**Abstract.** This study investigates the link between the interplanetary magnetic field (IMF)  $B_y$  component and the Noctilucent clouds (NLCs) measured by the Cloud Imaging and Particle Size (CIPS) experiment onboard the Aeronomy of ICE in the Mesosphere (AIM) satellite. The mean ice particle radius in NLCs is found to be positively/negatively correlated with IMF  $B_y$  in the Southern/Northern Hemisphere (SH/NH), respectively, on a day-to-day time scale in most of the 20-summer  
15 seasons during the 2007-2017 period with a near 0-day lag time, and the response in the SH is stronger than that in the NH. Moreover, the albedo, ice water content, and frequency of occurrence of NLCs present positive correlation with IMF  $B_y$  in SH but no significant correlation in NH. The superposed epoch analysis (SEA) further indicates the  $r_m$  on average changes by about 0.73 nm after IMF  $B_y$  reversals, which is significant at 90% confidence level in Monte Carlo sensitivity tests. Our results suggest an IMF  $B_y$ -driven pathway: the influence of the solar wind on the polar ionospheric electric potential affects  
20 the microphysical processes in NLCs, and consequently the ice particle radius and NLC brightness.

## 1 Introduction

### 1.1 NLCs

Noctilucent clouds are the highest and coldest clouds in the terrestrial atmosphere, forming in the high latitude summer mesosphere at ~83 km altitude, where the temperature can drop to ~140 K. The long-term trends in NLCs are supposed to be  
25 associated with global climate change, while NLCs are not only susceptible to perturbations from lower atmospheric activities such as gravity waves (Gao et al., 2018) and planetary waves (France et al., 2018), but may also be affected by solar activities on various time scales, including solar proton events (Bardeen et al., 2016; Winkler et al., 2012), the 27-day solar rotation (Robert et al., 2010; Thomas et al., 2015; Thurairajah et al., 2017), and the 11-year solar cycle (Dalin et al., 2018; DeLand and Thomas, 2019; Hervig et al., 2019). To distinguish the contribution of solar activity to polar mesospheric  
30 clouds from that of climate change, it is important to clarify the mechanisms of the solar influence on NLCs. Based on the

observed modest anti-correlation in NLCs with the 27-day and 11-year solar variations, both photodissociation and dynamic origins have been proposed in which the solar ultraviolet irradiance as characterized by the Lyman alpha ( $Ly-\alpha$ ) index is supposed to play a key role by altering the water vapor and temperature of NLCs (Dalin et al., 2018; Thomas et al., 2015), while in general the exact mechanism is still unclear. In this paper, the  $IMF B_y$  rather than the  $Ly-\alpha$  is applied as the solar activity index to explore the solar wind-NLC link, and a new hypotheses will be discussed in the next section.

## 1.2 $IMF B_y$ -related mechanisms for NLC-Solar link

The main  $IMF B_y$ -related process is the change of ionospheric potential in polar cap regions, which determines the flow of the regional downward ionosphere-earth current density  $J_z$ . The current flow is part of the global atmospheric electric circuit (GEC), with ionospheric potential being  $\sim 250$  kV positive relative to Earth's surface, maintained by the global thunderstorms and electrified clouds (Slyunyaev et al., 2019; Williams and Mareev, 2014). The Earth experiences a Lorentz electric field applied by the cross product of solar wind magnetic field and velocity, which is mainly northward/southward for positive/negative (duskward/dawnward)  $IMF B_y$ , and observations have shown that the  $IMF B_y$ -dependent daily-averaged perturbation of ionospheric potential ranges from  $-30$  to  $30$  kV at high geomagnetic latitudes and is opposite in the SH/NH (Tinsley and Heelis, 1993).

A possible link may exist between the solar wind  $B_y$  variations and polar surface meteorology through the ionospheric potential, which has been supported by a variety of observations, in term of polar surface pressure (Lam et al., 2013), geopotential height (Lam et al., 2014), temperature (Freeman and Lam, 2019; Lam et al., 2018), and below-cloud irradiance (Frederick et al., 2019; Frederick and Tinsley, 2018; Tinsley et al., 2021). It should be noted that these observations are characterized by two features: the responses in SH and NH are opposite, in line with the opposite  $IMF B_y$ -induced ionospheric potential in SH and NH; the delay time is short, lasting only a few days or less. A hypothesis has been proposed to explain the above observations: firstly, solar wind  $B_y$  induces changes in the ionospheric electric potential, as well as the downward current density  $J_z$  in the GEC; second, the microphysical processes inside clouds are sufficiently sensitive to space charge generated by  $J_z$  so that the cloud properties such as infrared opacity and albedo will consequently be affected. Finally, polar surface meteorology will be influenced by cloud radiative forcing (Lam and Tinsley, 2016). The invoked cloud microphysical changes have been detailed for individual aerosol-droplet collisions (Zhang et al., 2018, 2019; Zhang and Tinsley, 2017, 2018), but direct measurements in clouds and modelling are required to test this hypothesis.

In comparison with the tropospheric clouds within which many factors are involved, the polar mesospheric clouds provide a relatively pure scenario to study the role played by electric charges in the microphysical process of clouds. By extending the above 'solar - GEC - cloud microphysics - tropospheric meteorology' hypothesis, it is straightforward to propose the ' $IMF B_y$  - Ionospheric potential - NLC Microphysics - NLC brightness' hypothesis for the polar mesospheric clouds:  $IMF B_y$  induces changes in polar ionospheric potential, which will then affect electric charges on the ice particles in NLCs with implications for the ice particle formation and growth process, and ultimately affect the macroscopic properties of NLCs.

The CIPS/AIM began observing the NLCs in 2007 and 20-summer-season data in SH and NH from 2007 to 2017 are  
65 available now. Therefore, we investigated the hypothetical  $IMF B_y$ -driven solar-NLC link in this study. The paper is  
structured as follows: Section 2 provides a brief description of the CIPS data and solar wind data. Section 3 presents the  
results of NLC correlation with  $IMF B_y$  during the 20 NLC seasons on the day-to-day scale, as well as the superposed epoch  
analysis for NLCs response to  $IMF B_y$  reversals. Section 4 discusses the results and Section 5 summarizes our main  
conclusions.

## 70 2 Data

### 2.1 CIPS/AIM data

The aeronomy of ICE in the Mesosphere (AIM) satellite was launched on 25 April 2007 to a sun-synchronous polar orbit  
whose local time is mainly midday-midnight at high latitude regions. The Cloud Imaging and Particle Size (CIPS)  
experiment onboard AIM comprises a panoramic UV nadir imager, consisting of four cameras operating at 265 nm, with a  
75 field of view of  $120^\circ \times 80^\circ$  and a horizontal spatial resolution of  $5 \times 5$  km. This platform observes the scattered radiance from  
NLCs, and images the NLCs of  $\sim 40^\circ$ - $85^\circ$  latitude zone for the summer hemisphere  $\sim 15$  times per day. The CIPS has  
provided NLC data from the 2007 summer season until now, in terms of ice particle radius, albedo, and IWC, and detailed  
descriptions of the CIPS data products, calibration, retrieval algorithms, and retrieval uncertainties have been published  
(Carstens et al., 2013; Lumpe et al., 2013). The CIPS level 2 orbit data provide rectangular images of NLC properties for  
80 each of the 15 orbit strips per day, in which a single pixel represents a  $25 \text{ km}^2$  ( $5 \times 5$  km) area anywhere on the globe and a  
 $5800 \times 1000$  km strip region is covered, thus the cloud cover as well as the frequency of occurrence ( $FO$ ) of NLCs can be  
obtained by counting the number of pixels showing them in the images. This study applied the version 5.20 CIPS polar  
mesospheric cloud level 2 data to investigate the response of NLCs to solar variations during 10 NLC seasons (from 2007 to  
2016) in NH and 10 NLC seasons (from 2007/2008 to 2016/2017) in SH.

### 85 2.2 Solar wind data

The solar wind  $B_y$  data in GSM format were downloaded online from the GSFC/ SPDF OMNI Web interface  
(<https://omniweb.gsfc.nasa.gov/form/dx1.html>). In the geocentric solar magnetospheric (GSM) coordinate system, the origin  
locates at the center of the Earth,  $X$  points towards the sun,  $Z$  lies in the plane of the  $X$  and geomagnetic dipole and is  
perpendicular to  $X$  (roughly northward),  $Y$  completes the righthanded coordinate system, stretching toward the dusk. The  
90 solar wind structures are fairly complex, varying from 2-sector to 4-sector and sometimes irregularly, therefore, during a 27-  
day solar rotation period, the  $IMF B_y$  can reverse 2 or 4 or more times, unlike other solar indexes such as  $Ly-\alpha$  or F10.7  
which show regular 27-day period. In order to apply the widely used SEA method, the key days of  $B_y$  reversals are listed in  
Table 1, which have been selected to ensure that during the 5-day period before and after the key day there is no NLCs data  
missed and that the direction of  $IMF B_y$  is relatively stable. The  $IMF B_y$  changing from positive to negative (from negative to

95 positive) is denoted by  $p2n$  ( $n2p$ ); four groups of dates during 2007 and 2017 are listed in Table 1, corresponding to the  $n2p$  (28 cases) and  $p2n$  (29 cases) reversals during NH summer, and the  $n2p$  (23 cases) and  $p2n$  (18 cases) reversals during SH summer, respectively.

### 3 Results

#### 3.1 Correlation analysis of day-to-day responses of NLCs to $IMF B_y$

100 Figure 1 shows the variations of the daily-averaged solar wind magnetic field and NLC properties during the NLC seasons from 2007 through 2017. The daily-averaged  $IMF B_y$  varies between -5 nT and 5 nT, as shown in Fig. 1(a-b), and the periods of  $IMF B_y$  variations are complex, as noted above. Fig. 1(c-h) show the intensity of NLCs in terms of mean ice particle radius ( $r_m$ ), mean albedo ( $Alb_m$ ), and mean ice water content ( $IWC_m$ ), while Fig. 1(i-j) shows the cloud cover of NLCs, as calculated by counting of pixels, and is linearly proportional to  $FO$ . In order to diminish noise, the NLC data in the latitude  
105 bands  $65^\circ$ - $85^\circ$  are used because the NLCs are rarely observed by CIPS below  $65^\circ$  latitude, and an albedo threshold of  $5 \times 10^{-6} \text{ sr}^{-1}$  was applied. The intensity and coverage of NLC peak  $\sim 20$  days after the solstice, and show strong seasonal variations, with the exception of the mean ice particle radius,  $r_m$ .

Figure 2 shows the correlation coefficients of NLC intensity and coverage anomaly in the  $65^\circ$ - $85^\circ$  latitude zone with  $IMF B_y$  for each of the 20 summertime seasons, from 2007 to 2016 in the NH and from 2007/2008 to 2016/2017 in the SH.  
110 To remove the seasonal variation, the solar signals are extracted by subtracting the 40-day smoothed CIPS data. To avoid the no-cloud days, only the CIPS data during the period of 10 days before and 50 days after the solstice day are used (Fig. 1). The link between the anomalous mean ice particle radius  $r_m$  with  $IMF B_y$  is conspicuous, with positive correlation coefficients in all of the SH summer seasons and negative correlations in most of the NH summer seasons (Fig. 2a). These opposite responses in the SH and NH are consistent with the opposite ionospheric potential changes in SH and NH caused by  
115  $IMF B_y$ . Further, the response was stronger in the SH, with the correlation coefficient being about twice of that in NH. In NLCs, the larger the ice particle size is, the greater the albedo and IWC are, namely, the mean ice particle radius is normally positively correlated with the albedo and IWC, the 20-seasonal CIPS data show a correlation coefficient of  $\sim 0.52$  between  $r_m$  and  $Alb_m$  and of  $\sim 0.35$  for  $r_m$  and  $IWC_m$ . Conversely, the cloud cover of NLCs will also change in pace with the formation and growth process of ice particle radius, and the 20-seasonal CIPS data also show a correlation coefficient of  $\sim 0.48$  between  
120  $r_m$  and  $FO$ . It is thus reasonable to speculate that the albedo, IWC, and  $FO$  will respond to  $IMF B_y$  in concert with ice particle radius, and Fig. 2(b-d) show the correlation coefficients between the anomaly of  $Alb_m$ ,  $IWC_m$ , and  $FO$  with  $IMF B_y$  are pronounced in SH, but not in NH.

Furthermore, Figure 3 shows the mean correlation coefficients for time lags varying from 0 to 6 days. The error bars illustrate the standard deviation of the mean, which are calculated from the 10 seasonal correlation coefficients and are also  
125 given in Fig. 2 at 0-day lag time. A very short delay time was observed (Fig. 3), with the maximum correlations occurring near zero day, implying a microphysical response in NLCs to  $IMF B_y$  similar to the short delay time that has also been

observed in the solar-troposphere studies. In previous studies of the link between  $Ly-\alpha$  and NLCs, the proposed mechanisms involving photodissociation, heating, or circulation all required longer time. In contrast, the  $IMF B_y$ -related processes of ionospheric potential changes respond quickly to solar wind magnetic field reversals. In summary, the short delay time of NLC properties responding to  $IMF B_y$  variations implies a mechanism of electro-dynamic origin rather than thermal-dynamic origin.

In order to further verify the response of NLCs to solar wind at different latitudes, the approaches in Fig. 2 were repeated for the five latitude bands of  $80^\circ-85^\circ$ ,  $75^\circ-80^\circ$ ,  $70^\circ-75^\circ$ ,  $65^\circ-70^\circ$ ,  $60^\circ-65^\circ$ , respectively. The correlation coefficients of the anomaly of NLC properties with  $IMF B_y$  are shown in Figure 4, and the slope of the anomaly of NLC properties to  $IMF B_y$  are given in Figure 5. Fig. 4(a) and 5(a) show that in SH, the correlation and sensitivity of ice particle radius  $r_m$  to  $IMF B_y$  are both greater at higher latitudes, in agreement with the ionospheric potential perturbations caused by  $IMF B_y$  changes, while in NH the correlation and sensitivity are just about half of that in SH but still significant in latitude higher than  $65^\circ$ . For the  $60^\circ-65^\circ$  latitude region, the results are not significant, this may be because at lower latitudes the  $IMF B_y$ -induced processes are too weak and because the rare NLC occurrences at lower latitudes entail weaker signal/noise. Fig. 4(b-d) and 5(b-d) show that the responses of the anomaly of  $Alb_m$ ,  $IWC_m$ , and  $FO$  to  $IMF B_y$  are noticeable for high latitude in SH, and obvious for  $Alb_m$  only at latitudes higher than  $75^\circ$  in NH, but are not obvious for  $IWC_m$  and  $FO$  in NH. Dividing the slope given in Fig. 5 by the yearly averaged NLC properties in  $65^\circ-85^\circ$  latitudes bands, then the relative slope can be obtained:  $(0.71\pm 0.16)\%/nT$  in SH and  $(-0.28\pm 0.08)\%/nT$  in NH for  $r_m$ ,  $(1.36\pm 0.59)\%/nT$  in SH and  $(-0.52\pm 0.32)\%/nT$  in NH for  $Alb_m$ ,  $(0.74\pm 0.48)\%/nT$  in SH and  $(-0.26\pm 0.28)\%/nT$  in NH for  $IWC_m$ ,  $(2.28\pm 1.73)\%/nT$  in SH and  $(-0.38\pm 0.60)\%/nT$  in NH for  $FO$ , and in consideration of the  $\sim 5$  nT amplitude of  $IMF B_y$  variation during solar wind reversals, the responses of NLC intensity and coverage to  $IMF B_y$  are not negligible.

In addition, other solar wind parameters such as  $IMF B_z$ ,  $A_p$  index and  $Ly-\alpha$  irradiance have also been examined by the same processes; however, no correlations were found for them at 0-day lag time. The solar wind magnetic field line has an Archimedes spiral pattern, i.e.,  $IMF B_x$  is negatively proportional to  $IMF B_y$  and a correlation coefficient of about -0.67 between them was obtained during the period of 2007 to 2017, thus similar correlations also exist between  $IMF B_x$  and NLC properties, but with the opposite sign. The  $IMF B_z$  corresponds to a dawn-dusk solar wind electric field, and thus can generate a dawn-dusk ionospheric potential drop for both hemispheres, while the sun-synchronous orbit of AIM is designed to be midday-midnight with rare opportunity to pass the dawn-dusk regions, thus the zero correlations observed for NLCs with  $IMF B_z$  are just as expected.

### 3.2 Superposed epochs for NLCs response to $IMF B_y$ reversals

The superposed epoch analysis is frequently applied in the studies of atmospheric responses to short-term solar variations, in which solar signals are more obvious and easier to be extracted than for decadal or longer-term variations. Although the NLCs only occur in summer, during the 20-season period of CIPS data enough  $IMF B_y$  reversal cases have been accumulated,

as listed in Table 1, allowing the SEA method to be used to explore the NLCs responses. In the SEA method, the ice particle  
160 radius distribution is denoted by  $f(r)$ , where the distribution is of the values of  $r$  over the array of pixels on a given day. The  
averages of  $f(r)$  during 3 days before and 3 days after the key day are denoted by  $f_{3-pre}$  and  $f_{3-af}$  respectively, then the changes  
of ice particle radius distribution  $\delta f$  during  $IMF B_y$  reversals are given by  $\delta f = f_{3-af} - f_{3-pre}$ . The results of  $\delta f$  for the  $n2p$  and  
 $p2n$   $IMF B_y$  reversals in SH given in Table 1 are illustrated in Figure 6, with an albedo threshold of  $5 \times 10^{-6} \text{ sr}^{-1}$ . The mean ice  
particle radius  $r_m$  can be calculated by integrating the product of radius and its distribution,  $r_m = \int r f(r)$ , thus the changes of  $r_m$   
165 during  $IMF B_y$  reversals are obtained by  $\delta r_m = r_{m,3-af} - r_{m,3-pre} = \int r \delta f$ , and the values of  $\delta r_m$  are given in each panel of Fig. 6.  
For  $n2p/p2n$   $IMF B_y$  reversals, the polar ionospheric electric potential will increase/decrease in the SH, and the  $r_m$   
increases/decreases by about 0.88/1.07 nm in SH as shown in Fig.6. Similarly, the results of NH are illustrated in Figure 7,  
for  $n2p/p2n$   $IMF B_y$  reversals, the polar ionospheric electric potential will decrease/increase in the NH, the  $r_m$   
decreases/increases by about 0.25/0.71 nm in NH as shown in Fig.7. Generally, the ice particle average radius changes by  
170 about 0.73 nm during  $IMF B_y$  reversals, and the responses in SH is stronger than that in NH. The results in Fig. 6-7 were  
subject to Monte Carlo sensitive tests, in which the same number of key days in Table 1 were randomly generated and  $\delta r_m$   
can be calculated by SEA, by repeating this process for one thousand times, the distribution of  $\delta r_m$  are obtained, showing the  
results in Fig. 6-7 are significant at 90% confidence level.

In addition, we also investigate the responses of NLCs to  $IMF B_y$  reversals for different brightness of noctilucent  
175 clouds, namely, by setting the albedo of NLCs varying by  $5 \times 10^{-6} \text{ sr}^{-1}$ , the changes of particle radius  $\delta r_m$  for different albedos  
can be obtained. Figure 8 shows that for NLCs albedo varying from  $5 \times 10^{-6} \text{ sr}^{-1}$  to  $30 \times 10^{-6} \text{ sr}^{-1}$ , the particle radius  $r_m$  will  
changes consistently to  $IMF B_y$  reversals. The results in Fig. 8 further verify that the dark and light NLCs are all sensitive to  
 $IMF B_y$  reversals. The results in Fig. 8 also support that the responses of NLCs to  $IMF B_y$  is stronger in SH than that in NH.

#### 4 Discussion

180 Our results support the existence of a link between NLCs and solar wind magnetic fields, characterized by the two features  
of opposite responses in SH and NH in conjunction with a short lag time of 1-day at most, similar to the previously  
introduced solar-troposphere link.

The ‘ $IMF B_y$  - ionospheric potential - NLCs microphysics – NLCs brightness’ hypothesis is applied to explain the  $IMF B_y$ -driven solar-NLCs link:  $IMF B_y$  will firstly change the ionospheric potential at polar regions, then charge the ice particles  
185 inside NLCs and play a role in the ice particle formation or growth process, finally the ice particle radius as well as albedo  
and IWC will be affected. It’s critical to know how the microphysics in NLCs are influenced by the ice particles’ charges in  
this hypothesis, there are two alternatives: one explanation is the agglomeration of ice and dust particles in mesosphere may  
be affected by the charges attached to them, because image charges will be induced when their distance is close enough  
along with a strong attractive electric force exerted to them resulting in a collision, this process in polar mesospheric clouds  
190 has been initially simulated (Baptiste et al., 2021), it should be emphasized that this image charges-resulted collision is also

important in the solar-troposphere link (Zhang and Tinsley, 2017; 2018; Zhang et al., 2018; 2019); another explanation is the ionization of ice particles can help the growth of coagulation and thus enhance the formation of cloud condensation nuclei, it has been studied by simulations and experiments under tropospheric conditions (Svensmark et al., 2017; Yu and Luo, 2014), while it is unknown if it is still valid under the extremely low temperature and low pressure conditions at mesopause.

195 Although the above two explanations provide some insights into the charges-related ice particle formation process in NLCs, the detailed process is still unclear and further investigations are needed.

The mechanism involving the  $B_y$ -related changes in the ionosphere-earth current density  $J_z$  in the polar cap produces a change in space charge at the upper and lower boundaries of the NLCs, due to the large reduction of conductivity within NLCs caused by the attachment and recombination of electrons and ions on the ice particles. Gradients of electric field are created as the electric current enters and exits the NLC boundaries, requiring the formation of space charge according to Gauss's Law; this space charge is positive at the cloud top and negative at the cloud base (Zhou and Tinsley, 2007, 2012). Until measurements of electron and ion concentrations and charges on ice crystals become available, it is difficult to evaluate the importance of the  $B_y$ -related changes in electric charge and microphysics on the NLCs.

200

The *IMF*  $B_y$ -related mechanisms are concerned more about the microphysical process of ice particle formation and growth, namely, the changes of mean ice particle radius, and are distinct from the  $Ly-\alpha$  related mechanism, which focuses more on IWC changes. Unlike the  $Ly-\alpha$  irradiance has a regular 27-day period, the *IMF*  $B_y$  varies in a more complex way, thus its effect on NLCs are not necessarily to be regular 27-day periodic. To better understand the effect of solar activity on NLCs at different lags, periods, and latitudes, the *IMF*  $B_y$  and  $Ly-\alpha$  should both be considered in future works.

205

## 5 Conclusion

210 The responses of NLCs to solar wind magnetic fields were investigated using the CIPS/AIM data. Our findings suggest that such a solar-NLC link exists. The mean ice particle radius in NLCs was positively/negatively correlated with the *IMF*  $B_y$  in SH/NH on the day-to-day time scale in the majority of NLC seasons during the period of 2007-2017, with a short lag time of 1 day at most. The correlation and sensitivity of  $r_m$  versus *IMF*  $B_y$  were stronger in the SH, about twice as that in the NH, and more conspicuous in higher latitudes. Similar responses of albedo, IWC and *FO* in NLCs with *IMF*  $B_y$  were also noticeable

215 in the SH but not obvious in the NH. The superposed epoch analysis provides further insights into the mean ice particle radius responses during  $n2p$  and  $p2n$  *IMF*  $B_y$  reversals in SH and NH, and results show the  $r_m$  averagely changes by about 0.73 nm following *IMF*  $B_y$  reversals, which is significant at 90% confidence level in the Monte Carlo sensitivity tests. The solar-NLC links are interpreted from the perspective of an *IMF*  $B_y$ -driven mechanisms: opposite ionospheric electric potential changes in SH and NH induced by the *IMF*  $B_y$ , which change the downward current density  $J_z$  through the NLCs and affects their microphysics. However, it is necessary to further understand the underlying processes of NLCs proposed in

220 above mechanism, and to implement and verify them in polar mesospheric clouds modelling.

*Data Availability.* The version 5.20 CIPS polar mesospheric cloud level 2 data files are available on: <http://lasp.colorado.edu/aim/>. The solar wind magnetic field data are available on the GSFC/SPDF OMNI Web interface: <https://omniweb.gsfc.nasa.gov/form/dx1.html>.

225 *Author Contributions.* Liang Zhang, Brian Tinsley, and Limin Zhou conceived the idea together. Liang Zhang analyzed the data and drafted the manuscript. Brian Tinsley and Limin Zhou revised the paper and supervised the research.

*Competing Interests.* The authors declare that they have no conflict of interests.

*Acknowledgements.* This work was funded by the National Science Foundation of China (No. 41905059) and the Tongji SKL fund (No. 1350231101/055). We are especially grateful to the entire AIM program for providing us the continuous  
230 CIPS data, and we further wish to acknowledge the OMNI group for providing high-quality solar wind data.

2016-20	2016-38		

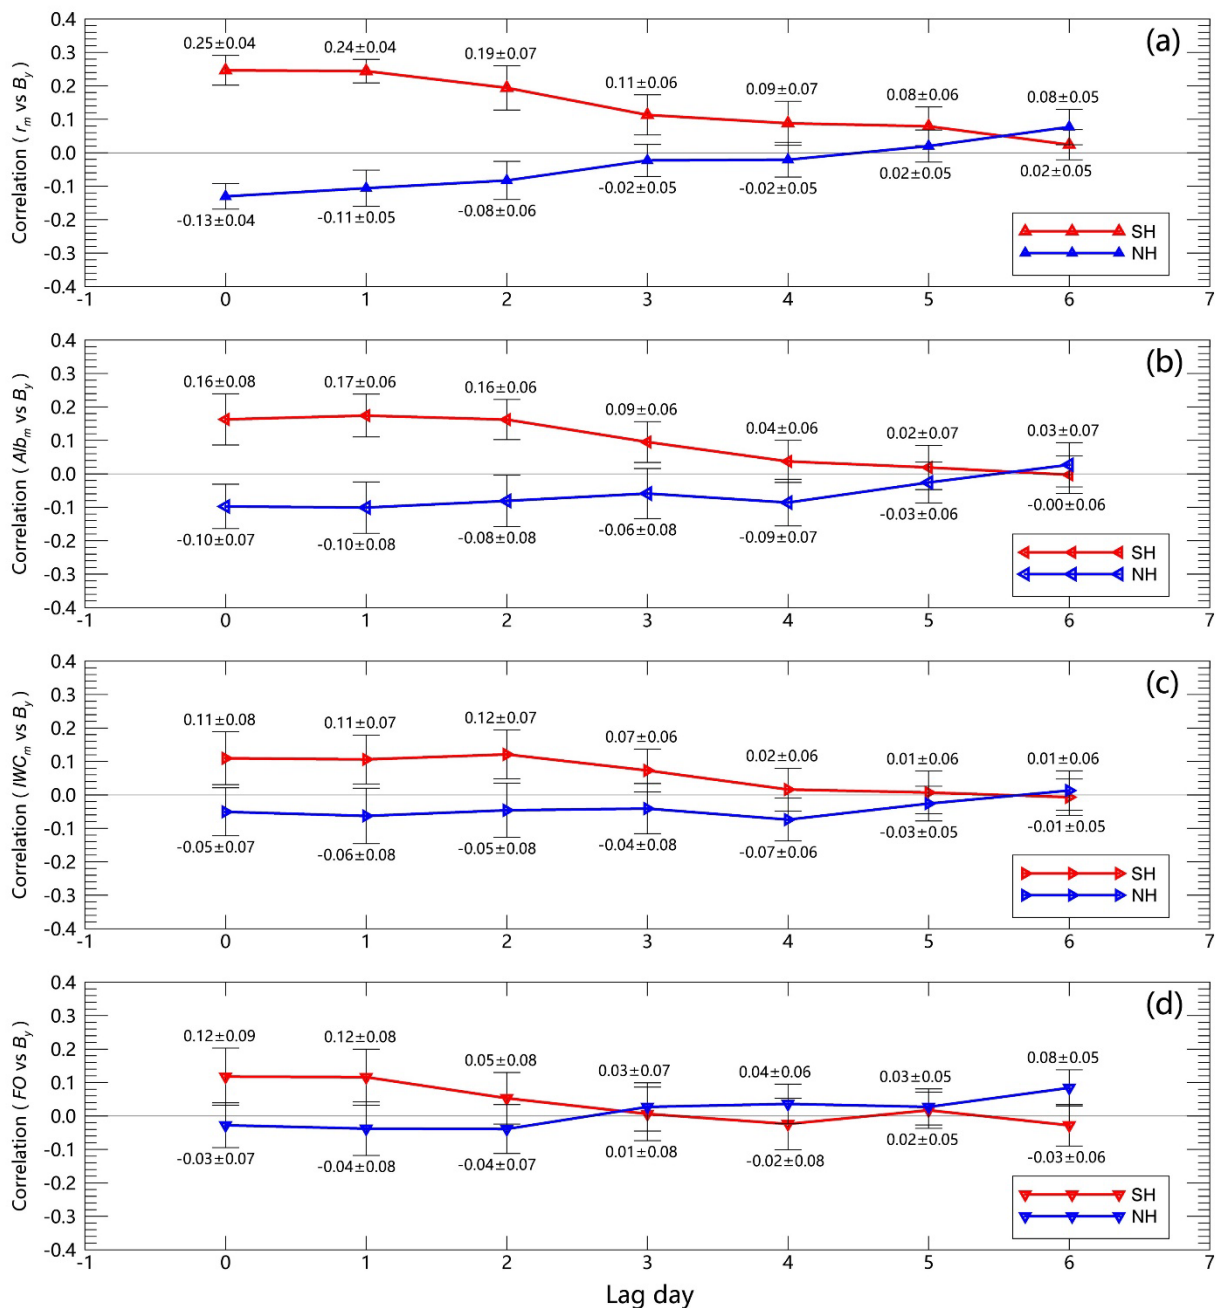

**Figure 1.** Daily-averaged IMF  $B_y$ , mean ice particle radius ( $r_m$ ), mean albedo ( $Alb_m$ ), mean ice water content ( $IWC_m$ ), and cloud cover observed by CIPS for NH (left) and SH (right) for each of the NLC seasons from 2007 through 2017.

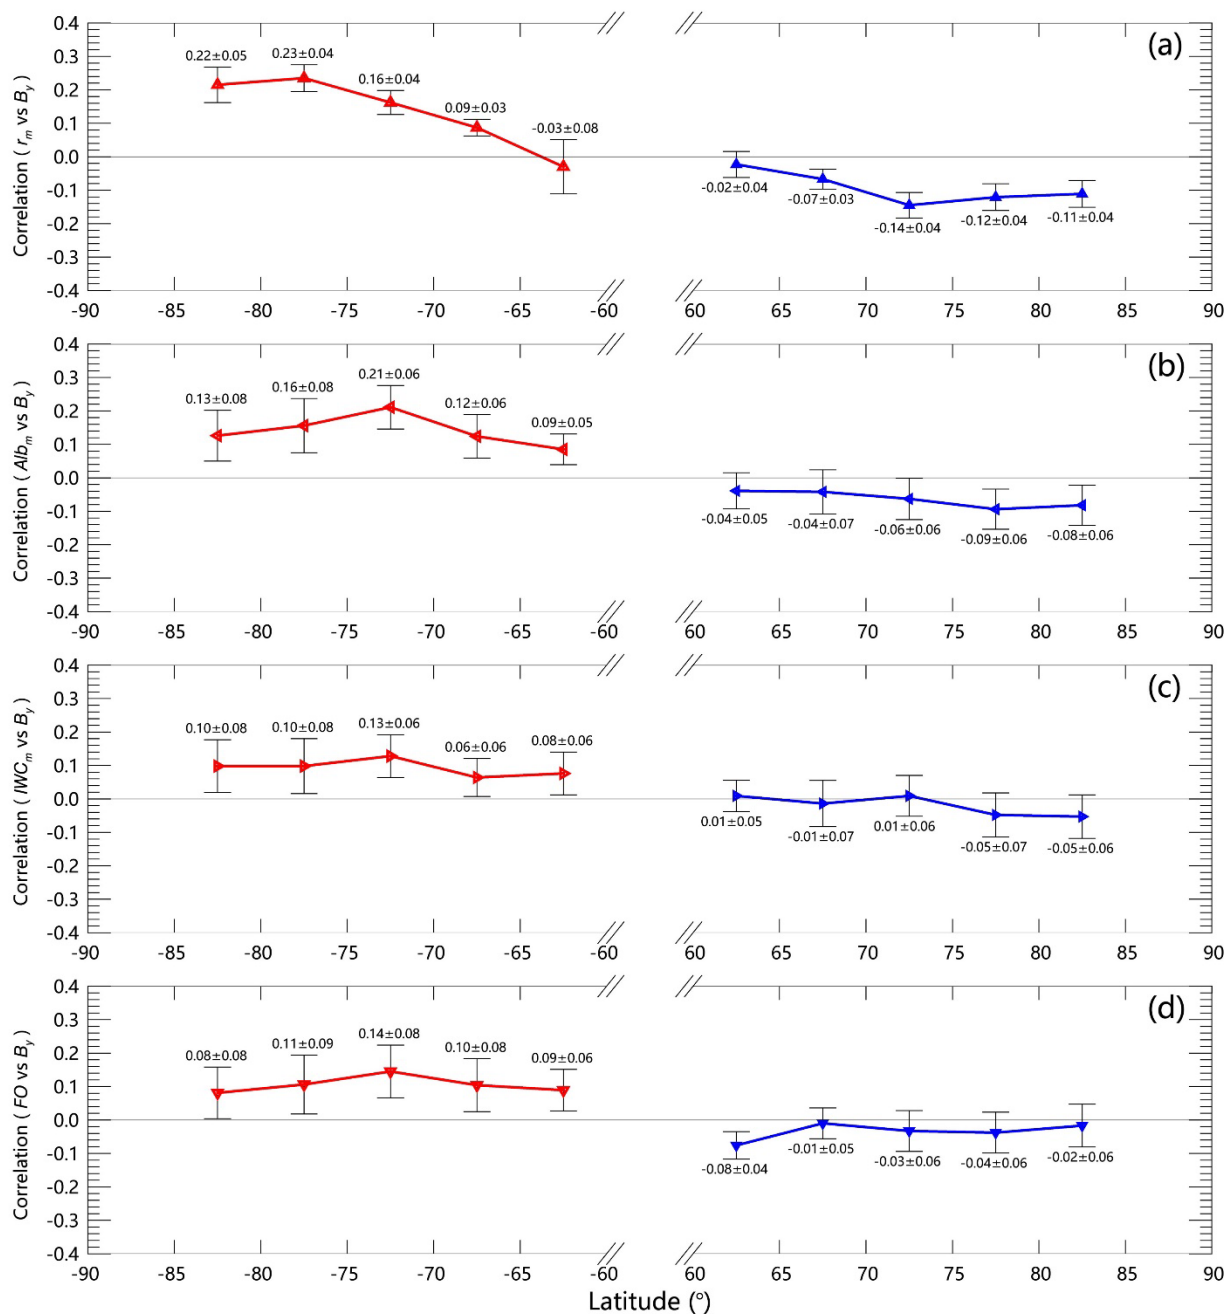

335

**Figure 2.** Correlation coefficients between the anomaly of  $r_m$ ,  $Alb_m$ ,  $IWC_m$  and  $IMF B_y$  from 2007 to 2017, with red/blue symbols representing the seasonal correlation coefficients and dashed red/blue lines illustrating the mean correlation coefficients for the SH and NH, respectively.

340

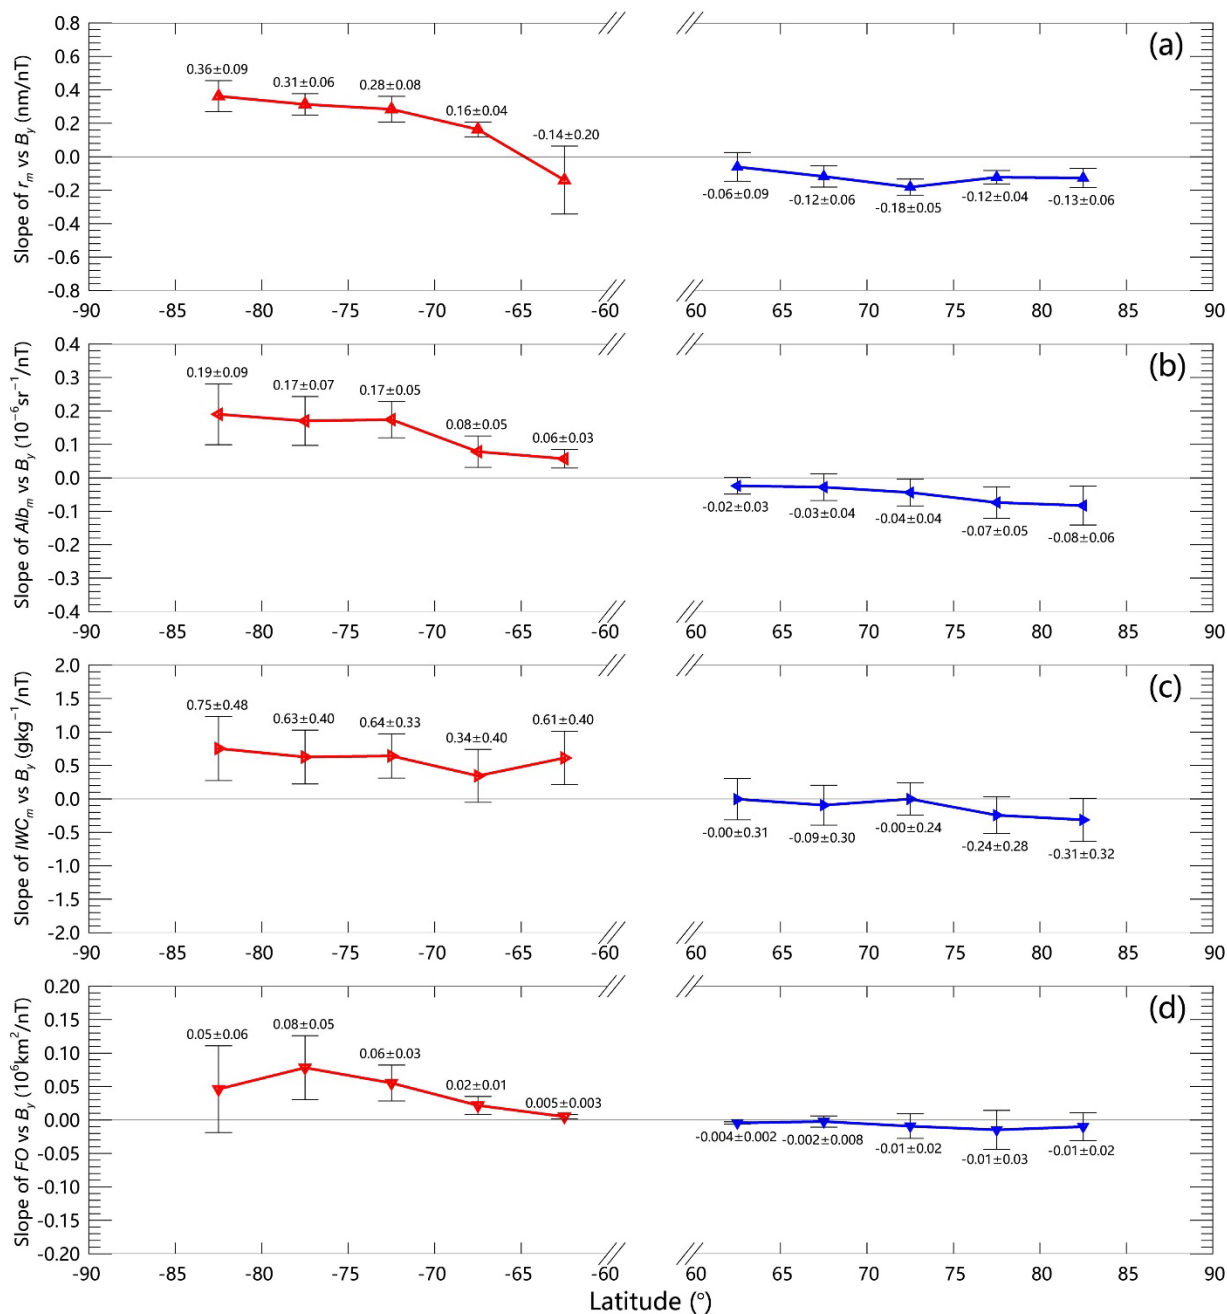

**Figure 3.** Correlation coefficients between the anomaly of  $r_m$ ,  $Alb_m$ ,  $IWC_m$  and  $IMF B_y$  for time lags varying from 0 to 6 days, with red/blue lines representing the mean correlation coefficients and error bars illustrating the standard deviation of the mean for the SH and NH respectively.

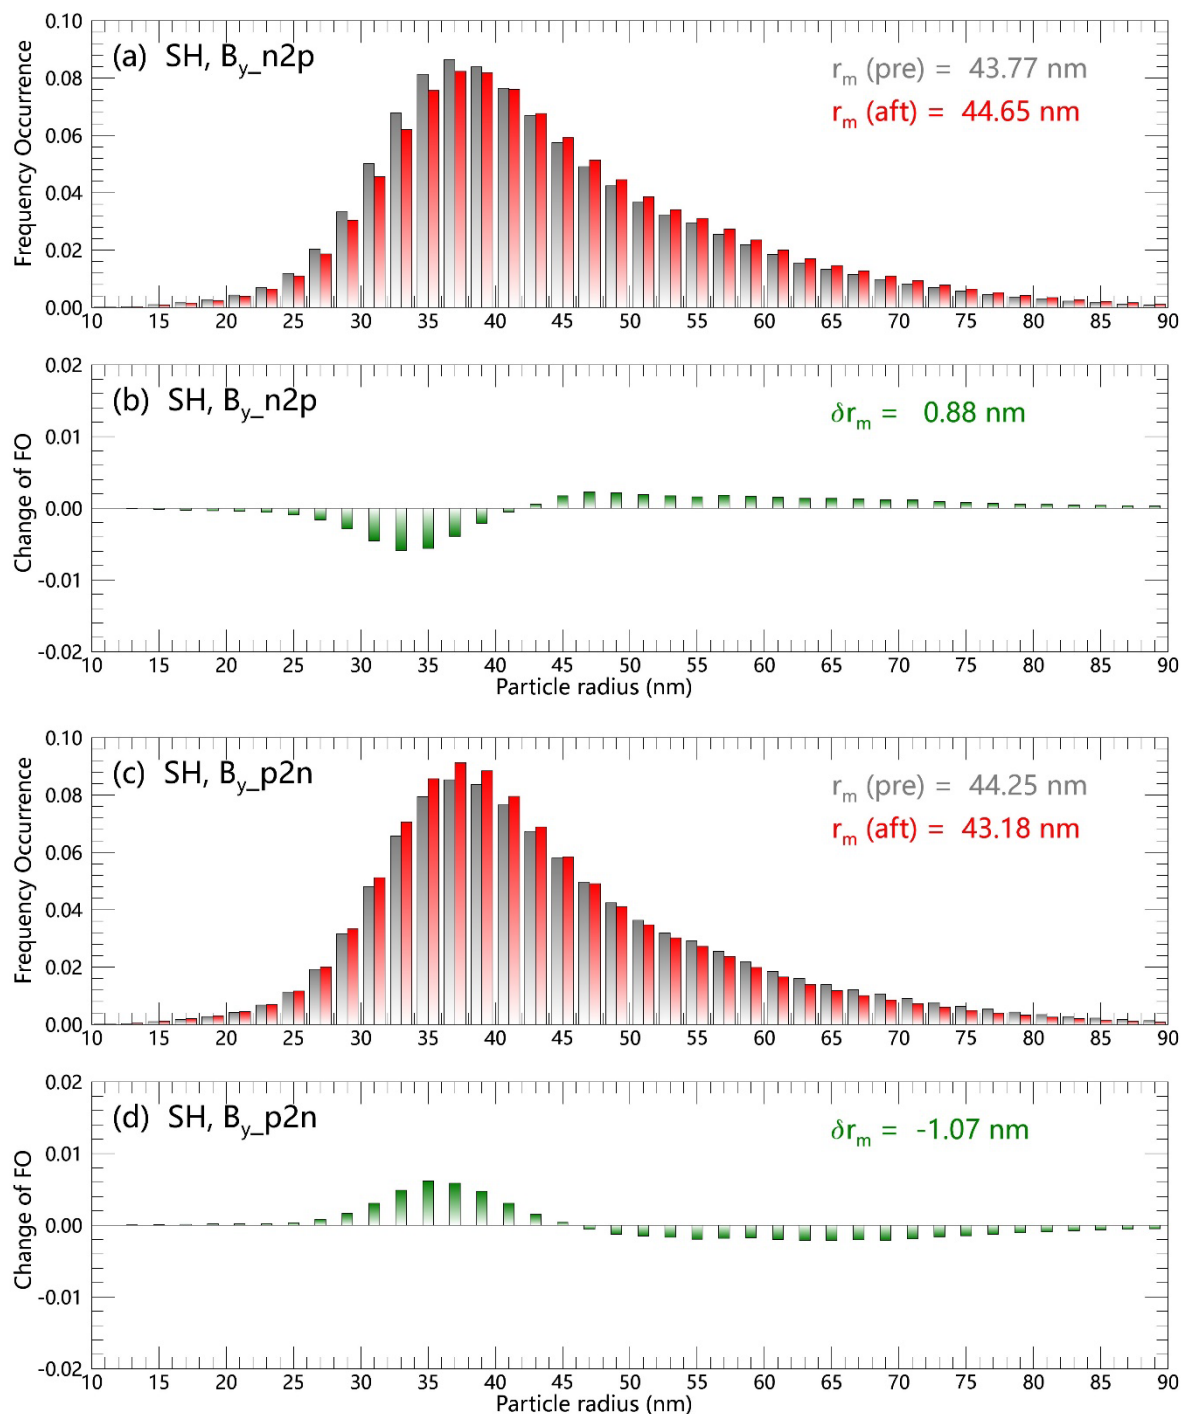

345

**Figure 4.** Correlation coefficients between the anomaly of  $r_m$ ,  $Alb_m$ ,  $IWC_m$  and  $IMF B_y$  at different latitude bands, with red/blue lines representing the mean correlation coefficients and error bars illustrating the standard deviation of the mean for the SH and NH respectively.

350 **Figure 5.** Slope of the anomaly of  $r_m$ ,  $Alb_m$ ,  $IWC_m$  versus  $IMF B_y$  at different latitude bands, with red/blue lines representing the mean slope and error bars illustrating the standard deviation of the mean for the SH and NH respectively.

**Figure 6.** Changes of ice particle radius distribution  $\delta f(r)$  during  $n2p$  and  $p2n$  IMF  $B_y$  reversals in the southern hemisphere. The distributions of  $r$  over all pixels on three days before/after the key days are indicated by the gray/red bars, and the changes between them are shown by the green bars.

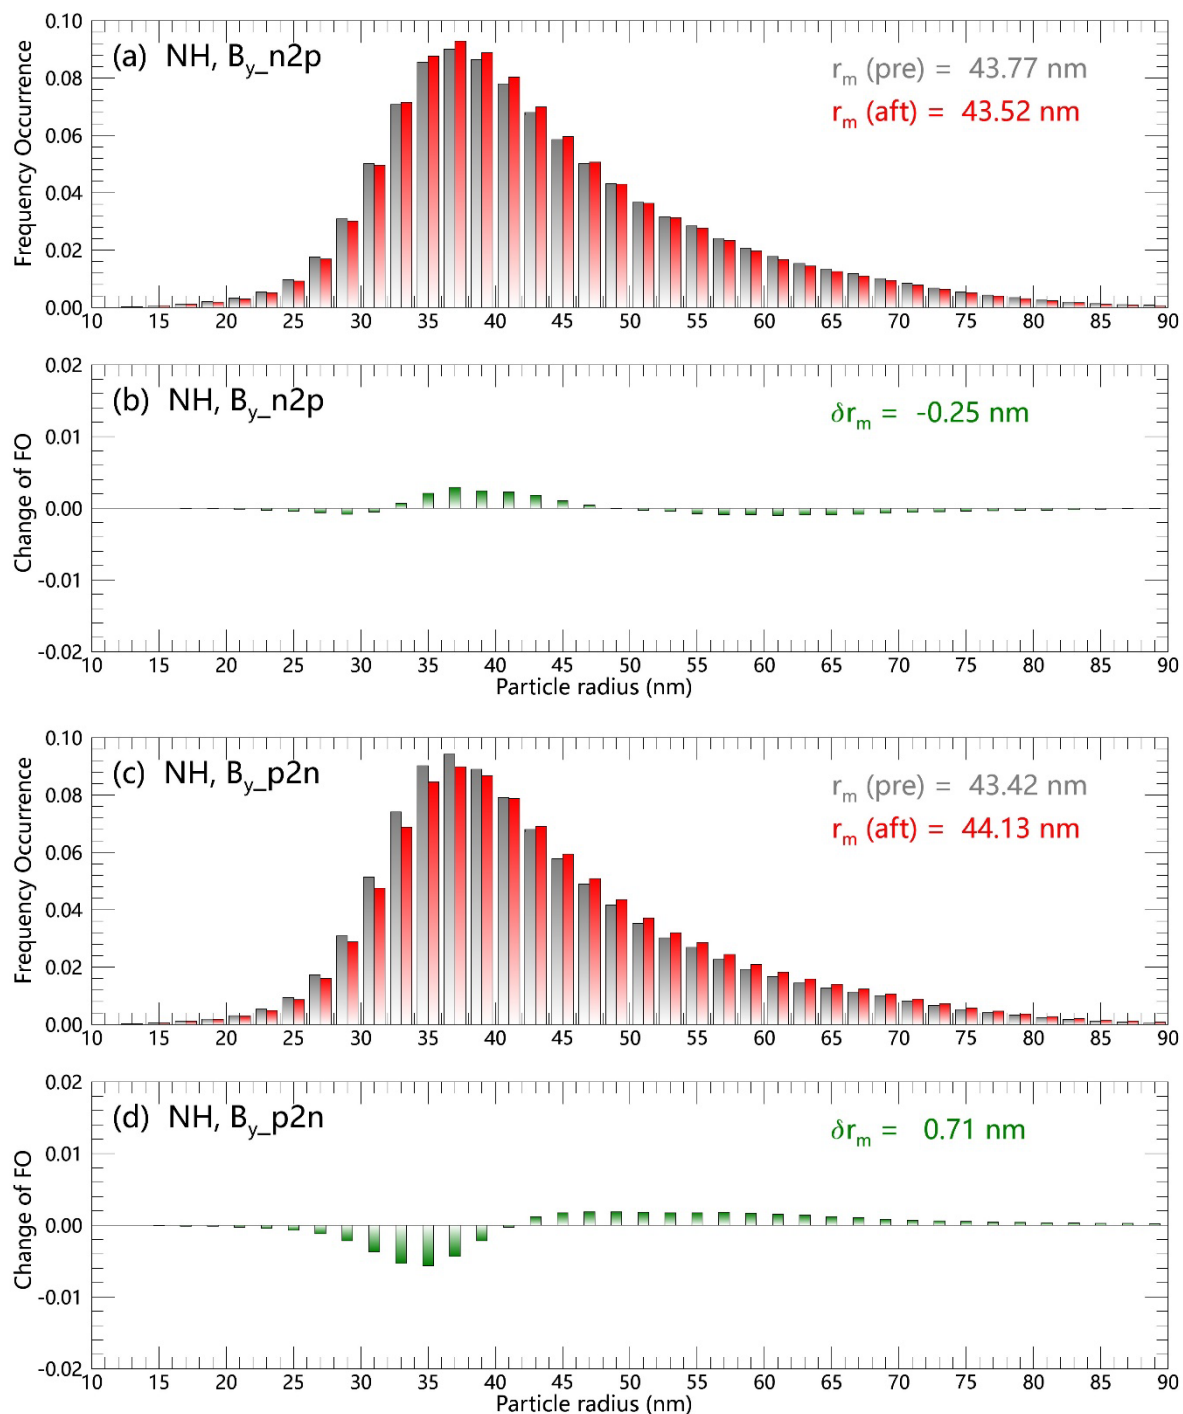

Figure 7. Similar as Figure 6, but for the results of the northern hemisphere.

**Figure 8.** The influences of *IMF*  $B_y$  reversals on the ice particle radius changes  $\Delta r_m$  at different NLCs brightness.
