Abstract. ~~The TROPospheric Monitoring Instrument (TROPOMI) onboard the Sentinel-5 Precursor (S-5P) satellite, launched in 2017, measures the total column concentration of the trace gas Carbon Monoxide (CO) daily on a global scale and at a high spatial resolution of $7 \times 7 \text{ km}^2$, improved to $5.5 \times 7 \text{ km}^2$ in August 2019. The TROPOMI observations show plumes of CO due to localized CO emissions from industrial sources and biomass burning. In this paper, we quantify these CO emissions for biomass burning by an automated algorithm, APE, to detect plumes and quantify the~~

~~This paper presents the Automated Plume Detection and Emission Estimation Algorithm (APE), developed to detect CO plumes from isolated biomass burning events and to quantify the corresponding CO emission rate using cross-sectional flux method. Furthermore, the influence of a constant and a varying plume height in downwind direction on emissions is investigated and algorithm uncertainties are quantified. The VIIRS- APE uses the CO product of the Tropospheric Monitoring Instrument (TROPOMI) aboard the Copernicus Sentinel-5 Precursor (S-5P) satellite, launched in 2017 and collocated active fire data in conjunction with the TROPOMI CO datasets is used to identify fires and the fire locations. Then of the Visible Infrared Imaging Radiometer Suite (VIIRS), the latter flying 3 min ahead of S-5P. After identifying appropriate fire events using VIIRS data, an automated plume detection algorithm using based on traditional image processing algorithms is developed and utilized to identify plumes. For these plumes, the selects plumes for further data interpretation. The approach is based on several thresholds which are tuned for data over the US on September 2020. Subsequently, the CO emission rate is estimated by the cross-section flux method at using cross-sectional flux method which requires the horizontal wind fields at the height of the plume. To infer proper wind fields from ECMWF reanalysis 5 data, we test three different plume heights. The first two are constant plume heights at a We consider a constant plume height at 100 m and an IS4FIRES injection height from at the injection height provided by Global Fire Assimilation System. And the last one is a varying (GFAS) and we simulate the plume height in downwind direction. A with a 3D Lagrangian model is used to simulate tracer particles where the source locations for the simulation are based on the VIIRS fire counts and IS4FIRES injection height. 3D velocities at 137 model levels (ERA5) are utilized to simulate tracer particles. We demonstrate the quality and validity of our automated approach by investigating biomass burning events and their emissions for Australia on Oct 2019 and the US on Sept 2020. A total of 110 and 31 individual fire plumes in Australia and the US, respectively were detected and their emissions estimated. The emissions were severely under-predicted and negative for 11 cases when based on. APE is configured to optimize performance of the~~

US and its performance is verified for observations over Australia and Siberia. APE identified 5562 fire clusters and only 1327 cases were deemed to have good TROPOMI CO data. 882 plumes were detected in 1327 cases and only 378 plumes were considered as 309 plumes were short and about 195 had multiple sources of fire in them. Finally, the emissions were estimated for 226 cases in 378 cases out of which 5 were further visually filtered leading to 221 cases. The constant plume height of at 100 m compared to emissions based on varying plume height. Furthermore, the effect of the changing plume height in downwind direction on the emission estimate compared to emissions from constant IS4FIRES plume height was minor as 124 cases are found to have emission variation less than 10%. However, we were able to identify several cases where the flux estimates become more reliable with varying plume height. Thus, the provides unacceptable emission estimates. The difference in emission estimates using a plume height at the GFAS injection height and using Lagrangian simulation, was found < 4% for Siberia but is significant for several cases for US and Australia. Therefore, APE will employ the simulated varying plume height in downwind direction is considered for the automated algorithm. The cross-section flux method is found to have an uncertainty of 38% in one of the idealized cases. However, overall uncertainty of the algorithm is difficult to quantify as conditions for each fire are unique. Finally, we provide a first estimate of the emission uncertainties. The assumption of a constant emission over the time of the plume formation and the spatial under-sampling of the CO column concentration by TROPOMI yields error < 20%. Mostly, an emission plume created by a burning and uncertainties in the GFAS injection height may cause errors < 100%. Errors in the wind data are considered to be significant but could not be quantified because of the lack of uncertainty information in the used wind fields.

1 Introduction

Carbon monoxide (CO) is an air pollutant and in high concentrations, it causes harmful health effects. Moreover, it is a weak an indirect greenhouse gas and an indirect contributor to increase in several greenhouse gases in the atmosphere (Spivakovsky et al., 2000). CO is produced mainly due to incomplete combustion. For example, biomass burning (Andreae et al., 1988; Watson et al., 1990), for example, Andreae et al. (1988); Watson et al. (1990) have showed that the biomass burning increases CO in atmosphere and Shi et al. (2015) quantified the total CO emissions from vegetation burning, fuel-wood combustion, and human waste for three in different tropical regions. Also, Granier et al. (2011); Crippa et al. (2018); Hoesly et al. (2018) show that the CO emissions due fossil fuel burning has been on increase increased since 2000. Additionally, CO emitted by localized sources at the ground leads to a prominent footprint in the atmosphere, namely plumes, due to its lifetime from days to several months (Holloway et al., 2000). Thus, it becomes essential to understand the effect of CO on air-quality and climate by measuring and quantifying it accurately on a global and local scales which helps to quantify CO emissions.

The TROPospheric Monitoring Instrument (TROPOMI) aboard the Sentinel-5 Precursor (S5P) satellite launched in 2017, monitors CO daily on global scale (Borsdorff et al., 2018) and at a high spatial resolution of 7×7 km², improved to 5.5×7 km² in August 2019. Rowe et al. (2022) compared the TROPOMI CO measurements to aircraft measurements for biomass burning plumes in 2018 and found that the difference between two measurements is about 7.2%. Furthermore due to TROPOMI Due to its high spatial resolution and the daily coverage of the TROPOMI CO Level-2 dataset, the CO emissions by cities (Borsdorff

et al., 2019a, 2020; Lama et al., 2020), wildfires (Schneising et al., 2020; Li et al., 2020; Magro et al., 2021; van der Velde et al., 2021) and industrial sources (Tian et al., 2021) have been quantified and studied. ~~Most of these~~ Rowe et al. (2022) compared the TROPOMI CO measurements to in-situ aircraft measurements for different biomass burning plumes in 2018 and found that the difference between the two measurements is about 7.2%. This shows that the TROPOMI CO measurements can be used to quantify the biomass burning events.

Furthermore, most of the above studies estimate CO flux on large-scale regions (Schneising et al., 2020; Magro et al., 2021; van der Velde et al., 2021) and mega-city scales (Borsdorff et al., 2019a, 2020; Lama et al., 2020). However, not many single point emissions are quantified from the TROPOMI CO dataset. Tian et al. (2021) showed CO emissions based on TROPOMI for single point industrial sources from India and China. ~~A similar approach has not been shown for~~ They were able to perform a statistical study for three years as the geo-location is known for the industrial source. A similar study to quantify emissions from single point biomass burning (fires) single-point sources using TROPOMI CO data has not been shown in the literature. ~~The as~~ geo-locations of the industrial sources in Tian et al. (2021) are known a priori, whereas the locations for fire events for fires are not known ~~in advance and are not fixed in time. The a priori. The geo-locations for fires can be detected using the~~ Visible Infrared Imaging Radiometer Suite (VIIRS) 375m thermal anomalies/active fire product (Schroeder et al., 2014) ~~can be used to detect single point sources.~~ The VIIRS instrument is aboard the joint NASA/NOAA Suomi National Polar-orbiting Partnership (Suomi NPP) satellites ~~-, which and~~ flies in the same orbit as S5P in loose formation with a temporal separation of 3.5 minutes between them. ~~The collocated~~ This short time difference helps in collocating observations of TROPOMI and VIIRS are presently used for cloud-clearing of the S5P methane data product (Lorente et al., 2021) and in a similar manner, the CO data and VIIRS active fire data product will be used in this study to identify the locations of fires for this study.

The CO plumes in the TROPOMI data can be used to estimate CO emission by ~~wild~~ fires and different methods are discussed in the literature, namely, the inversion methods coupled with Gaussian dispersion models (Krings et al., 2011; Nassar et al., 2017; Lee et al., 2019) or different Chemical Transport Models (CTM) (Brasseur and Jacob, 2017), Cross-sectional Flux Methods (CFM) (White et al., 1976; Beirle et al., 2011; Cambaliza et al., 2014, 2015; Kuhlmann et al., 2020) and integrated mass enhancement (IME) method (Frankenberg et al., 2016). The inversion coupled with a Gaussian plume model ~~is simple where~~ can be used for flux inversion of isolated single plume event assuming steady and uniform wind conditions. The method fits an analytically computed Gaussian plume is fitted to TROPOMI CO column observations. Here, wind conditions are assumed to be steady and uniform which might not be true for the fires. This can cause large deviations between the instantaneous plumes and the computed steady-state Gaussian plume. The method can only be applied to observations under very specific wind conditions (Varon et al., 2018). The IEM uses an empirical linear relation between the emission and the integrated mass in the observed plume that was established based on aircraft data (Frankenberg et al., 2016). Current implementations are only applicable for single emission events for methane plumes and no such relationship has been established for CO measurements in fires. Thus, we do not consider IME for the present work. The inversion methods using CTMs, such as Weather Research and Forecasting model coupled to Chemistry (WRF-Chem) (Grell et al., 2005), GEOS-Chem (Bey et al., 2001), and others can reduce uncertainties thereby predicting emissions more accurately. ~~However,~~ They can be applied to complex emission events, but the corresponding simulations are complex, computationally expensive and difficult to automate, in particular for a

large number of fires with different geolocations which is the objective of this study. The CFM is suited for the interpretation of isolated plumes but does not assume a particular plume shape. It needs comparatively less computational power and is easier to automate. It is based on the mass conservation of the pollutant transport in downwind direction of the plume. The CO emission is estimated from corresponding fluxes across different planes perpendicular to the direction of plume using the ~~the~~ wind velocity at the plume height. The plume height depends upon different aspects, namely, meteorology, emission height, etc (Brunner et al., 2019) and may not be explicitly available. Moreover, the CFM breaks down when diffusion is dominant, i.e, when the wind velocity is $< 2 \text{ ms}^{-1}$ (Varon et al., 2018).

The present work aims at developing an automated ~~plume-detection-and-emission-estimation-scheme-for-CO-flux-inversion-for-fires~~scheme to detect single and spatially isolated emission of biomass burning events on the spatial scale of TROPOMI observations and to estimate corresponding CO emissions. For this purpose, we employ and improve the CFM as it has the potential to be applied in an operational data processing. First, VIIRS fire data and satellite data are prepared for automated plume detection which is discussed in section 2.1. Plume detection algorithm from a single point source using VIIRS fire counts is the subject of section 2.2. Section 2.3 describes emission estimation using cross-sectional flux method where an appropriate choice of the plume height and the wind fields are discussed. The study results ~~will-be-deliberated~~are discussed in Section 3 and finally Section 4 concludes our study and sets recommendations for the future work.

2 Methodology

Figure 1 illustrates a high-level flowchart of ~~our Automated Plume detection and Emission estimation algorithm (APE).~~APE. Corresponding pseudo-code is given in Appendix B algorithm description 1. It is divided into three parts, namely data preparation, automatic plume detection, and emission estimation. During data preparation, the algorithm identifies single point fire sources from VIIRS 375 m active fire data product (Schroeder et al., 2014) and subsequently selects and extracts ~~a~~-TROPOMI CO data around ~~the located fire sources~~every located fire source. The plume detection algorithm searches for a plume in the extracted CO data which is required as an input for emission estimation. The emission estimation algorithm initially computes the background CO which is the usual observed CO concentration at that location without any CO emissions due to the fire. Subtracting the background allows us to obtain the enhanced CO which further is used to estimate the emissions by cross-sectional flux method. These three parts of the algorithm are discussed in the following sections.

2.1 Data preparation

2.1.1 Selection of fire events

Fire events ~~can-be-are~~ inferred from the VIIRS 375m active fire data product (Schroeder et al., 2014) provided by ~~LANCE FIRMS~~Fire Information for Resource Management System (FIRMS) which is operated by NASA ~~ESDIS's~~Earth Science Data and Information System, (<https://earthdata.nasa.gov/active-fire-data>). The data contains different parameters such as fire radiative power (FRP), temperature and the time of measurement defined at latitude-longitude coordinates which correspond

Figure 1. High-level flow chart of the APE algorithm.

125 to the center of a $375 \times 375 \text{ m}^2$ ground pixel. ~~Furthermore~~From now on, each of these latitude-longitude coordinates will be referred to as a fire count in this paper. Mostly, an emission plume created by ~~a burning in burning~~ a single VIIRS pixel cannot be detected by ~~Tropomi with a~~TROPOMI with its pixel size of 7×7 or $5.5 \times 7 \text{ km}^2$. ~~And only a cluster~~Only clusters of VIIRS fire counts can lead to a detectable CO plume in the observations. To identify ~~such appropriate fire~~ clusters, we employ the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) (Ester et al., 1996; Schubert et al., 2017) algorithm
 130 from the scikit-learn library (Pedregosa et al., 2011). It separates the areas ~~which are~~ densely packed with fire counts from the low ~~dense density~~ areas and has an ability to detect arbitrarily-shaped clusters. DBSCAN requires two inputs, first the maximum search radius, r_{max} , around a fire count and second the minimum number of fire counts within the area, n_{min} . r_{max} is set to 4 km which is approximately half of the TROPOMI pixel size. The minimum number of fire counts ~~have been has been empirically~~ set to $n_{min} = 10$. ~~Figure ?? illustrates the data selection of 63 clusters based on VIIRS fire counts on 6 October, 2019.~~
 135 For further analyses, we convert each cluster to a single point source using fire radiative power (FRP) as weights of the individual fire counts. This single point source will be referred to as fire source from now on and serves as an input to TROPOMI CO data preparation. ~~Fire counts on 2019-10-06. Cyan color depicts fire counts that were not clustered and black '+' markers represent a total of 63 clusters determined by DBSCAN algorithm.~~

2.1.2 TROPOMI CO data preparation

140 For the identified fire sources from VIIRS data, the corresponding TROPOMI orbit (~~See Table B1 for~~ L2 product version ~~1.03.02~~) is selected. Figure 2 illustrates the collocated information for ~~a data granule part of TROPOMI orbit number 10254~~ over Australia. The orbit is corrected for stripes (see Fast Fourier Transformation algorithm of Borsdorff et al. (2019b)). For each fire source, we extract a ~~41 × 41 pixel granule of TROPOMI CO data~~ data granule of 41×41 TROPOMI CO pixels centered around the source ~~by applying~~. ~~The granule size is minimum 220 km is chosen to capture the distance of the emission~~
 145 ~~traveled from the source to the granule edges within 6h with an average velocity of 5 ms^{-1} .~~ After extraction, two data quality filters ~~are applied~~.

DP-1 The maximum pixel size due to distortion in swath direction is ~~constrained~~restricted to < 12 km to avoid large pixel size and its variation within the granule. ~~The second data filter is based on number of pixels that satisfy the data quality value, (1) in the extracted 41×41 pixels granule and (2) in 7×7 pixels granule~~

150 DP-2 A sufficient number of CO pixels with data quality $q_a > 0.5$ (Apituley et al., 2018). $q_a > 0.5$ corresponds to clear-sky, clear-sky like and mid-level clouds observations. Within the entire data granule 80% of all pixels must fulfil this quality criteria. Additionally we require 85 % of 'good' pixels in an area of 7×7 pixels centered around the fire source. The data quality value (q_a) is given in the TROPOMI L2 product (Apituley et al., 2018) per ground pixel. If 80% and 85% ground pixels have $q_a > 0.5$ in more usable pixels around plume the better the plume can be disentangled from the atmospheric background (see discussion in Sec 2.3.1).

155

The threshold values are empirically determined for a reference data set from September 2020 over the US and verified for two other data sets over Australia and Siberia (see Tab. B1 in Appendix B for a detailed specification of the data sets). Finally, the ~~extracted 41×41 and 7×7 pixels granules, respectively, then the extracted CO granule is considered good.~~ The selected CO scene corresponding to a fire source is forwarded as an input to the plume detection algorithm.

160 2.2 Plume detection algorithm

~~Within~~ The next step of APE identifies plumes within each selected CO data granule, ~~we try to identify a plume~~. Kuhlmann et al. (2019) developed a plume detection algorithm based on statistical methods and Finch et al. (2021) used machine learning to detect plumes. A machine learning approach is not considered in the present study mainly due to non-availability of ~~gold standard data~~ data containing detected plumes and their sources for training. Instead, our plume detection approach is based on traditional image processing algorithms (van der Walt et al., 2014).

165

Using the extracted CO TROPOMI data, a plume is detected by a region-based segmentation algorithm where pixels with similar properties are clustered together to form a homogeneous region. One of the most commonly used and classic region-based segmentation algorithm is the 'marker based watershed transform method' (Beare, 2006; Gao et al., 2004). The CO column concentration represents metaphorically the altitude of a topographic map. Thus, the watershed algorithm segments the regions into valleys and mountains (CO enhancements) based on a given marker and a gradient map. In the following paragraphs, we describe the plume detection in more detail using an example.

170

The marker-based watershed algorithm in the scikit-image package (van der Walt et al., 2014) takes two inputs to segment an image, one is the 'elevation map' \mathbf{I}_{elev} gradient map' \mathbf{I}_{grad} where the changes in altitude are emphasized and homogeneous regions are dampened. The second input is a marker image \mathbf{I}_{mark} which provides the seed points referred by an integer label for the algorithm. The definition of both inputs is discussed in the following paragraphs.

175

We start with the extracted CO TROPOMI granule of a 41×41 pixel size $\mathbf{I}(i, j)$ with $i, j = 1, \dots, 41$. An example is shown in Figure 3(a). First, high frequency components or noise of the CO-image are reduced by a ~~Gaussian filter~~ 2D Gaussian filter with standard deviation $\sigma = 0.5$ (pixel), which was chosen empirically. The smoothed image is referred to as \mathbf{I}_s . From this image, the ~~elevation map \mathbf{I}_{elev}~~ gradient map \mathbf{I}_{grad} is computed using a Sobel operator (Sobel and Feldman, 1990; van der Walt

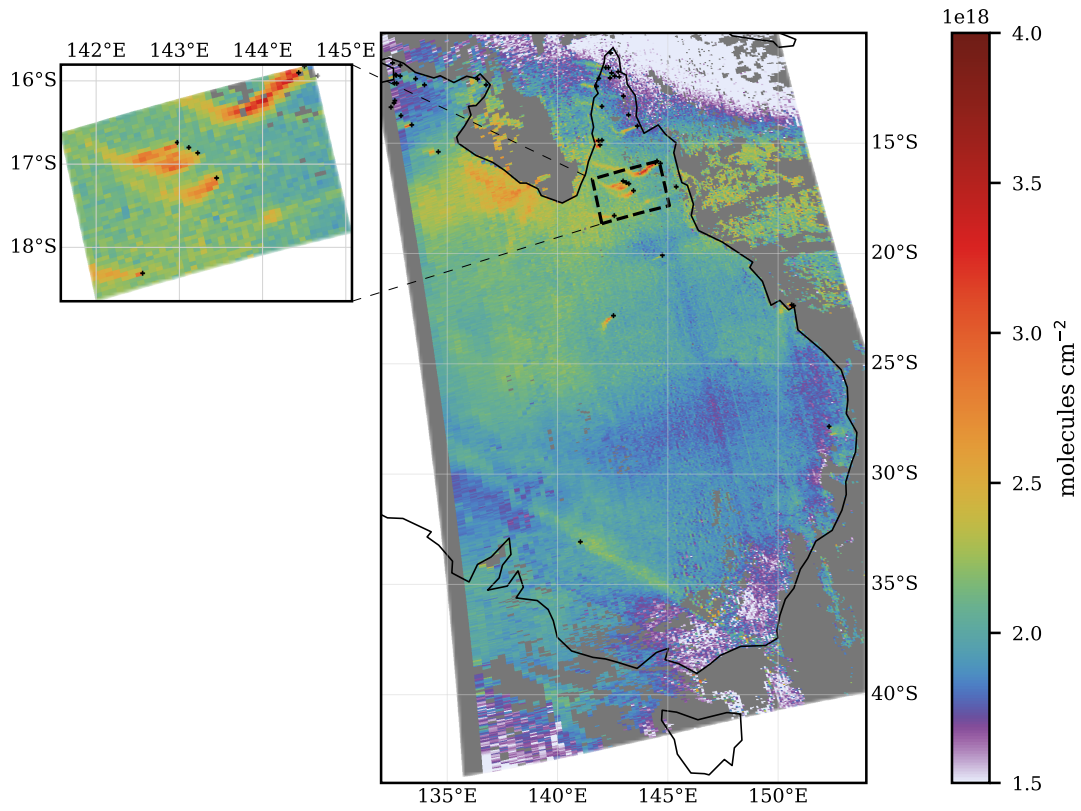

Figure 2. 49 detected fire sources represented by black '+' on 2019-10-06 overlapped with the TROPOMI level 2 CO data for orbit 10254. The dashed region represents a 41×41 pixel granule.

180 et al., 2014) **which is a discrete differentiation operator, computing an approximation of the gradient of the image to emphasize edges as shown below**

$$\underline{\mathbf{I}}_{\text{grad}} = \sqrt{\underline{\mathbf{G}}_x + \underline{\mathbf{G}}_y} \quad (1)$$

with

$$\underline{\mathbf{G}}_x = \begin{bmatrix} 1 & 0 & -1 \\ 2 & 0 & -2 \\ 1 & 0 & -1 \end{bmatrix} * \mathbf{I}_s \quad \underline{\mathbf{G}}_y = \begin{bmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{bmatrix} * \mathbf{I}_s, \quad (2)$$

185 **where * represents the convolution operator. Here, the gradient $\underline{\mathbf{I}}_{\text{grad}}$ emphasizes the edges of a plume as shown in Figure 3b.**

By default the marker image (\mathbf{I}_{mark}) is **initiated by-**

$$\underline{\mathbf{I}}_{\text{mark}}(i, j) = 0 \quad \forall \quad i, j = 1, \dots, 41$$

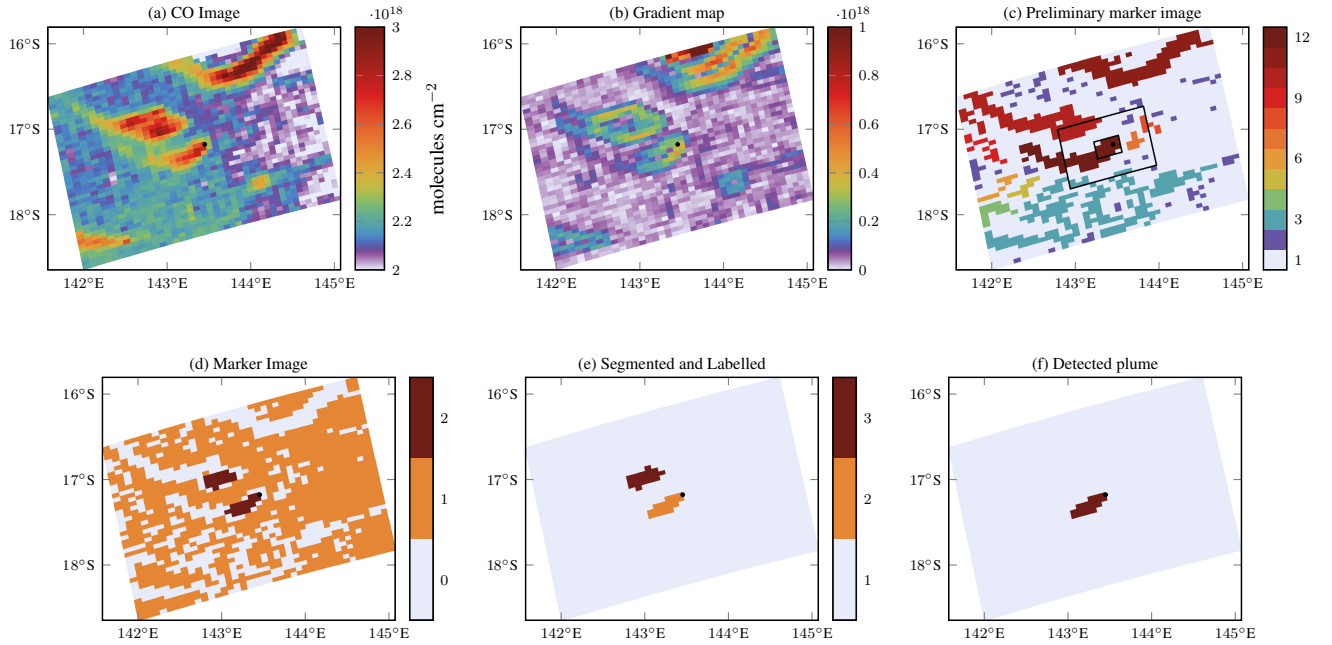

Figure 3. Plume detection algorithm. Figure shows different steps of the algorithm for an example plume for a fire [source](#) on 6th October 2019 in Australia.

Next, we define [initialized to zero and subsequently](#) two different seeds: $\mathbf{I}_{\text{mark}}(i, j) = 1$ are defined. One seed indicates regions which do not have a-CO enhancements and $\mathbf{I}_{\text{mark}}(i, j) = 2$ another refers to regions of clear CO enhancements. [Regions given](#) by $\mathbf{I}_{\text{mark}}(i, j) = 1$ and $\mathbf{I}_{\text{mark}}(i, j) = 2$, respectively. The seeds are defined as follows:

1. [The regions](#) of no CO enhancements are identified by the median M : A pixel $\mathbf{I}_{\text{mark}}(i, j)$ has no CO enhancement if it is either below the median of \mathbf{I}_S and a dynamically-computed threshold \mathbf{I}_{DT} , namely-

$$\mathbf{I}_{\text{mark}}(i, j) = 1 \quad \text{when} \quad \mathbf{I}_S(i, j) \leq M(\mathbf{I}_S) \quad \text{or} \quad \mathbf{I}_S(i, j) \leq \mathbf{I}_{DT}(i, j)$$

$$\text{where} \quad \mathbf{I}_{DT}(i, j) = \frac{1}{(2N+1)^2} \sum_{i'=i-N}^{i+N} \sum_{j'=j-N}^{j+N} \mathbf{I}_S(i', j')$$

with $N = 7$. Thus each pixel in \mathbf{I}_{DT} represents a localized mean of 15×15 pixels. For our example or below the mean of the 15×15 pixels centered at $\mathbf{I}_S(i, j)$. The size of 15×15 pixels is empirically chosen to account for the background variability. The pixels corresponding to no enhancement can be seen in Figure 3, the corresponding region is shown by the color c represented by label '1' in Figure 3c.

Using this and is referred to as preliminary marker image.

2. [The regions with CO enhancements:](#) Using the preliminary marker image with labels '0' and '1', we identify all the connected regions connected pixels with same marker value (referred to as connected regions hereafter) using the 'label'

algorithm (Fiorio and Gustedt, 1996) in the scikit-image (van der Walt et al., 2014) and assign a unique label to each region shown in different colors in Fig 3e. Further, in a. Each connected region is identified by a unique integer value per pixel (not to be confused with the seed marker). Next, we zoom in a 5×5 pixel area around the fire source, we extract the labels of and extract all connected regions as the potential plume areas. In Fig. 3e, there is only one connected region which corresponds to label '12' (dark red color). Next, all the pixels (dark red pixels) corresponding to the extracted label '12' within a potential plumes. We extend the potential plumes by going to a 15×15 pixel area pixels around the fire source are extracted. Finally, we calculate the upper threshold as the mean of these extracted pixels. This using pixels of the same label. We extract all labeled CO data in this area and calculate a CO threshold as their mean CO value. We mark all pixels within the 15×15 pixel area with a seed '2' which have CO values above this threshold, which further yields the remaining seed points which are defined only in a 15×15 pixel area around the fire source as shown below-

$$I_{\text{mark}}(i, j) = 2 \quad \text{when } I_S(i, j) \geq \text{upper threshold} \quad \text{for } i, j = 14, \dots, 28.$$

The.

The above selection process is illustrated in Fig. 3c with the different labels of connected regions. The final marker image is shown in Figure 3d.

Finally, the watershed algorithm calculates a segmented image using the elevation map image I_{elev} for the entire domain using the gradient map image I_{grad} and the marker image I_{mark} . Each region in segmented image is uniquely labeled as shown in Figure 3e. Further, the segmented image is checked for the existence of a plume. At first, the regions present in the gives an example of a segmented image. Using the gradient map, the watershed algorithm decided that the two areas of enhanced CO values are not connected and so do not belong to the same plume. From the segmented image, we extract the correct plume which should originate from emissions at the source location. Therefore, we consider only those labeled areas that overlap with the center 7×7 pixels are extracted and for all these regions, Figure 3f shows the detected plume. The detected plume in this case seem to be shorter, however the tail end of the total number of pixels and the maximum length of each region with respect to the source location are computed. The region, R, with maximum length is selected and is identified as plume if it satisfies the following four constrains plume i.e, $< 143^{\circ}\text{E}$, will fail background subtraction due to similar enhancements as the background. This can also be seen in gradient map where no gradient is detected on top side of the plume.

Finally, the extracted plume is evaluated regarding its suitability for further processing and the plume length is calculated for each extracted plume. Only the data are provided to the emission estimation module if:

- The number of pixels in R should be > 5
- The maximum length should be > 40 km
- There should be no other identified fire clusters within 0.1° distance from the plume
- There should be no 10

PD-1 the plume length > 25 km.

235 ~~If the plume length is < 25 km then the detected plume is flagged as short plume and will be ignored for further processing. The short plumes are difficult to quantify in an automated way as they can have different shapes which makes it difficult to identify the plume direction. Before starting the emission estimate module, we remove all plumes with multiple fire sources, as the aim of this paper is to quantify fires with single sources. This is done by the following filter:~~

~~PD-2 Check if there are not more than 9 non-clustered or 20 both clustered or non-clustered fire counts within fire counts or any other identified fire cluster within 0.05° distance from or in the plume the identified plume.~~

240 ~~With the first and second constrain, small plumes are filtered and the third and fourth constrains alleviate the overlapping of fires from different fire sources. A detected plume of our example is illustrated in Figure 3f.~~

2.3 Emission estimation

For the detected plumes, the emissions were estimated using the cross-sectional flux method (CFM) (White et al., 1976; Beirle et al., 2011). The CO emission E is defined as the mean flux through n cross sections perpendicular to the downwind direction of the plume, namely

$$E = \frac{1}{n} \sum_{i=1}^n Q_i$$

$$Q_i = \int \delta C_{co}^i(s, t_0) \cdot u^i(z_i, s, t_0) \cdot ds \int \delta C_{co}^i(s, t_0) \cdot v^i(z_i, s, t_0) \cdot ds \quad (3)$$

where Q_i (in kg s^{-1}) is the CO flux through cross section i , δC_{co}^i (in kg m^{-2}) is the background subtracted CO values along a cross-section i and $u^i \cdot v^i$ (in ms^{-1}) is the velocity perpendicular to the cross-section i . The wind velocity $u(z, s, t_0) \cdot v(z, s, t_0)$ at the plume height z , the cross-section position s and at the observation time t_0 is obtained from the European Center for Medium range Weather Forecasts (ECMWF) Reanalysis v5 (ERA5) data (Hersbach et al., 2018b). For error characterization, we define the standard error as (σ_E) as

$$\sigma_E = \frac{1}{n} \sqrt{\sum_{i=1}^n (E - Q_i)^2} \quad (4)$$

255 ~~Plume on 2019-05-19 at 04:55 UTC. (a) Plume and every second transection lines drawn based on the detected plume separated by 5 km in downwind direction. (b) The black dotted line corresponds to CO column along a transect in (a) and the red line shows recentered and cut-off CO used for Gaussian fitting. Blue dash dotted line corresponds to the Gaussian fit and orange line represents the enhanced CO along the transect. (c) $\sum C_{co}$ along a transect against the distance from source. (d) Background subtraction algorithm fails due to two plumes merging.~~

260 To determine the cross-sections, hereafter referred to as transects, we first calculate the direction of the plume in downwind direction. The plume line results from a second order curve fit through the pixel centers of the ~~identified pixels~~ detected plume

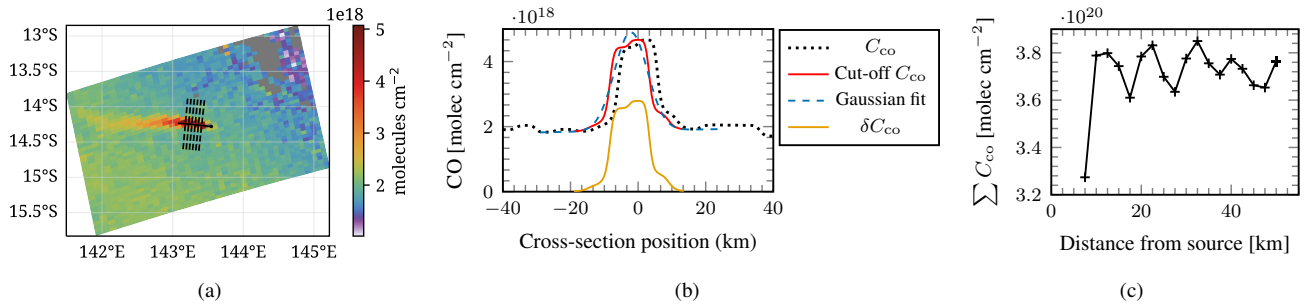

Figure 4. Plume on 2019-05-19 at 04:55 UTC. (a) Plume and every second transect lines drawn based on the detected plume separated by 5 km in downwind direction. (b) The black dotted line corresponds to CO column along a transect in (a) and the red line shows re-centered and cut-off CO used for Gaussian fitting. Blue-dash dotted line corresponds to the Gaussian fit and orange line represents the enhanced CO along the transect. (c) $\sum C_{CO}$ along a transect against the distance from source.

(see e.g. the black solid line in Fig. 4a). Next, we calculate the transects at every 2.5 km perpendicular to the plume line ~~which is and are~~ illustrated as dashed lines in Figure 4a. Transects are sampled at 2.5 km to reduce the errors due to interpolation discussed in next paragraph. To calculate Q_i in Eq. 3, each transect is sampled at distances of 500 m.

265 The points over an transects are over-sampled to get a smoother CO distribution which further helps in background subtraction discussed in Sec. 2.3.1. Along each transect, the CO column (C_{CO}) is extracted by linear interpolation of the original CO data and is illustrated by dotted black line in Figure 4b. This CO column is further used to compute δC_{CO} in Eq. 3. During the diagnostics tests of our interpolation algorithm, an oscillation was observed in the CO columns integrated along the transects as a function of the downwind distance from the fire source (see Figure 4c). The oscillation is due to ~~interpolation errors from the~~
 270 large-sized pixels the under-sampling of the CO distribution by the TROPOMI instrument. The distance between two minima is approximately equal to the TROPOMI pixel size. This error is found to propagate further into the CO enhancement δC_{CO} which is computed from background subtraction algorithm.

2.3.1 Background Subtraction

To determine the atmospheric background of CO per transect, first we re-center the C_{CO} such that the maximum is at the origin
 275 ~~Then the to facilitate the Gaussian fit.~~ The transect line is truncated at the first minima of CO on either side of the origin as illustrated by red line in the Fig. 4b. To determine the background for each transect (red line), we assume that the column CO along the transect can be expressed as

$$C_{CO} = H_0 + H_1 \cdot s + A_0 G(s) \quad (6)$$

280 ~~where $C_{CO}^b = H_0 + H_1 \cdot s$ describes a linear CO background per transect and the Gaussian- H_0 and H_1 represents background and the slope of change in background over the transect, respectively. A_0 is the amplitude of the Gaussian distribution (G accounts for the CO enhancement).~~ We determine the background by fitting Eq. 6 through the CO data, which we sub-

sequently subtract from the C_{co} data to calculate the CO enhancement

$$\delta C_{co} = \max\{0, C_{co} - H_0 + H_1 \cdot s\}. \quad (7)$$

Here, the negative CO column enhancements are ignored. The blue dashed line and the orange line in Fig. 4b represent Gaussian fit and δC_{co} , respectively.

2.3.2 Filtering during background subtraction

~~Background subtraction algorithm fails due to two plumes merging.~~

The background subtraction includes an important filtering mechanism to remove overlapping fires. ~~Figure ?? shows a plume highlighted by the black polygon and two overlapping fires from different fire sources. It is difficult to separate these two plumes completely, thus, in present study these cases are filtered out.~~ This is done during the background subtraction after the transect line is truncated. ~~If the difference between~~ The filter criteria

EE-1 Difference between the two minima on either side of a truncated transect ~~is higher than~~ $< 10\%$ ~~, then the transect is flagged as bad~~ of the smallest value ensures a smooth background and so the absence of any interference with adjacent emission events. It should also be noted that ~~the estimation of background CO might go wrong when the difference on two sides of transect is high. For the plume in Fig. ??, all the transects at least have a difference of 25%, thus the plume is rejected and filtered out.~~ this filter also account for background situation which are too demanding for the CFM.

2.3.3 Plume height

The plume height z_i at a transect/cross-section i is used to extract the appropriate wind velocity $u(z_i, s, t_0)v(z_i, s, t_0)$. For wildfires, Rémy et al. (2017) showed that the an Integrated monitoring and modeling System for wild-land Fires (IS4FIRES) injection height, z_{inj} , from the Global Fire Assimilation System (GFAS) database is in a good agreement with the observations. ~~The uncertainty in injection height is about~~ Sofiev et al. (2012) showed the IS4FIRES injection height deviated by less than 500 m (Sofiev et al., 2012) compared to MISR Plume Height Project (MPHP), thus we consider 500m as plume height uncertainty. First, we assume that the plume height is equal to z_{inj} and is constant throughout the plume, which may hold true for stable meteorological conditions. The constant plume height will be referred as z_c and uncertainty at this plume height is given as z_c^p and z_c^m which correspond of $z_{inj} + 500$ m and $z_{inj} - 500$ m, respectively.

It should be noted that the injection height computed in GFAS is for 24 h and may not be appropriate for a satellite plume which is a snapshot at time t_0 . Additionally, the plume height might vary due to meteorology in downwind direction. Therefore, we simulated alternatively particle trajectories starting at the fire location around the injection height with a three dimensional Lagrangian tracer dispersion model. This allows us to estimate the local plume height z_i by a vertical averaging of tracers along the downwind direction. The estimated plume height is referred as z_{lag} in the following, which captures the change in height in the downwind direction.

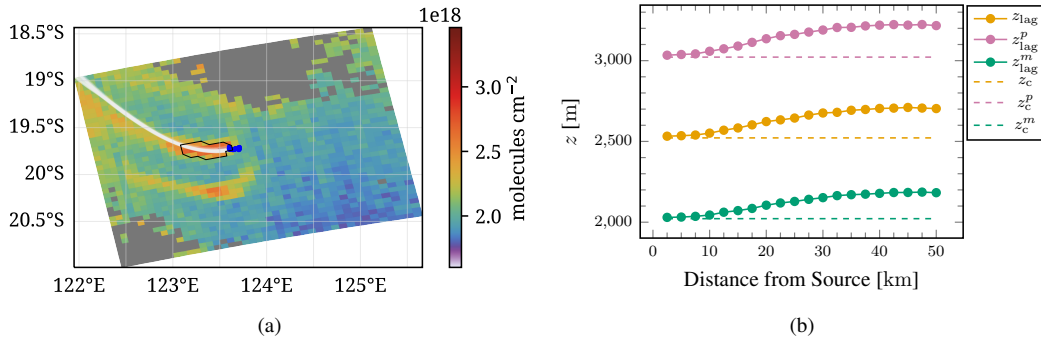

Figure 5. (a) The grayish-white band shows all tracer particles at the end of Lagrangian simulation and the red-blue dots show the fire counts on the detected plume. (b) Shows the plume height computed for different transects from Lagrangian simulations. The constant plume height (z_c) represented by orange dashed line is 1454.3 2521.87 m. (c) Detected plume is represented by the polygon in black line and the injection height was found to be zero for this case. (d) An example where the particles are not aligned with the plume. (e) Particle trajectories are slightly rotated compared to plume.

The Lagrangian simulations are performed using tracer particles. The motion of tracers is simulated according to

$$\frac{d\mathbf{x}_p(t)}{dt} = \mathbf{v}(\mathbf{x}_p(t)) \quad (8)$$

where $\mathbf{v}(\mathbf{x}_p)$ represents the fluid velocity at the instantaneous particle position \mathbf{x}_p . The explicit forward Euler scheme (Butcher, 2003, p. 45) is employed to integrate the equation in time. The velocity on the right-hand side of the Equation. (8) is calculated by the trilinear interpolation of the ERA5 velocity fields. The source locations for the Lagrangian simulations are based on the fire counts described in Section 2.1.1. At each source location, 3 tracer particles are released at z_{inj} and $z_{inj} \pm 500$ m and the particle trajectories are simulated. Particles are released at $z_{inj} \pm 500$ m for uncertainty analysis. The end time of the simulations is the TROPOMI measurement time t_0 , which is about 13:30h local time (Veefkind et al., 2012), and the simulation start is starts at $t_0 - 6$ h. The particles are released from the source locations every 2 minutes. Figure 5(a) shows the tracer particle simulation for a plume and the grayish band indicates them at TROPOMI measurement time. The contribution to emissions from fires is low in early morning as shown in the ecosystem-specific diurnal cycles by Li et al. (2019) and so we ignore trajectory simulations before $t_0 - 6$ h. Additionally the process of heating due to fires is not accounted in our Lagrangian simulation as we assume the ERA5 velocity fields contain some aspect of it as ERA5 assimilates skin surface temperatures.

At each intersect, the height of the tracer particles released at z_{inj} are extracted and the mean height, $z_{lag,i}$ is computed. The mean height or plume height is and assumed to be constant along the transect. Figure 5(b) shows the plume height for different transects from the fire source which is used to compute velocity, \mathbf{w} , in Equation 3. The uncertainty in plume height is defined as z_{lag}^p and z_{lag}^m and are computed from tracer particles that were released at height $z_{inj} + 500$ m and $z_{inj} - 500$ m, respectively and can be observed in Figure 5(b). Finally, the velocity, \mathbf{w} , is used to compute emissions.

330 2.3.4 Filtering during Lagrangian simulations

During Related to the Lagrangian simulation, we apply three filters, ~~two of them are before the start of the simulation and one is done after the simulation.~~ These filters are described below.

The injection height in GFAS is not always available for all the detected plumes and these cases are ignored. This can happen
:

335 EE-2 The injection height from GFAS must be available.

EE-3 If the simulated trajectories are not aligned in the direction of the plume then the plume is rejected.

EE-4 If the wind velocity at the TROPOMI measurement time which is used to compute emissions is less than 2 ms^{-1} then the plume is rejected.

Filter EE-2 may become relevant due to false detection of plume or false fire in VIIRS active fire database or just the data
340 is missing in GFAS database. ~~Figure 5(e) shows a case where there is a plume but no data for injection height was available. Additionally, the fire radiative power (FRP) for this case was found to be comparable to other detected plumes with the non-zero injection height. This can be attributed to either false detection of fire in VIIRS dataset or missing data in GFAS database.~~

The second filter is after the Lagrangian simulations where the particle-plume alignment is checked. If the particles are not
aligned in the direction of the plume then the plume is rejected (see Fig. 5(d)). Sometimes the particle trajectory was observed
345 to have a slight rotation from the plume as illustrated in Fig. 5(e). This can be due to the rotation Reason for filter EE-3 might be a rotation or the errors in the ERA5 velocities or due to the spatial and temporal resolution of velocity fields or inaccurate injection height. ~~However, such cases were considered when the particle trajectories overlapped with the transaction lines.~~

The third filter is based on velocities. If the velocity at the TROPOMI measurement time which is used to compute emissions
is less than 2 ms^{-1} then the plume is rejected with the assumption that the ~~Finally, if the wind speed is below the specified~~
350 value in EE-4, diffusion dominates the pollutant transport and CFM is not appropriate to estimate the CO emission.

3 Algorithm application

Table 1. Results for automated plume detection and emission estimation algorithm (APE v1.0.1) for ~~two-four~~ months in US ~~and~~ Australia and Siberia

<u>Location-Regions</u>	Fire Clusters	CO data	Plume detection	Emission estimation	Visual Inspection
US	1081	<u>228-213</u>	<u>64-130</u>	<u>33-37</u>	<u>31-35</u>
<u>Australia-AU</u>	2013	<u>394-385</u>	<u>132-266</u>	<u>111-129</u>	<u>110-128</u>
<u>Total cases-Sib Jun</u>	<u>3094-416</u>	<u>622-130</u>	<u>196-83</u>	<u>144-35</u>	<u>141-34</u>
<u>Sib Jul</u>	<u>2052</u>	<u>599</u>	<u>94</u>	<u>25</u>	<u>24</u>
<u>All Regions</u>	<u>5562</u>	<u>1327</u>	<u>378</u>	<u>226</u>	<u>221</u>

The quality and validity of the algorithm, APE v1.0, is illustrated for fire sources in Our APE algorithm targets at global performance and includes several threshold values, which needs to be determined carefully for optimal performance. For the current version APE V1.1, we decided to determine the thresholds using the region encapsulating the United States of America (US) on Sept 2020. The algorithm is verified by applying it to other regions encapsulating Australia (AU) on October-Oct 2019 and the United States of America (US) on September 2020. These months were chosen as large number of fires were observed during this time Siberia (Sib) on Jun and Jul 2021 (see Table. B1 for more details on the selected regions). It is important to note that these regions are not used to configure APE and so can be used to test the overall performance of the algorithm. The different time periods were chosen to focus on the regional burning season and so to maximize number of observed fires. Table 1 shows the result of our automated plume detection number of plume evaluated in the different modules of APE. Fire cluster and CO data columns highlight the results of data preparation (see Section. 2.1) part. The columns plume detection and emission estimation show the results for plume detection (sec. 2.2) and emission estimation (sec. 2.3) parts. Furthermore, the details corresponding to filtering can be found in Tables B2, B3 and B4 in appendix.

A total of 3094 fire clusters were detected 5562 fire clusters (see Table. 1) were identified in the VIIRS active fire data product for both US and Australia all regions based on the clustering method discussed in 2.1.1. TROPOMI CO overpasses were then identified and the CO Section 2.1.1. For each fire cluster, TROPOMI CO data was filtered for maximum pixel size and quality (see Sec. 2.1.2) which resulted in 622 cases with good TROPOMI CO data. Furthermore, the filter on the TROPOMI pixel size (DP-1) filtered about 1533 cases out of 5562 cases which mostly belonged to Australia and US. The quality of TROPOMI CO data (DP-2) was found to be bad for about 2553 cases in 5562 cases. For the Siberian region on July 2021 more than 50% of all fire clusters are flagged as bad quality data because of more cloudy observations at these latitudes. Finally the data preparation part yielded a total of 1327 good CO data granules for all regions for further processing.

The plume detection algorithm described in Sec. 2.2 identified 196 plumes among 622 cases, a total of 378 plumes for all regions from available 1327 good CO data cases. A total of 445 cases were found to have no enhancements (see Table B3) which means that the CO enhancement from these fires was not significant enough to be measured by TROPOMI. In addition to this, about 309 identified plumes were flagged as short as the length of these plumes was found to be shorter than 25 km (PD-1 filter). Further, the PD-2 filter identified a total of 195 cases where other fire sources and clusters were present in the detected plumes.

The emission estimation algorithm computed takes 378 plumes as an input and computes emissions using CFM for a total of 144 plumes. So about 52 cases were filtered by emission estimation algorithm. At first, the injection height filter described in Sec. 2.3.4 led to removal of 19 cases (10 US and 9 AU). Then a total of 9 cases (7 US and 2 AU) were found to be overlapping with another plume from different fire source and were flagged as bad plumes during background subtraction (see Sec. ?? 26 cases. So a total of 152 plumes were rejected by filter EE-1, EE-2, EE-3, and EE-4 during the emission estimation (See Table. B4 for details). The injection height from GFAS database was not available for 57 cases (EE-2) and 29 plumes failed because overlapping with other plumes (EE-1). Furthermore, particles-plume alignment filter described in Section 2.3.4 removed 20 cases (11 US and 9 AU). And finally four plumes (3 US and 1 AU) were rejected by EE-3 removed a total of 51 cases. This is mostly due to bad plume detection, inaccurate velocities or injection heights. Lastly, the velocity filter discussed

Figure 6. Removal by visual inspection~~False positive detection of plumes~~. Black dots ~~at~~ indicate the center of each figure, white bands and black polygon represent fire counts, white bands the tracer particles and the black polygon depicts the detected plume, respectively. Black dashed lines are transaction lines. (a, b) Bad plume detection and doesn't get filtered by any of the above mentioned filters. (c) The plume and particles are oriented north-west whereas the transaction lines are drawn towards south-east which due to bad plume detection-

in Sec. 2.3.4 due to velocities being lower than 2 ms^{-1} . Plumes were also visually inspected to check the quality of algorithm. A total of 3 plumes were falsely identified as shown in EE-4 rejects about 15 cases. Finally, the automated plume selection can be verified with a visual inspection. For the US region difference are small by construction as the threshold values were tuned for this data ensemble. For the verification areas Australia and Siberia we see similar good performance of the detection algorithm, and in total only 5 of the 226 plumes were flagged as false identifications. Fig. 6. To conclude, presented automated algorithm can successfully detect plumes and compute emissions for ≈ 97.9 gives three examples of the false positive detection. Thus, our analysis confirms the applicability of our algorithm to other areas with a confidence of 97.7% of the cases.

3.1 Cross-Sectional Massflux method (CFM)

3.1.1 Constant and Lagrangian plume height

The CFM was used to compute emissions for the selected 141 computed emissions for 221 cases. To compare the effect of plume heights, two variables are defined, namely, mean plume height \bar{z}_{lag} , which is mean of z_{lag} of all transects along the downwind direction of the plume and the maximum rise in plume height (δz) ~~w.r.t with respect to~~ z_c . They are given as

$$\bar{z}_{\text{lag}} = \frac{1}{m} \sum_{i=0}^m z_{\text{lag},i} \quad (9)$$

$$\delta z = \max\{z_{\text{lag}}\} - z_c \quad (10)$$

The mean plume height \bar{z}_{lag} is plotted against the constant plume height (z_c) in Figure 7(a) and (c) for US and Australia, and Siberia region, respectively. The δz decreased and increased in downwind direction for about 21 and 120-43 and 178 fires, respectively. Additionally, the plume height δz in the downwind direction is found to vary significantly and is highlighted by error bars $> 500 \text{ m}$ for 30 fires in regions encapsulating Australia and US as represented by the orange color in Figure 7(a). The δz was $> 500 \text{ m}$ for a total of 22 fires and are highlighted by red color points in Fig. 7(a) However, no such cases were found in Siberia (see Fig 7(c)). Among these 22-30 fires, about 10-11 fires had $\delta z > 1000 \text{ m}$. As the total fire radiative power (FRP) and

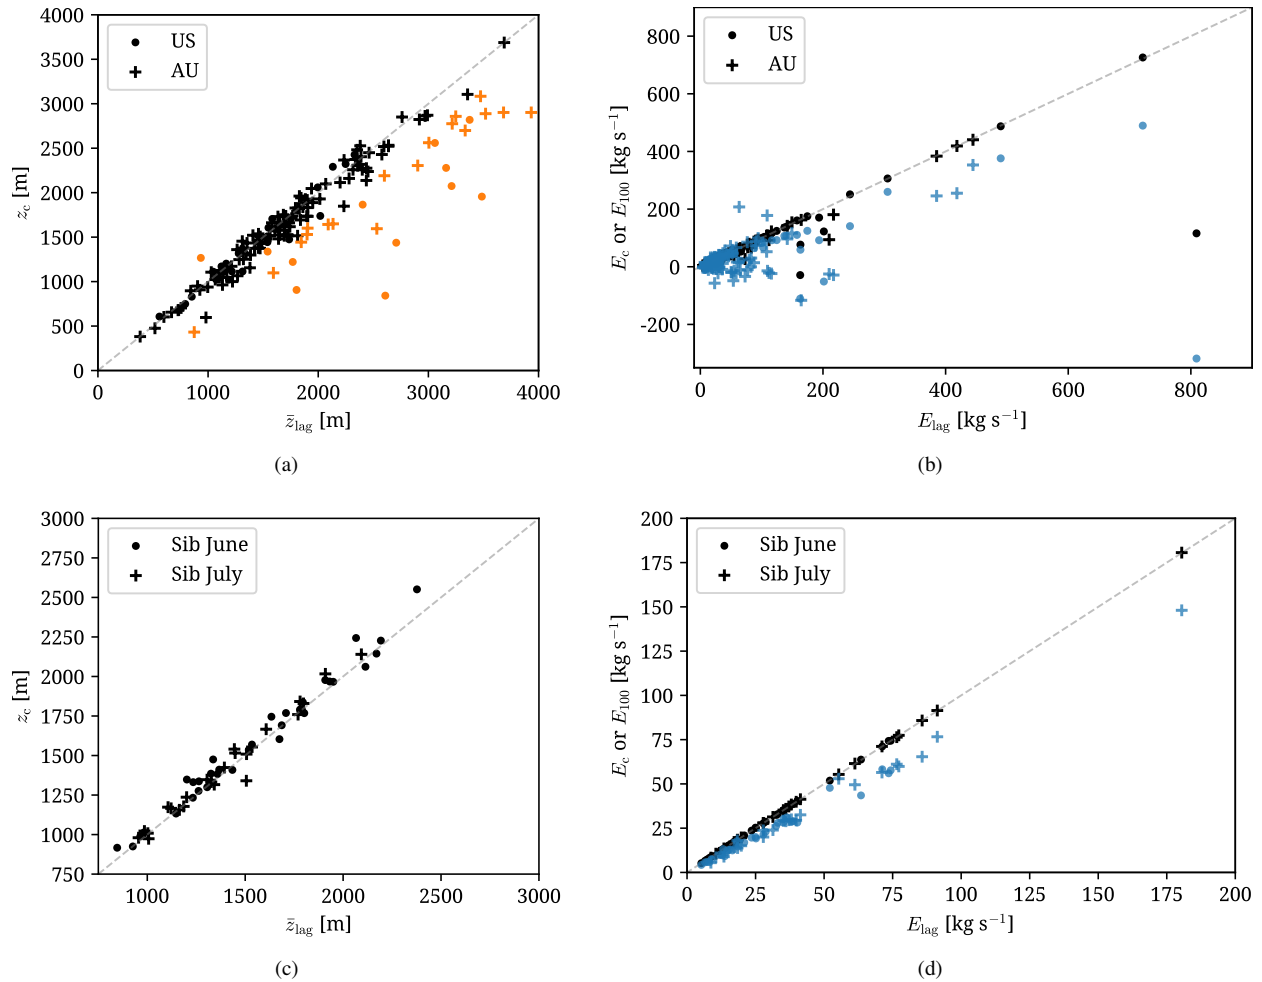

Figure 7. Plume height variation and emissions for regions encapsulating US and Australia (top figures) and Siberia (bottom figures). (Panel a and c) The mean plume height (see Eq. (9)) versus the constant plume height for each fire. The error bars indicate the standard deviation of z_{lag} in downwind direction. Reddish-purple markers indicate $\delta z \geq 500$ (see Eq. (10)) black color represents $\delta z \leq 500$ m and blue orange color indicates $\delta z < 500$, $\delta z > 500$ m (Panel b and d) Comparison between the emissions computed at plume height z_{lag} vs versus z_c . The error bars in respective direction indicate standard error E_{se} defined in Eq. (4). Colors indicate the plume height deviation (δz) shown in (a). (c) Same as Fig. (b) except the error bars show the uncertainty in emissions due to variation in plume height (z_{lag}^p represented by black color and z_{lag}^m) and z_{lag} versus a constant plume height (z_c^p and z_c^m). Explained in text in Section 3.2. (d) Comparison between the emissions computed at plume height z_{lag} vs the emissions at of 100 m plume height, z_{100} represented by blue color.

fire counts represent the heat generated and the area burnt, a relation between plume height rise and these two variables can be expected as higher FRP means higher temperature which heats up the air, leading rise of the warm air. However, no such relation was observed and there were cases with low FRP or low fire counts where the $\delta z > 1000$ m. However Additionally, it

410 was difficult to find an appropriate reason for large rise in plume height in downwind direction. Obviously, this plume height variation can influence the emissions due to the change in the velocity with height.

~~A US fire (red) Figure 7(b) and (d) compare the emissions computed from Lagrangian plume height (E_{lag}) with the emissions computed from constant plume height (E_c) represented by black color and 100 m plume height (E_{100}) represented by blue color. Combination of all cases in figures 7(b) and (d) show that the E_c varied less than 10% from the E_{lag} for a total of 198 cases. And the fires in Siberia varied by less than 4%. However, 23 cases in US and AU had variation larger than 10%. Thus, the overall effect of the Lagrangian plume height to the constant plume height on the emission estimate is considered minor, however we could identify several cases where the emissions estimate from Lagrangian plume height become more reliable. For example, a US fire (black color) on the bottom right of Figure 7(b) was found to have high $E_{lag} = 809 \text{ kgs}^{-1}$ and low $E_c = 115.9 \text{ kgs}^{-1}$. The total fire radiative power (FRP) for this case was found to be the highest among all the detected plumes and the burnt area (number of fire counts in VIIRS data) was third highest among all the detected cases. Additionally, the CO enhancement was large, thus, a high emission estimate is expected. Furthermore, the high FRP is correlated with higher temperatures, so an increase in the plume height in downwind direction is normal. This It should be noted that the Lagrangian simulations do not consider the heating. However, we assume that the velocities in ERA5 cover this as it assimilates the surface temperature. The increase in plume height is observed in the Lagrangian simulations as the z_{lag} increases by 1350 m compared to constant plume height in the downwind direction at 32.5 km from the fire source. From this, one can conclude that the E_{lag} is can be more appropriate than E_c . A similar reasoning can be used to explain why the E_{lag} was higher by $> 30\%$ compared to E_c for 9 out of 22 the fires where the FRP on average was higher and the δz was > 500 m. Additionally, for one US fire among these 9 fires, we observe a negative E_c (see Figure 7(b)) due to velocities being negative at z_c along the plume, however the E_{lag} was found to be positive. It should also be noted that the emissions from constant plume height varied less than 10% from the Lagrangian estimate for a total of 124 cases. Thus, although the overall effect of the Lagrangian estimate of the plume height on the emission estimate is minor, we could identify several cases where the emissions estimate become more reliable.~~

3.1.1 100 m plume height

~~Three-dimensional velocity fields and (d) also compare emissions from Lagrangian plume height to a constant 100 m plume height. We considered 100 m plume height as three-dimensional velocity fields, which are required to compute the CO emissions based on the plume heights z_c and z_{lag} which amounts, amount to a large quantity of data. The approach would be much simplified when the three-dimensional velocity data could be reduced to a two-dimensional velocity field at Furthermore, computing emissions by scaling 100 m close to the surface (Hersbach et al., 2018a). Therefore, we computed the emission also for a 100 m plume height. Figure 7(d) shows a comparison of the emissions E_{lag} computed from versus a corresponding simulations E_{100m} for constant plume height of 100 m. Emissions varied more than 10% with respect to Lagrangian emissions for winds would simplify the the approach to a large extent. However, we found no correlation between the difference in the emissions ($E_{100} - E_{lag}$ or E_c) and the variation in plume heights. Additionally a total of 105 cases out of 141 cases. The figure depicts large deviations between emissions and the differences increase with increasing emission. Overall E_{100m} is mostly~~

under-predicted. Additionally, $E_{100\text{m}}$ is negative for 11 fires. 37 fires were found to negative values for E_{100} due to a negative velocity at 100 m. Furthermore, we could not find a correlation between the difference in the emissions and the variation in plume heights. This makes it difficult to find an appropriate scaling to obtain emissions at z_{lag} from the velocities at 100 m. This highlights Thus, highlighting the importance of using three-dimensional velocity fields rather than surface near wind fields at a fixed altitude.

From all these observations, we conclude that the varying plume height is more reliable to compute emissions by an automated algorithm.

It should be noted that the emission estimations in this paper are not compared to any existing database as we are not aware of any in-situ studies except by Rowe et al. (2022) which compares the CO column from aircraft measurements to TROPOMI data.

3.2 Emission uncertainty

We estimate two different contributions to the uncertainty of the estimated emission, where we assumed constant emissions in time for each plume. First, we consider the relative variation of the CO fluxes through the different intersects Q_i . Different error sources may cause this variation and the corresponding error on the flux estimate can be characterized by the standard error σ_E in Eq. 4. Second, errors that affect the different fluxes Q_i equally cannot be address by this approach, and so require a dedicated discussion. These errors are TROPOMI bias, ERA5 velocity bias and injection height uncertainty. In addition to these two errors, we verify the emission uncertainty in APE, i.e., the standard error, using data from WRF simulations where the wind velocities, CO and injection height are known.

The error bars in figure 7(b) represent the standard error $\pm E_{se}$ defined in Equation (4). They indicate uncertainties in respective direction and

3.2.1 Standard errors

The standard error encompass various uncertainty sources such as, e.g., the interpolation error due to sampling (large grid sizes) in both the ERA5 velocity fields and the TROPOMI observations, the under-sampling of the CO field by TROPOMI (shown in Fig. 4(bc)), the systematic bias and precision errors in TROPOMI CO, uncertainties relative wind errors with respect to the ERA5 velocity fields, the precision of the TROPOMI CO data, the uncertainty variation in defining the atmospheric CO background, the local variation in velocity fields and the assumption of a constant CO fire emission in time. These uncertainties are difficult to quantify individually as the true value is unknown and the uncertainties can be different for different fires.

Figure 7(e) is per intersect, and the same as 7(b) except that the error bars indicate the uncertainties in emissions due to the temporal variation of the emission around its mean. σ_E does not allow us to disentangle these error sources, except for the TROPOMI CO precision. This is $< 10\%$ even for dark scenes over land (Landgraf et al., 2016). For the flux estimate, this yields an negligible error contribution. To compare the standard error for different fires, Table. 2 reports the maximum relative standard error for the four regions using the Lagrangian plume height and the constant plume height z_c . For individual fires errors can be accessed in the data base (Goudar et al., 2023). The data shows that the maximum standard error for the

Table 2. Maximum values of standard error and emission uncertainties due to plume height for different regions among all fires.

Region	$\sigma_E(z_{lag})\%$	$\sigma_E(z_c)\%$	$\Delta E_{lag}^p\%$	$\Delta E_{lag}^m\%$	$\Delta E_c^p\%$	$\Delta E_c^m\%$
US	15.11	35.51	71.28	82.27	246.93	163.54
AU	18.79	28.10	94.78	95.41	130.17	170.37
Sib Jun	18.21	18.13	17.34	14.95	17.37	8.84
Sib Jul	19.72	19.57	14.88	13.12	15.47	12.1

Lagrangian plume height is significantly smaller than for z_c for both the US and Australia data. This is another indication to use the Lagrangian plume height as baseline for APE. For the Siberian region there is no difference between the two methods because the plume height does not vary much as depicted in Figure. 7c. Overall, the standard error of the emission estimate is $< 20\%$.

3.2.2 Other errors

One potential error which cannot be addressed with the standard error is an overall bias in the TROPOMI CO product. Borsdorff et al. (2019b) reported a CO bias of 3.4ppb for the TROPOMI product compared to the Total Carbon Column Observing Network (TCCON). This corresponds to a typical relative error $< 1.7\%$ for a plume concentration of about 200 ppb in a plume. Assuming the CO bias to be constant over the plume, it yields the same relative error on the emission estimate and so can be neglected.

Another error of this category is the emission uncertainty because of the uncertainty in plume height, which is further related to uncertainty in the injection height in GFAS database. The injection height is assumed to have an uncertainty ± 500 m. The positive and negative error bar in x-axis correspond to two uncertainties namely, $E_{lag}^p - E_{lag}$ and $E_{lag} - E_{lag}^m$, respectively, where emissions E_{lag}^p and E_{lag}^m are computed Sofiev et al. (2012). For each fire, we calculate the emission uncertainty

$$\Delta E_{lag}^{p/m} = \left| \frac{E_{lag}^{p/m} - E_{lag}}{E_{lag}} \right| \quad (11)$$

using plume heights z_{lag}^p and z_{lag}^m , respectively (see Fig 5b). Analogously, the uncertainties ΔE_c^p and ΔE_c^m for E_c are computed, are computed and the maximum number per region is again given in Table 2. The uncertainties changes from fire to fire and can be found in the data (Goudar et al., 2023). For the Siberian region, the maximum uncertainties are small indicating little vertical variation in the velocity. The size of the error bars highlights the variation in the velocity at different plume heights. For small error bars, this can either mean that plume height doesn't vary i.e., z_{lag}^p and z_{lag}^m converge to z_{lag}) thus low variation in velocity or plume height varies a lot but the velocity variation is low. In our case, smaller error bars were mainly observed when the velocity didn't vary much with the plume height.

An overall systematic bias in the velocity field is not computed in the presented work as it is unknown and either hard to estimate or may vary. For US and Australia region, the corresponding uncertainties are much larger where the uncertainties

for the constant emission height exceeds those using the Lagrangian simulation by a factor of 2-3. This hints at a more variable wind field for these regions. Overall, we estimate this APE error term to be the largest error contribution with error < 100 % for each fire. However, it should be noted that 1% systematic bias in velocity leads to a 1% error in the emission estimated due to the linearity in Eq. (3). We can assume that the localized uncertainties in velocity are covered by the standard error, E_{se} . This uncertainty quantification is also applicable to systematic biases on the whole TROPOMI CO data. The TROPOMI CO data has a positive bias of 6.5% on average compared to NDACC, TCCON, and COCCON monitoring networks (Sha et al., 2021; Lambert et al., 2022; Borsdorff et al., 2019b). It should be noted that this uncertainty has been reduced to 3.4ppb in the newer versions of L2 product (Borsdorff et al., 2019b).

The CFM estimated emissions are same as actual if the emissions and velocities are constant in time. However this assumption does not hold for the fires, thus an uncertainty due to these assumptions is quantified. Additionally, as the pixel size of TROPOMI is high, the uncertainty due to low and high spatial resolutions is studied using three model cases. The Weather Research and Forecasting (WRF) Finally, we consider errors in the wind velocity that are constant over the plume domain. The error propagate one-to-one into error of the flux estimate. Uncertainties of the ERA5 wind fields in the tropospheric boundary layer are not reported. Gualtieri (2022) derived surface near wind errors of 1.76 m/s (root-mean-square error) for ERA5 data. A typical wind speed at the plume height is 3-11 m/s and although at the plume height the wind speed error might be smaller, we consider this error as a significant error contribution. However, we refrain from quantifying this error because of lack of reliable the knowledge on the wind.

3.2.3 Verification of emission uncertainty

We verify our uncertainty estimates evaluating WRF simulations of a CO plume using APE. The WRF simulation was performed using real atmospheric forcing at 1 km resolution for a fire with the highest FRP (USA, September 12, 2020, see Sec. 3.1). The details on the WRF simulation can be found in the Appendix A. Three plumes at three different UTC times shown in Figure 8a-c were selected and emissions were estimated by our algorithm. Additionally, the simulation grid was degraded to the Tropomi grid and can be observed in Figs. 8e-g. It should be noted that the averaging kernels were not used to degrade to TROPOMI grids data and only the enhancements were simulated in the model, thus the background is set to zero by simulation. The plume height (z_{lag}) was computed as the maximum height where the concentration became zero and fire sources were same as the sources used in WRF simulation. The velocity used in both Lagrangian simulations and emission estimations was WRF velocity data. The emissions for these plumes were estimated by our automated plume detection and emission estimation algorithm APE assuming a constant emission in time and are presented in Table 3. The Here, the actual emission is the mean of the known total CO emission from all fire sources with time. This considered time is based on the release time of the particles around the final transect used to compute emission. Additionally, we degraded the simulation grid to the TROPOMI grid shown in Figs. 8e-g.

The highest uncertainty in cross-sectional flux method compared to actual emissions was uncertainties of the APE emission estimate ranges between -1.5 % and +38.5% at UTC time 18:00 (Table 3). In all three plumes, the velocity and plume height used by APE are appropriate, however the emissions computed by our algorithm differed from the actual emissions. This is

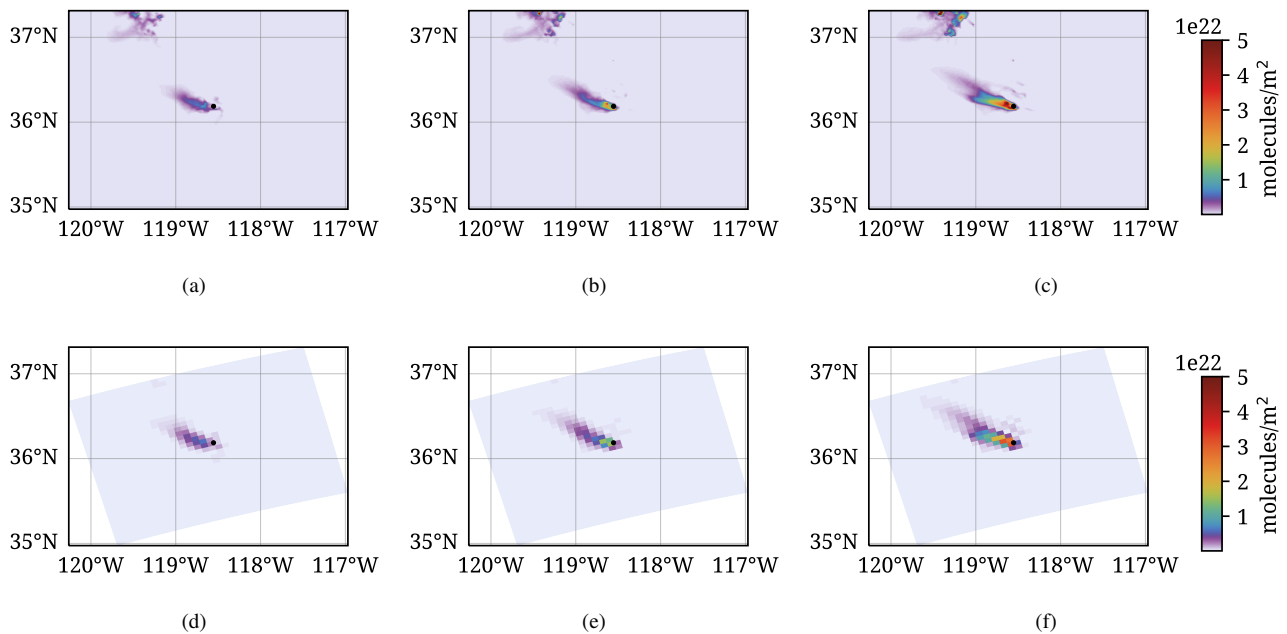

Figure 8. Three selected plumes at three different UTC times (a, d) at 17:00, (b, e) at 18:00 and (c, f) at 19:00. Top (a-c) represent plumes at 1 km grid resolution and bottom (d-f) represent TROPOMI grid resolution.

Table 3. Comparison of actual emissions to the emissions computed at plume height z_{lag} for the three selected plumes shown in Fig. 8. The uncertainty in the table is computed as $100 \times (\text{Actual} - \text{Computed}) / \text{Actual}$.

Time in UTC (H:M)	Actual (kgs^{-1})	1 km grid (kgs^{-1}); <u>Uncertainty</u>	Tropomi -TROPOMI grid (kgs^{-1}); <u>Uncertainty</u>
17:00	28.45	20.26; <u>28.8%</u>	20.67; <u>27.3%</u>
18:00	56.84	34.92; <u>38.5%</u>	34.52; <u>37.5%</u>
19:00	97.86	99.15; <u>-1.5%</u>	99.36; <u>-1.53%</u>

attributed to the error in the cross-sectional flux method due to the assumption of ~~constant wind and a constant~~ emissions which might not be the case for a fire. It should be noted that this uncertainty is for one particular case and it can vary depending upon the case. For the three selected cases, the CFM method leads to an error of 28.8, 38.5 and 1.5% which ~~highlights that even with accurate wind fields, there can be large errors depending upon the fire.~~

540 is in the range of the derived standard error. The difference in emissions between high resolution (1 km grid) and low resolution (TROPOMI grid) was found to be less than 2%. ~~The integrated CO with distance from source as shown in 4(c) was found to be same for all three plumes for both high (1 km) and low (TROPOMI) resolution grids.~~ If the velocity is accurate, then it can be concluded that having higher resolution data ~~doesn't does not~~ have much effect on the cross-sectional flux method.

Overall this analysis suggests that the assumption of a constant emission is the major error source next to errors in the wind field and uncertainties in the injection height.

4 Conclusions and recommendations

An automated plume detection and emission estimation scheme for CO flux inversion for single point fires was developed by integrating four freely available data sources, such as, VIIRS active fire dataset, TROPOMI CO dataset, injection height from GFAS and ERA5 meteorological data. The automated plume detection and emission estimation algorithm (APE v1.0) ~~was tested for two months for US and Australia and it was shown that the fire plumes can be detected and their emissions can be estimated automatically for~~ 1) was optimized for one region and its performance is verified for three months data for two other regions, Australia and Siberia. For all the regions, 1327 fires had clear sky TROPOMI CO data of sufficient quality among 5562 identified fire clusters. Even though 882 plumes were identified in 1327 cases, only 378 plumes were considered as 309 plumes were too short and about 97.9195 had multiple sources of fire in them. Lastly, the emissions were estimated for only 226 cases among 378 plumes. We can conclude that APE can reliably detect and estimate emissions automatically for 97.7% of the cases.

The key to automatically detect fire plumes in TROPOMI CO dataset and estimate emissions was knowing the fire source a priori. ~~If a fire source is not known then it is a complex problem as the CO plume in TROPOMI data needs to be identified first and then the fire source need to computed from the identified plume. However in~~ In the present study, VIIRS active fire data product from Suomi NPP helped in identifying fire source which was used to detect plumes in TROPOMI CO data. This highlights the potential for flying the satellites Suomi NPP and SP5 in the same orbit and in formation with a temporal separation of 3.5 minutes to identify fires.

~~The emission estimation using~~ We considered three different assumption on plume heights, first a constant plume height may not be appropriate as it doesn't include the effect of plume height variation in downwind direction. Plume height in downwind direction varied by more than 500 m for a total of 22 cases. This plume height variation could be due to variation in air temperatures caused by the ~~at 100 m altitude, second a constant plume height at the GFAS injection height and third a varying plume height using a Lagrangian model. The varying plume height was chosen based on the characteristics of a fire. If the a~~ fire is at its peak then the air around is heated and rises in the atmosphere and at the same time, it will be transported away from the fire source. Thus, one can observe the CO rise with distance from the source. ~~We observed this trend in few cases where the~~ varying plume height could give a better and reliable emission predictions compared to constant plume height. Additionally, ~~emissions from constant~~ It should be noted that we assume the ERA5 velocity fields incorporate this heating effect to a certain extent as it assimilates the surface temperature from satellites. In our simulations, the plume height varied by less than 10% for 124 cases compared to Lagrangian plume height. Therefore, the overall effect of the changing plume height in downwind direction on the emission estimate was minor. However, we were able to identify several cases where the flux estimates become more reliable.

~~The emission computed based on more than 500 m in downwind direction for 30 cases out of 221 cases and all 30 cases were in US and Australia. The plume height variation was found to be minimal in Siberia.~~

580 ~~The assumption of plume height at 100 m winds (considered plume height) were severely under-predicted due to low to negative velocities. A total of 105 cases had more than 10% variation between the emissions from 100 m plume height and the Lagrangian plume height. It was difficult to find an appropriate scaling of velocity at 100 m to the velocity at plume height z_{tag} as the negative velocities cannot be scaled to positive velocity. Additionally, in many cases the velocity was found to be constant with height thus using a general scaling factor to scale velocity with height might result in unrealistic emissions~~
585 ~~led to unreliable emission estimates and was discarded. The difference in estimation emission for the constant injection height from GFAS and varying plume height, was observed to be less than 4% for Siberian region. Larger differences we observed for the US and Australia, where the maximum uncertainty using the varying plume height is half of that using a constant plume height. However, for many plumes the difference in the uncertainty estimate was minor. Based on this findings, we decided to use the Lagrangian model for the plume height as processing baseline of APE.~~

590 ~~The combined effect of uncertainties due to different parameters is difficult to quantify for fires due to the missing ground truth. The CFM was found to have significant uncertainties compared to actual emissions for fires even though the atmospheric transport and plume height considered were accurate. This stems from the CFM assumptions of constant emissions and velocity in time which is not~~
595 ~~Overall, we estimated the uncertainty of our product with the standard error $< 20\%$, which mainly accounts for errors in the spatial under-sampling of the CO field by TROPOMI and the ~~case for fires~~ assumption of a constant emission for the time frame relevant for the plume formation. The TROPOMI CO data is of high quality regarding precision and bias and does not provide any significant contribution to the CO emission estimate of APE. Additionally, ~~as the uncertainty can vary from a fire to another, it is difficult to quantify it in an automated way~~ we analyzed emission errors due to the GFAS uncertainty in the injection height. Depending on the meteorological situation at the different regions, errors are $< 100\%$. Errors due to wrong wind information is also considered to be important but could not be specified as the ERA5 data product does not provide an uncertainty estimate of the provided wind field at the plume height.~~

600 Finally, for the first time the presented algorithm is appropriate to estimate CO emissions from fires from TROPOMI/VIIRS data by a fully automated algorithm. ~~We identified the assumption of constant wind and emissions in time for the CFM as one of the significant contributor to the uncertainty in our data product.~~

605 ~~It is considered as a baseline for future APE upgrades to optimize automated emission estimates of CO point sources. As a next step, we consider (1) the processing of entire CO TROPOMI data set will be processed and, (2) expanding emission estimations for multiple fire sources and (3) develop an improved inversion scheme. This can done by developing algorithms that maps the simulated tracer particles from Lagrangian simulations to the TROPOMI CO concentrations to compute emissions. Thus, including the history of the emissions to a certain extent. (3) A database of the fires with single sources will be created and further studied to understand the effect of vegetation and topography, and (4) verifying emissions predicted by APE to available in-situ emissions databases.~~

Appendix A: The ~~Weather Research and Forecasting (WRF)~~ Model description

610 The WRF model configured in a two-domain configuration is applied in the tracer mode to simulate the transport and dispersion of CO emitted by a wildfire in the US. The outer and inner domains are run at a horizontal grid spacing of $5 \times 5 \text{ km}^2$ - km^2 and $1 \times 1 \text{ km}^2$, respectively. The model domains are centered at 36.16225°N , 119.1528°E and have 43 vertical levels stretching from the surface to a model top of 50 hPa. The outer domain has 200×200 grid points while the inner domain has 400×350 grid points in the west-east and north-south directions. The meteorological initial and boundary conditions for the outer domain
615 are based on the Global Forecast System (GFS) forecasts available every 3 hours at a horizontal grid spacing of $0.25^{\circ} \times 0.25^{\circ}$. The static geographical fields and the GFS output are mapped onto the WRF domains using the WRF pre-processing system (WPS). The physical parameterizations follow Kumar et al. (2021) except the cumulus parameterization that is turned off in the inner domain.

Biomass burning emissions are obtained from the Fire Inventory from NCAR (FINN; Wiedinmyer et al., 2011) version 2.5
620 and are distributed vertically online using a plume rise parameterization developed by Freitas et al. (2007). This parameterization selects fire properties appropriate for the land use in every grid box containing fire emissions and simulates the plume rise explicitly using the environmental conditions simulated by WRF. Since we are using the model in the tracer mode, the chemical evolution of the plume is not simulated. To describe the loss of CO in the model, we allow the CO fire emissions to decay with an e-folding lifetime of 30 days. No other source (anthropogenic emissions, biogenic emissions or ~~photochemical~~
625 photo-chemical production from hydrocarbons) is included in the simulation. The model run started on 12 Sep 2020 at 12 UTC and stopped at 13 Sep 00 UTC. We used a time step of 20 s for the outer domain and 4 s for the inner domain. The model output is saved every min and used for further analysis.

Appendix B: Algorithm and Simulation details

Code availability. APE v1.1 code is archived on Zenodo (<https://doi.org/10.5281/zenodo.7361559>).

630 *Data availability.* The TROPOMI CO dataset of this study is available for download at <ftp://ftp.sron.nl/open-access-data-2/TROPOMI/tropomi/co/> (last access: 5 Feb October 2023). The IS4FIRES injection height and the 3-d velocities at 127 model levels were obtained from the Global Fire Assimilation System (GFAS) database and the European Center for Medium range Weather Forecasts (ECMWF) Reanalysis v5 (ERA5), respectively on 10 October 2020. The Visible Infrared Imaging Radiometer Suite 375m thermal anomalies/active fire product was also accessed on October 2020 (https://firms.modaps.eosdis.nasa.gov/active_fire/). The processed data is available DOI:10.5281/zenodo.7728874.
