength. Hence,
611 S_{Hmax} orientations successively re-orient along those formerly active faults and eventually
612 rotate into a N-S orientation along active intra-rift faults. In contrast, where faulting activity
613 is strongly localized along rift boundary faults, re-orientation occurs rapidly by a jump from E-
614 W to a N-S orientation. This suggests that formerly active faults act as a wider zone of pre-
615 weakened material, where stresses deflect sequentially rather than with a rapid jump. Similar
616 observations have been made in previous studies of numerical models (Gudmundsson et al.,
617 2010; Kattenhorn et al., 2000). These experiments suggest that earlier fractures lead to
618 subzones (within a broader damage zone), where stresses subsequently rotate away from the
619 regional stress field. Although our analog and numerical models do not feature elastic
620 deformation, they indicate that stress deflection is an ongoing process, even after elastic
621 material failure. Such a stress deflection further implies that stress orientations in rocks with

622 pre-existing weaknesses can substantially deviate from predicted orientations in isotropic
623 media (Anderson, 1905).

624

625 It has been proposed that early faulting and propagation in the Rukwa and North Malawi Rifts
626 (Fig. 1c) were guided by pre-existing basement fabrics (Heilman et al., 2019). This region is
627 further shaped by a flip in the boundary fault polarity in the present-day geometry within the
628 interaction zone between Rukwa Rift and North Malawi Rift (Bosworth, 1985). Our i-seed
629 models show identical geometries for increasing intermediate angles (Figs. 7h,i and S5), where
630 plastic strain near pre-existing structures is mostly accommodated along prominent rift
631 boundary faults that flip fault polarity from the frontal to the rear rift segment. This flip in
632 fault polarity occurs prominently in models with an intermediate angle $\geq 10^\circ$. We speculate
633 that the increasing obliquity of the southward propagating rift segment favors asymmetric
634 graben evolution with one dominant boundary fault accommodating a larger amount of strain.
635 In contrast to small intermediate angles (i.e., 10°), seed configurations with a higher obliquity
636 provoke local rotation of S_{Hmax} within the interaction zone into a strike-slip regime near the
637 subordinate boundary fault (Fig. S5). Hence, strain accommodation along incipient faults
638 within the dip-slip regime is favored. This facilitates propagation along those dominant rift
639 boundary faults and eventually defines the final rift geometry.

640

641 Kolawole et al. (2018) further propose two different types of strain accommodation at early
642 rift phases. Prominent strain accommodation localized onto a discrete and narrow zone along
643 large rift boundary faults (Style-1; sensu Kolawole et al., 2018) and faulting distributed over
644 a broader zone, where fault clusters may reflect pre-conditioning of the material (Style-2;
645 sensu Kolawole et al., 2018). With this perspective, jumps and gradual rotation of S_{Hmax}
646 orientations are comparable to Style-1 and Style-2 strain localization, respectively, as
647 proposed by Kolawole et al. (2018). Hence, the type of weakness (narrow discrete zone or

648 distributed cluster zone) should also be reflected by the stress re-orientation distribution
649 (Morley, 2010).

650

651 **4.2. Local S_{Hmax} re-orientation and its influence on rift segment interaction** 652 **and rift deflection**

653 A particular observation in our experiments with a v-, and y-seed configuration is that two
654 sub-parallel rift segments, which propagate approximately in the same direction deflect away
655 from each other at early stages. This is somewhat surprising as one would expect the two rift
656 segments to cut towards each other by minimizing fault length. The occurrence of rift
657 deflection in both analog and numerical experiments validates that the results are robust and
658 require discussing the role of S_{Hmax} re-orientation and how it influences rift segment
659 interaction.

660

661 We speculate that, while both rear rift segments in our y-seed models equivalently
662 accommodate strain in the early stages (i.e., when the overall stress distribution is symmetric;
663 Fig. 8), S_{Hmax} orientations are dominated by the influence of the two competing rear rift
664 segments that accommodate strain in equal parts. It is only after fault activity along one rear
665 segment ceases that deformation localizes along the active rear and frontal segments and
666 linkage intensifies. Strain localization and linkage occur coevally with a switch from a
667 symmetric to an asymmetric stress distribution resembling the stress distributions in v-, and
668 i-seed configuration models, respectively. The switch from a symmetric to an asymmetric
669 stress distribution in y-seed models also marks the switch from a system that was formerly
670 dominated by the competing rear rift segments (i.e., v-seed configuration) to a system that
671 is dominated by the linkage of two obliquely oriented segments (i.e., i-seed configuration).

672

673 In models with a v-seed configuration, however, the symmetric phase prevails and causes
674 coeval S_{Hmax} re-orientations and rift deflection that cause divergence of the two propagating
675 rift segments. A similar process of extensional segment interaction via stress rotation is known
676 from mid-ocean ridge settings: Pollard and Aydin (1984) argue that paths of two opposingly
677 propagating oceanic ridges weakly diverge due to shear stresses that divert propagating ridges
678 as they approach each other. Once the two ridges overlap, the stress field changes causing
679 convergence and intersection. Similarly, Nelson et al. (1992) describe interference of
680 compressional zones of propagating cracks diverting their tips before they overlap and turn
681 back toward another. In this respect, our models with a v-seed configuration suggest that
682 stresses also cause divergence of two rift segments that propagate approximately in the same
683 direction. However, overlap never occurs (as they propagate approximately in the same
684 direction) and hence, the two segments remain in a stress field that further diverts their paths.
685

686 Only in models with a y-seed configuration, compressional zones and rift deflection can be
687 overcome once the opposingly propagating rift segment links with one of the competing rift
688 segments. Linkage occurs after about the first million years, concurrently with rift deflection
689 and abandonment of the right rear segment (Figs. 9a and S6). Moreover, remaining activity
690 in the right rear segment depicts low strain rates along numerous arcuate intra-rift faults (Figs.
691 9b and S6). This suggests that linkage and rift abandonment are closely coupled and faulting
692 along the linked segments intensifies when the activity along the remaining rift segment
693 ceases. In addition, the left rear segment displays a rather asymmetric half graben geometry
694 (Figs. 5c,d, 7i and S4) with one prominent rift boundary fault accommodating a larger part of
695 plastic strain similar to our models with a i-seed configuration (see also Figs. 7e,f and S5).
696 Dominant strain accommodation occurs along the west-dipping rift boundary fault of the left
697 rear segment coinciding with jumps in the S_{Hmax} orientation (Fig. 8m-o). Our modelling results
698 show that stress deflection along rift segment tips is a mechanical consequence of the

699 interaction between weak zones and far-field stresses offering a potential explanation for
700 naturally occurring rift deflection. However, we must emphasize that complexities in natural
701 rift settings pose additional difficulties that require further investigations of stress orientations.

702

703 An example of rift deflection in nature has been described in the Main Ethiopian Rift.
704 Geophysical and geologic studies evidence that pre-existing structures controlled the
705 approximately 11 Ma southward propagation of the Northern Main Ethiopian Rift and its
706 contemporaneous westward deflection along the Yerer-Tullu Wellel Volcanotectonic
707 Lineament (YTVL; Abebe et al., 1998; Keranen and Klemperer, 2008; Muhabaw et al., 2022).
708 Only after the rotation of the principal stress direction at about 5-6 Ma (Bonini et al., 2005),
709 extension along the YTVL ceased and deformation localization along the Central Main
710 Ethiopian Rift became more favorable. Our models document similar rift deflections and
711 moreover indicate that, even in the absence of changing plate motions, rift segments deflect,
712 and may cease while competing rift segments prevail and strain further localizes.

713

714 For the Canyonlands National Park, it has been proposed that it is mainly the lateral offset
715 between pre-existing structures that explains the diversity of structures (Allken et al., 2013;
716 Fig. 1d). With larger offsets, interaction between adjacent rift segments is limited and
717 competing grabens persist and endure ongoing propagation coevally. We find that stresses,
718 in combination with the geometry of pre-existing structures, play an important role and that
719 they have a mutual effect on one another. Hence, stress distribution must be considered as
720 an important factor especially in early rifting stages when segments link and predetermine
721 strain localization during subsequent progressive rifting.

722

Figure 9: Summary plot showing the geometric similarity of rift segment linkage, deflection of competing branches and abandonment in analog and numerical models. a) Observed key features at the final stage of the analog model. b) Final strain and strain rate pattern in the numerical reference model. c) Conceptual interpretation of rift deflection and linkage based on our analog and numerical results (for details see text).

724 **5. Conclusions**

725 We present a series of analog and numerical rifting experiments. Our results suggest that,
726 even in a relatively simple iso-viscous two-layer crustal setup, pre-existing weaknesses
727 substantially disturb the regional stress pattern, which impacts rift propagation and the overall
728 rift evolution. The complex stress re-orientation is distinct for different seed configurations
729 (i.e., v-seed, i-seed, and y-seed) and closely interacts with the final rift geometry. The most
730 important findings of our study can be summarized as follows:

731

- 732 • Our numerical experiments reproduce rift segment deflection seen in our analog
733 models. This highlights the robustness of our results and their applicability to
734 interpreting rift segment propagation, interaction, and linkage in natural settings of
735 continental rifting.
- 736 • Pre-existing structures may control localization of rift segments that successively
737 propagate into previously undeformed areas. Consequently, stress re-orientation
738 initially occurs along pre-conditioned zones and propagates, coevally with rift segment
739 propagation and strain accrual, into formerly undeformed areas.
- 740 • Interacting stresses between two competing rift segments may cause outward
741 deflection of the propagating rift tips resulting in a successively broader rift geometry
742 along-strike.
- 743 • Outward deflection of competing rift segments is less prominent if an opposingly
744 propagating rift segment is present. With progressive extensional deformation, strain
745 accrual along one of the competing rift segments prevails whilst faulting activity along
746 the other segment ceases. Coevally, the general stress orientation changes from a
747 symmetric to an asymmetric distribution indicating the onset of rift linkage.
- 748 • Our modelling results reproduce first-order structures of natural examples from the
749 East African Rift System and, on smaller scale, graben structures in the Canyonlands

750 National Park. The combined investigation of surface stresses and strain localization
751 provides an explanation for distinct rift deflection among competing rift segments and
752 rift linkage structures where ongoing deformation and stresses mutually affect each
753 other.

754

755 While changes in rift orientation are often used to infer changes in plate-motion, we
756 demonstrate that local stress field re-orientations can occur under constant plate motions.
757 Albeit on a smaller scale, implications from our observations corroborate findings from
758 previous studies (Brune; 2014; Duclaux et al., 2020; Gapais et al., 2000). Locally, stress and
759 strain can largely deviate from a regional, far-field pattern and instead represent local
760 deformation interference. In addition, the observed stress re-orientations change over time
761 indicating that stresses measured in natural examples may depict transient stages that change
762 with progressive deformation due to subsequent changes in material strengths (Morley et al.,
763 2004). This implication must be considered in processing local fault-slip data when interpreting
764 the evolution of rifts at any scale.

765

766 **Data availability**

767 Rheological measurements of the used analog materials are available in the form of open
768 access data publications provided by the GFZ Data Service (brittle materials: Schmid et al.,
769 2020a; Schmid et al., 2020b; viscous materials: Zwaan et al., 2018). The input files, custom
770 ASPECT plugins and post processing scripts used in this publication can be found in Zenodo
771 repository <https://zenodo.org/badge/latestdoi/610197324> (Glerum; 2023).
