21 **Abstract** Accurate representation of aerosol optical properties is essential for modeling and remote sensing of
22 atmospheric aerosols. Although aerosol optical properties are strongly dependent upon the aerosol size distribution,
23 use of detailed aerosol microphysics schemes in global atmospheric models is inhibited by associated computational
24 demands. Computationally efficient parameterizations for aerosol size are needed. In this study, airborne
25 measurements over the United States (DISCOVER-AQ) and South Korea (KORUS-AQ) are interpreted with a global
26 chemical transport model (GEOS-Chem) to investigate the variation in aerosol size when organic matter (OM) and
27 sulfate-nitrate-ammonium (SNA) are the dominant aerosol components. The airborne measurements exhibit a strong
28 correlation ($r = 0.83$) between dry aerosol size and the sum of OM and SNA mass concentration (M_{SNAOM}). A global
29 microphysical simulation (GEOS-Chem-TOMAS) indicates that M_{SNAOM} , and the ratio between the two components
30 ($\frac{\text{OM}}{\text{SNA}}$) are the major indicators for SNA and OM dry aerosol size. A parameterization of dry effective radius (R_{eff}) for
31 SNA and OM aerosol is proposed, which well represents the airborne measurements ($R^2 = 0.74$, slope = 1.00) and the
32 GEOS-Chem-TOMAS simulation ($R^2 = 0.72$, slope = 0.81). When applied in the GEOS-Chem high-performance
33 model, this parameterization improves the agreement between the simulated aerosol optical depth (AOD) and the

34 ground-measured AOD from the Aerosol Robotic Network (AERONET; R^2 from 0.68 to 0.73, slope from 0.75 to
35 0.96). Thus, this parameterization offers a computationally efficient method to represent aerosol size dynamically.

36 **1 Introduction**

37 Aerosol size has numerous effects on aerosol physical and chemical properties and further on atmospheric chemistry.
38 Aerosol size-dependent heterogeneous chemistry affects gaseous oxidants that in turn affect production rates of
39 aerosol components such as sulfate and secondary organic aerosol (Ervens et al., 2011; Estillore et al., 2016). Aerosol
40 size also affects loss rates due to dry and wet deposition (Seinfeld & Pandis, 2016). Both direct and indirect aerosol
41 radiative forcing are sensitive to aerosol size due to the strong size dependence of aerosol extinction and of the number
42 of cloud condensation nuclei (Adams & Seinfeld, 2002; Emerson et al., 2020; Faxvog & Roessler, 1978; Mishchenko
43 et al., 2002). The size dependence of aerosol extinction and scattering phase function also affects the retrieval of
44 aerosol properties from satellites (Jin et al., 2022; Kahn et al., 2005; Levy et al., 2013). Aerosol size affects the fraction
45 of particles that deposit in the body when breathing as well as location within the body where they deposit (Hinds &
46 Zhu, 1999). An appropriate representation of aerosol size is essential for modeling aerosol composition and optical
47 properties (Kodros & Pierce, 2017), interpreting satellite data (Kahn et al., 2005; Levy et al., 2013), studying climate
48 processes (Kellogg, 1980; Twomey, 2007), and moving from aerosol exposure towards dose in health studies (Kodros
49 et al., 2018).

50 The evolution of the aerosol size distribution is affected by various processes, such as nucleation, condensation,
51 coagulation, and deposition. Nucleation events contribute to the number of particles in the nucleation mode (diameters
52 less than about 10 nm) and thus tend to decrease the mean aerosol size for a population (Aalto et al., 2001). In polluted
53 areas with high emission rates of aerosol precursors, mean aerosol size tends to increase by condensation and
54 coagulation (Sakamoto et al., 2016; Sun et al., 2011). Dry and wet aerosol deposition have strong size dependencies
55 due to competing physical processes (Emerson et al., 2020; Reutter et al., 2009; Ruijrok et al., 1995). The aerosol size
56 distribution can be simulated using aerosol microphysical schemes, such as the Two Moment Aerosol Sectional
57 (TOMAS; Adams & Seinfeld, 2002) microphysics model, the Advanced Particle Microphysics (APM; Yu & Luo,
58 2009) model, the Global Model of Aerosol Processes (GLOMAP; Mann et al., 2010), and the Modal Aerosol Module
59 (MAM4; X. Liu et al., 2016). These schemes have valuable prognostic capabilities; however, their computational cost
60 has limited their use in Chemistry Climate Models (CCMs) or Chemical Transport Models (CTMs). For example,
61 only 3 of the 10 models that included aerosols, studied by the Atmospheric Chemistry and Climate Model
62 Intercomparison Project, include online size-resolved aerosol microphysics (Kodros & Pierce, 2017; Lamarque et al.,
63 2013).

64 Methods are needed to better represent aerosol size in CCMs or CTMs without a microphysics scheme (referred to as
65 bulk models). These bulk models usually use prescribed relationships to obtain size-resolved aerosol properties (Croft
66 et al., 2005; Karydis et al., 2011; Zhai et al., 2021), which may insufficiently represent the temporal and spatial
67 variation (Kodros & Pierce, 2017). For example, in the GEOS-Chem CTM, a fixed dry aerosol geometric mean radius
68 (R_g) is assumed for organic matter (OM) and sulfate-nitrate-ammonium (SNA), which is based on analysis of long-

69 term aerosol composition and scattering measurements provided by the IMPROVE network across the continental
70 U.S. (Latimer & Martin, 2019). However, subsequent analysis by Zhai *et al.* (2021) found that this aerosol size
71 underestimated the aerosol mass scattering efficiency and the aerosol extinction coefficients during an aircraft
72 campaign over South Korea (KORUS-AQ). Thus, neglect of aerosol microphysical processes that shape aerosol size
73 distributions can be a significant source of uncertainty in aerosol optical properties in a CTM. A balance between
74 computational cost and representativeness of aerosol size is needed. One option is to use models with size-resolved
75 aerosol microphysics models to inform bulk models, such as was done for the parameterization of biomass burning
76 aerosol size by Sakamoto *et al.* (2016).

77 Recent airborne measurements offer information to evaluate and improve the simulation of aerosol size. DISCOVER-
78 AQ (Deriving Information on Surface Conditions from Column and Vertically Resolved Observations Relevant to Air
79 Quality) was a multi-year campaign over four U.S. cities that provides 3-D resolved measurements of atmospheric
80 gas composition, aerosol composition, size distribution, and optical properties (Choi *et al.*, 2020; Chu *et al.*, 2015;
81 Sawamura *et al.*, 2017). KORUS-AQ (the Korea-United States Air Quality Study) offers similar measurements in a
82 different environment with higher aerosol mass loadings (Choi *et al.*, 2020; Jordan *et al.*, 2020; Nault *et al.*, 2018; Zhai
83 *et al.*, 2021).

84 To study the global variation in aerosol size, we explore airborne measurements from DISCOVER-AQ and KORUS-
85 AQ, as well as output from the GEOS-Chem-TOMAS microphysics model. We focus on OM and SNA, which
86 dominate fine aerosol composition in populated areas. The driving factors for variation in aerosol size are examined.
87 A parameterization of aerosol size using these driving factors is proposed. This parameterization is then applied to a
88 GEOS-Chem high-performance model bulk simulation for global aerosol optical depth (AOD), which is evaluated by
89 ground-measured AOD from the Aerosol Robotic Network (AERONET).

90 **2 Observations and Models**

91 **2.1 Observations**

92 **2.1.1 Aircraft measurements**

93 We examine airborne measurements from two NASA campaigns, DISCOVER-AQ and KORUS-AQ. DISCOVER-
94 AQ includes four deployments in Maryland (MD), California (CA), Texas (TX), and Colorado (CO). KORUS-AQ is
95 an international cooperative field study program conducted in South Korea (KO), sponsored by NASA and the South
96 Korean government through the National Institute of Environmental Research. The year as well as the date and altitude
97 ranges of each deployment are in Table 1.

98 **Table 1. Temporal and spatial coverage of each aircraft deployment**

Campaign	Year	Date Range	Altitude from surface
MD	2011	07/01-07/29	0 to 5 km
TX	2013	09/04-09/29	0 to 5 km

CA	2013	01/16-02/06	0 to 4 km
CO	2014	07/17-08/10	0 to 6 km
KO	2016	05/02-06/11	0 to 8 km

99

100 Measurements used in this study include aerosol composition, ambient aerosol extinction coefficients, aerosol number
 101 size distribution, gas tracer species, and meteorological data. Measurement methods are listed in Table 2. Measured
 102 aerosol mass is converted from standard to ambient condition before analysis using ambient temperature and pressure.
 103 We use OM directly measured during KORUS-AQ. We use water soluble organic carbon (OC) and a parameterized
 104 ratio between OM and OC (Philip et al., 2014) to calculate OM for DISCOVER-AQ. The parameterized OM is
 105 evaluated with KORUS-AQ data, and overall consistency is found (Figure A1; Appendix A). For both campaigns,
 106 dust concentration is derived from Ca^{2+} and Na^+ assuming non-sea salt Ca^{2+} accounts for 7.1% of dust mass (Shah et
 107 al., 2020):

$$Dust = \frac{([Ca^{2+}] - 0.0439 \frac{[Na^+]}{2})}{0.071} \quad \text{Eqn. (1)}$$

108 Sea salt is calculated from measured Na^+ following previous studies (Malm et al., 1994; Remoundaki et al., 2013;
 109 Snider et al., 2016). The crustal component is removed by subtracting 10 % of $[Al^{3+}]$ (Remoundaki et al., 2013). A
 110 2.54 scalar is applied to $[Na^+]_{ss}$ to account for $[Cl^-]$ (Malm et al., 1994):

$$Sea\ Salt = 2.54([Na^+] - 0.1[Al^{3+}]) \quad \text{Eqn. (2)}$$

111 Effective radius (R_{eff} ; Hansen & Travis, 1974), defined as the area-weighted mean radius of a particle population, is
 112 used as a surrogate for aerosol size:

$$R_{eff} = \frac{\int r \pi r^2 n(r) dr}{\int \pi r^2 n(r) dr} \quad \text{Eqn. (3)}$$

113 Measurement data are screened for dust influence by excluding data with the sum of SNA and OM (M_{SNAOM}) $< 4 \times$
 114 dust mass.

115 **Table 2. Aircraft observations used in this study***

Variables	DISCOVER-AQ	KORUS-AQ
Bulk aerosol ionic composition	IC-PILS ^a	SAGA ^b
Sub-micron non-refractory aerosol composition	TOC-PILS ^c	HR-ToF-AMS ^d

Dry aerosol size distribution	UHSAS ^f or LAS ^g	LAS ^g

	Aerosol extinction profile at 532 nm	HSRL ^h
	NO ₂	4-Channel Chemiluminescence Instrument ⁱ
	Relative humidity (RH)	DLH ^j

116 * Adapted from Zhai et al. (2021)

117 ^a Ion Chromatography Particle-Into-Liquid Sampler, with a 1.3 μm inlet cutoff aerodynamic diameter
118 (Hayes et al., 2013; Lee et al., 2003).

119 ^b Soluble Acidic Gases and Aerosol (SAGA) instrument (Dibb et al., 2003). The cutoff aerodynamic
120 diameter of the inlet is around 4 μm (McNaughton et al., 2007).

121 ^c Water-soluble organic carbon Particle-Into-Liquid Sampler, with a 1 μm inlet cutoff diameter at 1
122 atmosphere ambient pressure (Sullivan et al., 2019; Timonen et al., 2010).

123 ^d University of Colorado Boulder High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-
124 AMS) with a 1 μm inlet cutoff diameter (Canagaratna et al., 2007; Guo et al., 2021; Nault et al., 2018).

125 ^e Single-Particle Soot Photometer (SP2), measuring refractory black carbon with a volume equivalent
126 diameter of 100-500 nm (Lamb et al., 2018; Schwarz et al., 2006).

127 ^f Particles with mobility diameters between 60 to 1000 nm can be measured by Ultra-High Sensitivity
128 Aerosol Spectrometer (UHSAS), which illuminates particles with a laser and relate the single-particle light
129 scattering intensity and count rate measured over a wide range of angles to the size-dependent particle
130 concentration (Moore et al., 2021). Particles in the sample are dried to less than 20 % RH.

131 ^g Particles between 100 to 5000 nm measured by Laser Aerosol Spectrometer (LAS, TSI model 3340). The
132 principle of LAS is the same as that of UHSAS, but with a different laser wavelength (1054 nm for the
133 UHSAS and 633 nm for the LAS) and intensity (about 100 times higher for the UHSAS). These differences
134 affect how the instrument sizes non-spherical or absorbing aerosols (Moore et al., 2021). Particles in the
135 sample are dried to less than 20 % RH.

140 2.1.2 AERONET AOD

141 We use ground-based AOD observations to evaluate our parameterization and simulated AOD. Aerosol Robotic
142 Network (AERONET) is a worldwide network that provides long-term sun photometer measured AOD. We use the
143 Version 3 Level 2 database, which includes an improved cloud screening algorithm (Giles et al., 2019). AOD at 550
144 nm wavelength, interpolated based on the local Ångström exponent at 440 and 670 nm channels, is used in this study.
145 For each site, we use data for the year 2017, excluding months with less than 20 days of measurements and excluding
146 sites with data less than 4 months.

147 2.2 GEOS-Chem simulation

148 We interpret the aircraft observations with the GEOS-Chem chemical transport model (www.geos-chem.org, last
149 access: 30 October 2022). GEOS-Chem is driven by offline meteorological data from the Goddard Earth Observing
150 System (GEOS) of the NASA Global Modeling and Assimilation Office (Schubert et al., 1993). We use the high-
151 performance implementation of GEOS-Chem (GCHP; Eastham et al. 2018) to examine the effect of variation in
152 aerosol size on AOD. We also use the TOMAS microphysical scheme, coupled with the standard GEOS-Chem
153 implementation (GEOS-Chem classic), to explicitly resolve aerosol microphysics. The bulk and the microphysics
154 simulations share common emissions and chemical mechanisms. They are both conducted for the year 2017 and driven
155 by MERRA-2 meteorological fields.

156 The GEOS-Chem aerosol simulation includes the sulfate-nitrate-ammonium system (Fountoukis & Nenes, 2007; Park,
157 et al., 2004), primary and secondary carbonaceous aerosols (Marais et al., 2016; Park et al., 2003; Pye et al., 2010;
158 Wang et al., 2014), sea salt (Jaeglé et al., 2011), and mineral dust (Fairlie et al., 2007). The primary emission data are
159 from the Community Emissions Data System (CEDSGBD-MAPS; McDuffie et al. 2020). Dust emission inventories
160 include updated natural dust emission (Meng et al., 2021), and anthropogenic fugitive, combustion, and industrial dust
161 (AFCID; Philip et al., 2017). Resolution-dependent soil NO_x, sea salt, biogenic VOC, and natural dust emissions are
162 calculated offline at native meteorological resolution to produce consistent emissions across resolution (Meng et al.,
163 2021; Weng et al., 2020). Biomass burning emissions use the Global Fire Emissions Database, version 4 (GFED4)
164 (Van Der Werf et al., 2017). We estimate organic matter (OM) from primary organic carbon using the same OM/OC
165 parameterizations as applied for DISCOVER-AQ (Canagaratna et al., 2015; Philip et al., 2014). Dry and wet
166 deposition follows Amos *et al.* (2012), with a standard resistance-in-series dry deposition scheme (Wang et al., 1998).
167 Wet deposition includes scavenging processes from convection and large-scale precipitation (Liu et al., 2001).

168 Global relative humidity dependent aerosol optical properties are based on the Global Aerosol Data Set (GADS;
169 Koepke et al. 1997; Martin et al. 2003) with updates for SNA and OM (Latimer & Martin, 2019), mineral dust (Zhang
170 et al., 2013), and absorbing brown carbon (Hammer et al., 2016). In the current GEOS-Chem model, the SNA and
171 OM R_{eff} of particular interest here are based on co-located measurements of aerosol scatter and mass from the
172 IMPROVE network at U.S. national parks over the period 2000-2010, together with a κ -Kohler framework for aerosol
173 hygroscopicity (Kreidenweis et al., 2008) as implemented by Latimer and Martin (2019). Aerosol extinction is

174 calculated as the sum of extinction from each aerosol component with aerosol optical properties listed in Table A1, as
175 described in Appendix A2.

176 A global GCHP simulation (Eastham et al. 2018) version 13.0.0 (DOI: 10.5281/zenodo.4618180) that includes
177 advances in performance and usability (Martin et al., 2022), is conducted on a C90 cubed-sphere grid corresponding
178 to a horizontal resolution of about 100 km.

179 The TOMAS microphysics scheme, coupled with the GEOS-Chem simulation, conserves aerosol mass, and tracks
180 particles with diameters from approximately 1 nm to 10 μm (Adams & Seinfeld, 2002). Microphysical processes in
181 TOMAS include nucleation, condensation, evaporation, coagulation, and wet and dry deposition (Adams & Seinfeld,
182 2002). Nucleation in TOMAS follows a ternary scheme (sulfuric acid, ammonia, and water) when ammonia mixing
183 ratios are greater than 0.1 ppt; otherwise, a binary nucleation scheme is used (Napari et al., 2002). The nucleation rate
184 is scaled by 10^{-5} to better match the observations (Westervelt et al., 2013). The condensation and evaporation algorithm
185 is based on a study from Tzivion *et al.* (1989), including interaction with secondary organic aerosol (D'Andrea et al.,
186 2013). Interstitial coagulation in clouds is also included (Pierce et al., 2015).

187 For each size bin, TOMAS tracks the mass and number of sulfate, sea salt, black carbon, OC, dust, and water. Primary
188 sulfate emissions have 2 lognormal modes: 15% of the mass with a number median diameter (NMD) of 10 nm and
189 geometric standard deviation (σ) of 1.6 and the remainder with a NMD of 70 nm and σ of 2 (Adams & Seinfeld, 2003).
190 The size of emitted carbonaceous particles varies depending on the source: those produced by fossil fuel have a NMD
191 of 30 nm and σ of 2, while biofuel and biomass burning particles are emitted with a NMD of 100 nm and σ of 2 (Pierce
192 et al., 2007). Meteorology and most of the emissions in GEOS-Chem-TOMAS follow the bulk simulation, except that
193 online schemes are used for dust (Zender et al., 2003) and sea salt (Jaeglé *et al.* 2011).

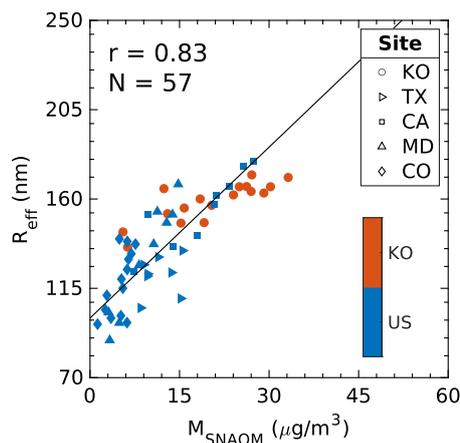

194 A one-year global GEOS-Chem-TOMAS (version 13.2.1. DOI: 10.5281/zenodo.5500717) simulation is conducted
195 with a horizontal resolution of $4^\circ \times 5^\circ$ and 47 vertical layers from surface to 0.01 hPa. Aerosols are tracked in 15 size
196 bins with particle diameters ranging from about 3 nm to 10 μm .

197 **3 Development of a Parameterization of Aerosol Size**

198 We first examine the aircraft measurements for insight into the observed variation in aerosol size. Then we apply the
199 size-resolved GEOS-Chem-TOMAS model to extend our analysis to the global scale and identify driving factors of
200 aerosol size. We subsequently develop and test a parameterization of aerosol size for use in bulk models.

201 **3.1 Observed variation in aerosol size**

202 Figure 1 shows the daily-mean dry effective radius from DISCOVER-AQ and KORUS-AQ as a function of aerosol
203 mass. Aerosol size, in terms of dry R_{eff} , ranges from 90 nm to 179 nm for DISCOVER-AQ, which is generally smaller
204 than for KORUS-AQ that ranges from 135 nm to 174 nm. M_{SNAOM} from DISCOVER-AQ ($1.4 \mu\text{g}/\text{m}^3$ to $27.4 \mu\text{g}/\text{m}^3$)
205 is also generally less than that from KORUS-AQ ($5.5 \mu\text{g}/\text{m}^3$ to $33.2 \mu\text{g}/\text{m}^3$). A strong correlation ($r = 0.83$) between
206 aerosol size and M_{SNAOM} is evident.

207

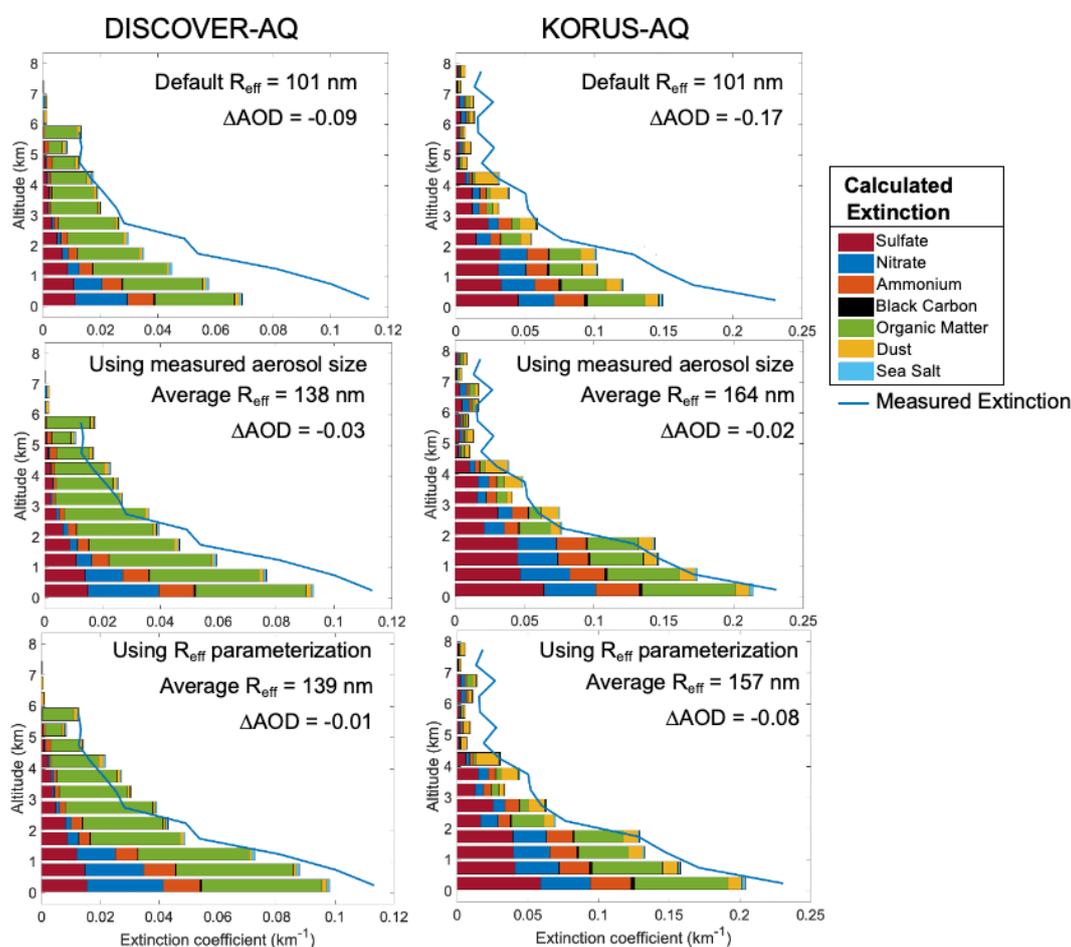

208 **Figure 1. Airborne measurements of dry effective radius (R_{eff}) versus the sum of SNA and OM mass**
209 **(M_{SNAOM}) for DISCOVER-AQ (Maryland is abbreviated as MD, California as CA, Texas as TX, Colorado as**
210 **CO) and for KORUS-AQ (KO) campaigns. Each point represents a daily average for the entire flight profile.**
211 **Only data with $M_{\text{SNAOM}} > 4 \times$ Dust mass is used.**

212 The positive relationship between dry aerosol size and mass of SNA and OM reflects the roles of emission,
213 condensation, and coagulation in simultaneously increasing aerosol size and mass. This general tendency is also
214 observed by many other studies (e.g., Bahreini et al., 2003; Rodríguez et al., 2007; Sakamoto et al., 2016; Sun et al.,
215 2010) despite variable aerosol sources and growth mechanisms. In cities, the joint increases in aerosol size and mass
216 are usually attributable to anthropogenic emissions and condensation (Huang et al., 2013; Sun et al., 2011; Tian et al.,
217 2019). In remote areas, biomass burning shifts the particle size distribution toward larger radii due to high emission
218 rates and coagulation in plumes (Ramnarine et al., 2019; Rissler et al., 2006) that, for example, increase both aerosol
219 size and mass from the wet season to the dry season in Amazonia (Andreae et al., 2015; Rissler et al., 2006). The
220 positive relationship between aerosol size and mass suggests the possibility of using aerosol mass as a predictor of
221 R_{eff} .

222 We examine the ability of the GEOS-Chem bulk model to reproduce the observed extinction. The top panel of Figure
223 2 compares the measured aerosol extinction profiles to calculated aerosol extinction profiles using default R_{eff} . Details
224 about the calculation are described in Appendix A2. Both measured and calculated extinction profiles exhibit
225 increasing extinction toward the surface associated with increasing aerosol mass concentrations. However, biases are
226 apparent for both DISCOVER-AQ and KORUS-AQ. The R_{eff} from KORUS-AQ shown in Figure 1 have a mean value
227 of 164 nm, larger than the value of 101 nm inferred by Latimer & Martin (2019) based on measurements of aerosol
228 scatter and mass by the U.S. IMPROVE network. This bias was previously noted by Zhai *et al.* (2021). The mean R_{eff}
229 from DISCOVER-AQ of 138 nm is also larger than the inferred value. This likely reflects representativeness
230 differences since the DISCOVER-AQ deployments focused on major urban areas during months of high aerosol
231 loadings, while the IMPROVE measurements were at national parks throughout the year. The middle panel shows the

232 calculated extinction using the measured aerosol size distribution. Applying the measured aerosol size distribution
 233 addresses most discrepancies between the calculated and measured aerosol extinction profile for both KORUS-AQ
 234 and DISCOVER-AQ. The corresponding discrepancies in AOD estimation also significantly decreased (from 0.09 to
 235 0.03 for DISCOVER-AQ and from 0.17 to 0.02 for KORUS-AQ). The reduced discrepancies support the conclusions
 236 from Zhai *et al.* (2021) that the GEOS-Chem aerosol size is underestimated for KORUS-AQ and motivate
 237 parameterization of R_{eff} for efficient representation of aerosol size for global scale aerosol modeling.

238
 239 **Figure 2.** Aerosol extinction profile for the DISCOVER-AQ and KORUS-AQ aircraft campaigns. Blue lines
 240 are the measured extinction profiles. Horizontal bars are calculated extinction using (top) default GEOS-
 241 Chem R_{eff} , (middle) measured R_{eff} , and (bottom) parameterized R_{eff} (described in Section 3.3), together with
 242 measured aerosol composition and RH. The aerosol extinction calculation is described in Appendix A.

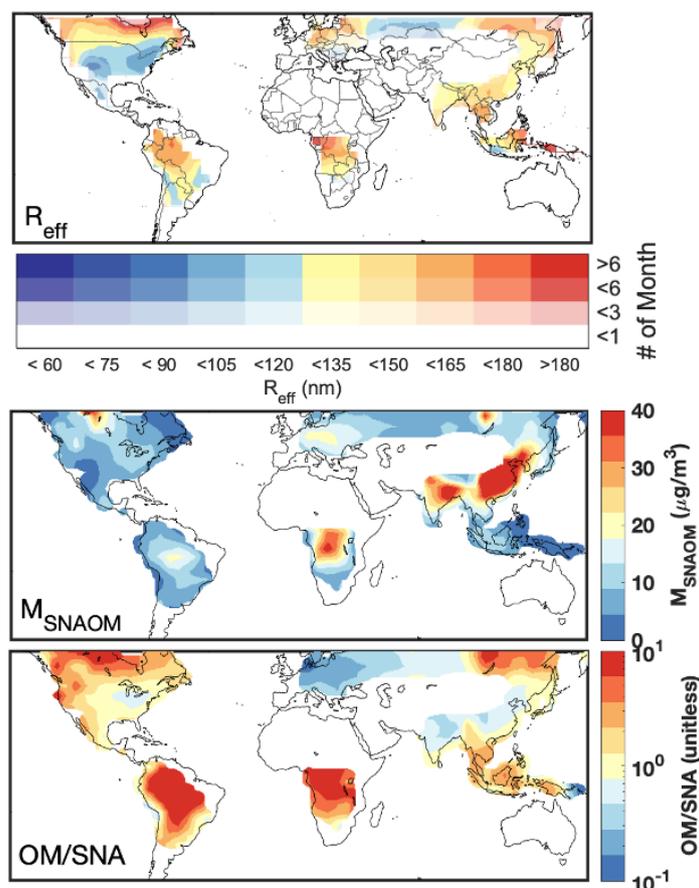

243 **3.2 Driving factors**

244 Given the strong positive correlation of aerosol mass with aerosol size, we further examine this relationship globally
245 using GEOS-Chem coupled with the TOMAS aerosol microphysics scheme. The top panel of Figure 3 shows the
246 geographic distribution of annual mean surface layer dry R_{eff} for locations and months where aerosol mass is
247 dominated by SNA and OM, as indicated by $M_{\text{SNAOM}} > 90\%$ of the aerosol mass. Among the areas of interest, biomass
248 burning regions of Central Africa, South America, and boreal forest of North America exhibit the highest surface R_{eff}
249 of about 180 nm. Industrial areas such as East Asia and South Asia also exhibit high R_{eff} of about 130 nm, given an
250 abundance of particle emissions and gaseous precursors. The lowest surface R_{eff} of about 80 nm is found in North
251 America, where aerosol mass concentrations are low.

252 The middle panel of Figure 3 shows the simulated M_{SNAOM} from GEOS-Chem-TOMAS. Enhanced M_{SNAOM}
253 concentrations of over $40 \mu\text{g}/\text{m}^3$ are apparent over East Asia and South Asia, reflecting intense anthropogenic
254 emissions. Another M_{SNAOM} hotspot can be seen in Central Africa, driven by biomass burning during the dry season
255 (McDuffie et al., 2021; Van Der Werf et al., 2017) and sometimes exacerbated by anthropogenic emissions (Ngo et
256 al., 2019). Moving from North America, to Europe, and then to Asia, M_{SNAOM} concentrations exhibit a generally
257 increasing tendency, consistent with the R_{eff} tendency in the top panel and aligning with the relationship between
258 aircraft measurements over the U.S. and South Korea.

259 However, in South America, where R_{eff} is among the highest, M_{SNAOM} is relatively low. This discrepancy motivates
260 the search for other factors, such as aerosol composition, that are associated with aerosol size. In South America,
261 aerosol mass is mostly from natural sources, particularly biomass burning during the dry seasons. R_g for a particle
262 population from biomass burning ranges from 60 nm to 170 nm (Janňall et al., 2010; Reid et al., 2005; Rissler et al.,
263 2006), usually larger than that of primary sulfate aerosol (5 to 35 nm; Plaza et al., 2011; Whitey, 1978). Therefore,
264 the relative abundance of OM in the total M_{SNAOM} can serve as another predictor of R_{eff} . The bottom panel of Figure
265 3 shows the ratio between OM and SNA mass. In addition to the Amazon basin, the biomass burning regions of Central
266 Africa and boreal forests in Asia and North America are all areas with high OM mass fractions, which contribute to
267 their high R_{eff} despite the low M_{SNAOM} .

268

269 **Figure 3: Geographic distribution of GEOS-Chem-TOMAS-simulated annual mean surface layer aerosol**
270 **properties; (top) R_{eff} with color intensity indicating the number of months included (Mass of SNA and OM >**
271 **90% of aerosol mass), (middle) the sum of SNA and OM mass (M_{SNAOM}), and (bottom) OM/SNA.**

272 3.3 Parameterization and evaluation

273 We use Multiple Linear Regression (MLR) to derive a parameterization of dry R_{eff} as a function of M_{SNAOM} and
274 OM/SNA. We sample the GEOS-Chem-TOMAS simulation for locations dominated by M_{SNAOM} (> 90%). We include
275 all qualified data (8,569 grid boxes) from the planetary boundary layer (PBL) to focus on this region, while randomly
276 sample 0.5% of simulations in the free troposphere (217,772 grid boxes) to allow the influence of remote regions in
277 the training set. The reason for focusing on the PBL is twofold. First, the PBL generally has the highest aerosol loading
278 that largely determines the columnar mass and AOD (Koffi et al., 2016; Tian et al., 2019; Zhai et al., 2021). Second,
279 the PBL is the domain where the model-measurement difference exists (Figure 2, top panel).

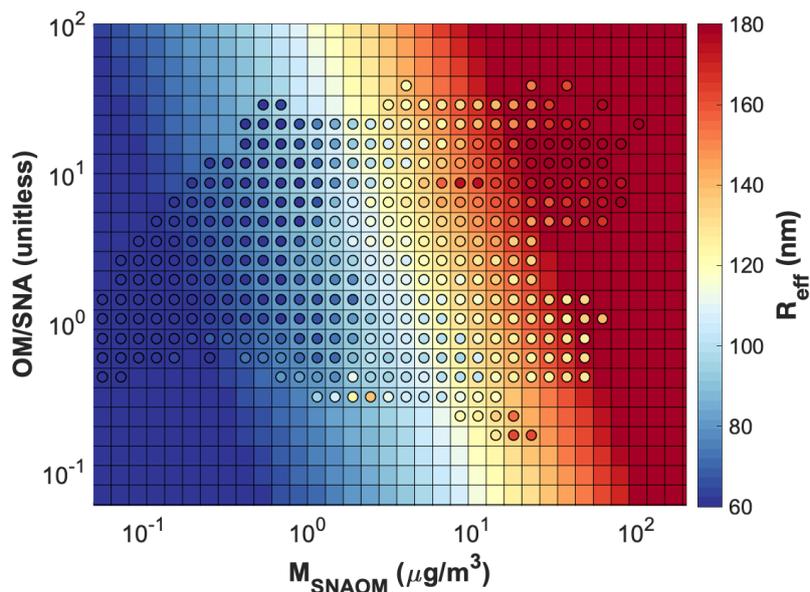

280 Taking the logarithm of R_{eff} and the logarithm of the two predictors facilitates linear relationships for regression,
281 which yields the initial parameterization

$$R_{\text{eff}} = 78.3 M_{\text{SNAOM}}^{0.20} \left(\frac{\text{OM}}{\text{SNA}} \right)^{0.065} \quad \text{Eqn. (4)}$$

282 where R_{eff} has units of nm, M_{SNAOM} has units of $\mu\text{g}/\text{m}^3$, and OM/SNA is unitless. The R_{eff} parameterization is driven
283 primarily by the mass of SNA and OM, modulated by the ratio of OM to SNA. This equation well represents the
284 variation of R_{eff} during the aircraft campaigns with an R^2 of 0.74 (Figure B1, top left). The slope below unity (0.90)
285 likely reflects the effect of coarse model resolution, which dilutes the particle or precursor concentration in turn
286 reducing condensation and coagulation growth (AboEl-Fetouh et al., 2022; Ramnarine et al., 2019; Sakamoto et al.,
287 2016). Adjustment to this parameterization to account for these effects and align the slope with the airborne
288 measurements rather than the model results in a final parameterization of

$$R_{\text{eff}} = 87.0 M_{\text{SNAOM}}^{0.20} \left(\frac{\text{OM}}{\text{SNA}} \right)^{0.065} \quad \text{Eqn. (5)}$$

289 Figure 4 shows the distribution of dry R_{eff} based on GEOS-Chem-TOMAS and Eqn. (5). Circles in Figure 4 show the
290 mean values of the sampled GEOS-Chem-TOMAS simulated R_{eff} as a function of simulated M_{SNAOM} concentrations,
291 ranging from 0.02 to 102 $\mu\text{g}/\text{m}^3$, and OM/SNA ranging from 0.13 to 55. Simulated R_{eff} extends from 15 nm when both
292 M_{SNAOM} and OM/SNA are low (0.09 $\mu\text{g}/\text{m}^3$ and 1.3, respectively), up to 282 nm when M_{SNAOM} and OM/SNA are high
293 (about 44 $\mu\text{g}/\text{m}^3$ and 14 respectively). The background color indicates our parameterized R_{eff} . A high degree of
294 consistency exists between the parameterized R_{eff} and simulated R_{eff} , especially in the free troposphere where large
295 gradients in R_{eff} exist, with overall for the troposphere an R^2 of 0.72, and a slope of 0.81 (Figure B1, bottom right).
296 Despite the overall consistency, a few differences exist. When aerosol mass concentration is high, the parameterization
297 tends to yield a higher R_{eff} than in the GEOS-Chem-TOMAS simulation, since the adjustment using aircraft
298 measurements led to 11% increase in R_{eff} . At M_{SNAOM} near 10 $\mu\text{g}/\text{m}^3$ and OM/SNA near 10, the simulation indicates
299 higher R_{eff} than the parameterization, reflecting dilution downwind of biomass burning that reduces the aerosol mass
300 concentration but has little influence on particle size in GEOS-Chem-TOMAS. A 10-20% underestimation in the
301 parameterization at low OM/SNA reflects the advection and dilution of downwind of urban areas and in the free
302 troposphere.

303

304 **Figure 4. Dry R_{eff} as a function of M_{SNAOM} and OM/SNA when SNA and OM are dominant (>90%). Each**
305 **circle represents the mean value of the GEOS-Chem-TOMAS simulated R_{eff} in each bin. Background color**
306 **indicates the parameterized R_{eff} .**

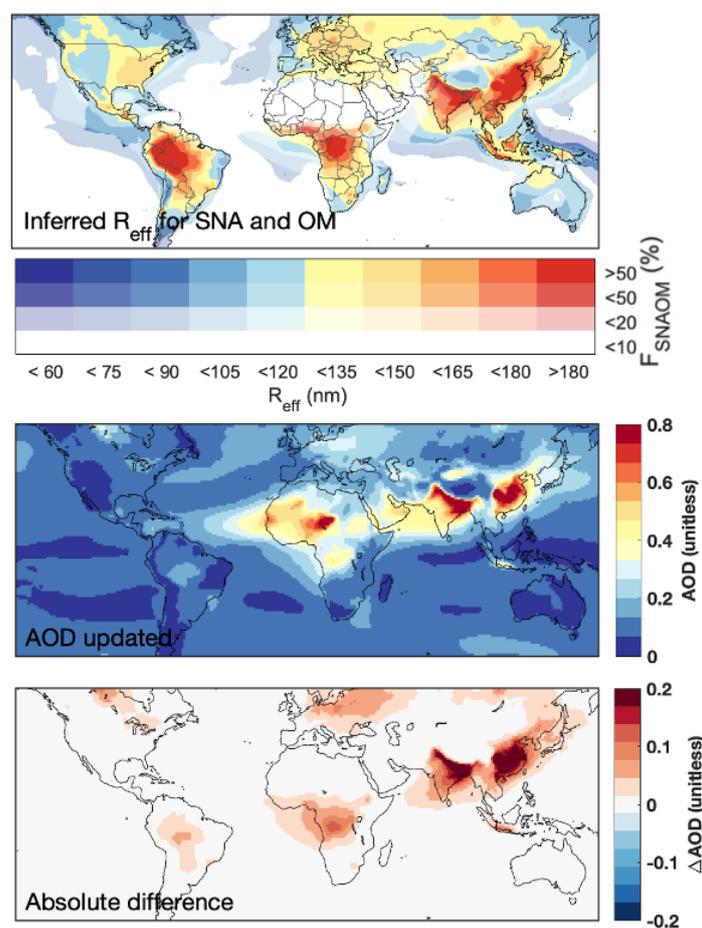

307 When applied to the airborne measurements, this parameterization only slightly overestimates the measured R_{eff} from
308 DISCOVER-AQ (139 nm vs. 138 nm) and slightly underestimates R_{eff} from KORUS-AQ (157 nm vs. 164 nm). Most
309 discrepancies between calculated and measured extinction from aircraft campaigns are eliminated (Figure 2, bottom
310 panel) with AOD discrepancies reduced to 0.01 and 0.08 for DISCOVER-AQ and KORUS-AQ, respectively.

311 We then apply Eqn. (5) to a GEOS-Chem bulk simulation to calculate R_{eff} and AOD. The top panel of Figure 5 shows
312 the annual mean dry R_{eff} for surface SNA and OM aerosol with the color intensity indicating the ratio of SNA and
313 OM mass to total aerosol mass at the surface. The parameterized R_{eff} is usually higher than the default value of about
314 100 nm in GEOS-Chem over land, and lower than that over the ocean, with a normalized root mean square deviation
315 (NRMSD) of 43.8%. The spatial pattern well represents the GEOS-Chem-TOMAS simulation, with high R_{eff} found
316 in biomass burning regions in South America and Central Africa, as well as industrial regions in Asia. The horizontal
317 variation diminishes with altitude (Figure B2), with the mean R_{eff} decreasing from 85 nm (surface) to 43 nm (10 km).

318 The middle panel of Figure 5 shows the simulated AOD, with the corresponding difference between the base
319 simulation and the updated simulation in the bottom panel. To accommodate the parameterized R_{eff} , a look-up table
320 with a wide range of R_{eff} (0.02 μm to 1.7 μm) and the corresponding extinction efficiencies for OM and SNA is created
321 based on Mie Theory (Mishchenko et al., 1999, 2002). This update generally increases aerosol mass scattering by
322 increasing the mass extinction efficiency, in turn, increasing AOD over regions with strong anthropogenic sources,

323 such as East Asia (by 0.13, 35.4%) and South Asia (by 0.13, 28.3%). It also slightly increases AOD over regions
324 influenced by wildfires, such as South America (by 0.02, 12.2%), Central Africa (by 0.03, 17.4%), and the boreal
325 forests in North America, Europe, and Asia (by 0.01-0.03, 12.1 to 16.9%). Most increases occur near the surface
326 (Figure B3), where the highest aerosol mass loading and mass extinction efficiency exist. The NRMSD between
327 original and updated GEOS-Chem simulated AOD is 20.9% globally, and 28.8% over continents.

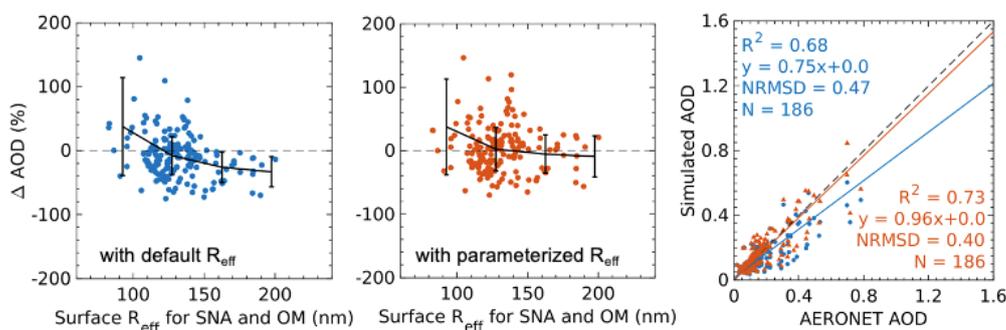

328

329 **Figure 5. (Top) Surface dry R_{eff} for SNA and OM calculated using Eqn. (5) and GEOS-Chem bulk model**
330 **simulated SNA and OM mass. F_{SNAOM} is the ratio of SNA and OM mass to the total aerosol mass at the**
331 **surface. (Middle) The GEOS-Chem simulated AOD using inferred R_{eff} . (Bottom) the absolute difference**
332 **between updated AOD and default AOD using dry $R_{\text{eff}} = 101$ nm.**

333 Although R_{eff} is only one of many processes affecting AOD, we evaluate the effect of the parameterization on the
334 GEOS-Chem simulation of AOD to assess its implications. The left panel of Figure 6 shows for the default R_{eff} , the

335 percent difference between GEOS-Chem simulated AOD and AERONET AOD as a function of the parameterized
336 surface R_{eff} for SNA and OM. The simulation using the default R_{eff} slightly overestimates AOD in regions with small
337 parameterized R_{eff} and underestimates AOD in regions with large parameterized R_{eff} . The overestimates occur
338 primarily in western Europe where SNA and OM concentrations are low, while the underestimates happen mainly
339 over industrial regions in East Asia, Southeast Asia, and biomass burning areas in South America and Central Africa,
340 where the SNA and OM mass loading are high (Figure B4). The underestimates are mitigated when applying the
341 parameterized R_{eff} in GEOS-Chem (Figure 6, middle panel), yielding increased consistency between the measured
342 (AERONET) AOD and simulated AOD (Figure 6, right; R^2 change from 0.68 to 0.73, slope from 0.75 to 0.96).

343

344 **Figure 6. (Left and middle) Percent increase in GEOS-Chem simulated AOD minus AERONET AOD as a**
345 **function of parameterized surface dry R_{eff} for SNA and OM. Black lines represent the mean values of ΔAOD**
346 **in each 35 nm bin; error bars represent the corresponding standard deviation. (Right) Scatter plot of**
347 **AERONET versus simulated AOD with the default R_{eff} (blue dots, line, and text), and with the parameterized**
348 **R_{eff} (red dots, line, and text). The 1:1 line is dashed. NRMSD is the normalized root mean square deviation**
349 **between the two datasets. N is the number of points in each dataset.**

350 4 Conclusion

351 Aerosol size strongly determines mass scattering efficiency with implications for calculation of aerosol optical
352 properties. Prior work found that the global mean dry aerosol size used in a bulk aerosol model induced low bias
353 versus measured extinction in a region with a high aerosol loading (Zhai et al., 2021). We interpreted aircraft
354 measurements from DISCOVER-AQ and KORUS-AQ with a chemical transport model (GEOS-Chem) to better
355 understand regional variation in aerosol size. The measurements had a strong positive correlation ($r = 0.83$) between
356 aerosol size and mass of sulfate-nitrate-ammonium (SNA) and organic matter (OM), reflecting the high condensation
357 and coagulation rates where emissions of particles and the gaseous precursors are abundant, indicating the possibility
358 of using aerosol mass as a predictor of aerosol size.

359 To gain a broader perspective of the global variation in aerosol size, we used the TOMAS microphysics package of
360 the GEOS-Chem model to simulate the monthly mean aerosol mass, composition, and size distribution. We used
361 effective radius (R_{eff}) as a surrogate of aerosol size and examined its relationship with aerosol mass and components

362 where SNA and OM were dominant. We found that the sum of SNA and OM concentration, and the ratio between
363 them, were the major predictors of R_{eff} . We used GEOS-Chem-TOMAS model output to derive a parameterization of
364 R_{eff} , which well reproduced R_{eff} measured from the aircraft campaigns ($R^2 = 0.74$). When applied in the bulk GEOS-
365 Chem high-performance model, the parameterization tended to increase R_{eff} of SNA and OM over regions with high
366 concentrations of SNA and OM, and decrease R_{eff} elsewhere relative to the standard model. This led to a global
367 normalized root mean square deviation (NRMSD) of 43.8% between the original and updated surface R_{eff} . The
368 parameterized R_{eff} tended to increase the vertical gradient in extinction relative to the standard model, due to the
369 decrease in R_{eff} with altitude. The NRMSD of global mean AOD between the original and updated simulations was
370 20.9%, with the most significant regional AOD increase of about 0.13 in South and East Asia, where aerosol mass
371 loadings are high. This parameterization led to improved consistency of GEOS-Chem simulated AOD with
372 AERONET AOD (R^2 from 0.68 to 0.73; slope from 0.75 to 0.96), by increasing AOD at high R_{eff} .

373 Overall, the simple parameterization of R_{eff} derived in this study improved the accuracy in modeling aerosol optical
374 properties without imposing additional computational expense. Other chemical transport models and modeling of
375 other size-related processes, such as heterogeneous chemistry, photolysis frequencies, and dry deposition, may also
376 benefit from the parameterized R_{eff} . Further developments in computational efficiency of aerosol microphysics models
377 and more abundant measurements of aerosol size and optical properties would both offer opportunities for further
378 advances.

379

380 *Data availability.* AERONET data can be found at <https://aeronet.gsfc.nasa.gov/>. Aircraft data during DISCOVER-
381 AQ are available at <https://asdc.larc.nasa.gov/project/DISCOVER-AQ>. KORUS-AQ data can be found at
382 <https://doi.org/10.5067/Suborbital/KORUSAQ/DATA01>.

383 *Author contributions.* HZ and RVM designed the study. HZ performed the data analysis and model simulations with
384 contributions from BC, SZ, CL, LB, JRP, IS, DC, and RYWC. BEA, LDZ, JWH, RAF, CAH, JLJ, PCJ, JED, JSS,
385 AW, and BAN contributed to KORUS-AQ and DISCOVER-AQ campaign measurements. HZ and RVM wrote the
386 paper with input from all authors.

387 *Competing interests.* The contact author has declared that neither they nor their co-authors have any competing
388 interests.

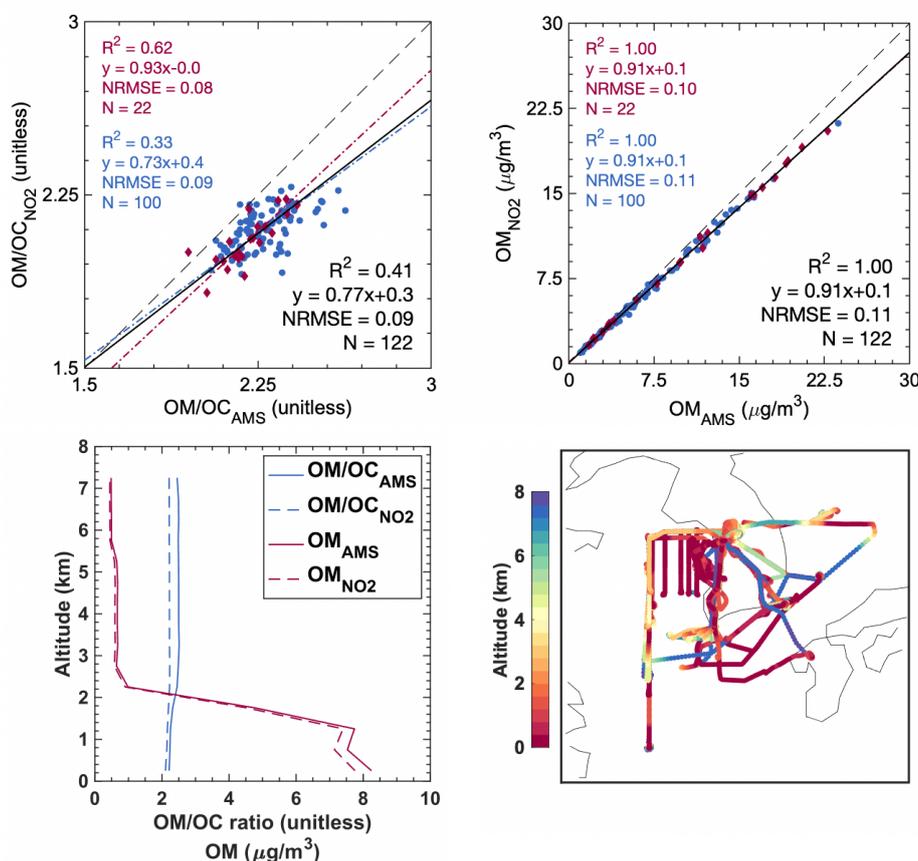

389 *Financial support.* This work was supported by NASA Grant 80NSSC21K1343. JRP was funded by the US NSF
390 Atmospheric Chemistry program, under grant AGS-1950327. JLJ and PCJ were supported by NASA Grant
391 80NSSC21K1451 and NNX15AT96G. BAN was supported by NASA Grant 80NSSC22K0283. JED was supported
392 by NASA Grant NNX15AT88G.

393 **Appendix A**

394 **A1 Application of spatially and temporally varying OM/OC ratio**

395 The top panel of Figure A1 shows scatter plots of the estimated and measured OM/OC and OM during the KORUS-
 396 AQ campaign. The estimation is obtained by applying to OC measurement a NO₂ inferred OM/OC from Philip *et al.*
 397 (2014), with a subsequent correction factor of 1.09 suggested by Canagaratna *et al.* (2015). Estimated OM is compared
 398 with measured OM by AMS during the campaign. Overall consistency is evident between NO₂-derived OM/OC and
 399 measured OM/OC. The agreement is better below 500 m than above (left panel, R² = 0.62 vs. 0.33). The discrepancy
 400 at high altitudes is mainly due to the low NO₂ (<0.2 ppbv), where the Philip *et al.* (2014) equation is not applicable.
 401 An average OM/OC ratio (2.1) is applied in this case. A high degree of consistency exists between the estimated OM
 402 and measured OM, with R² = 0.99 and slope = 0.91 for data from all altitudes (right panel), thus supporting the use of
 403 estimated OM in our analyses. The bottom left panel compares the vertical profile of the estimates and measurements,
 404 yielding overall consistency.

405

406 **Figure A1. Scatter plots of estimated and measured OM/OC (top left) and OM (top right) during KORUS-**
407 **AQ. Each point represents a mean value of AMS measurement for a 1-hour interval. Red diamonds, lines,**
408 **and texts represent data from 0-500 m altitude. Blue dots, lines, and text represent data above 500 m from the**
409 **ground. Black solid lines and texts represent the line of best fit for all the data. The 1:1 line is dashed.**
410 **NRMSD is the normalized root mean square deviation between the two datasets. N is the number of points in**
411 **each dataset. (Bottom left) Mean values of OM/OC and OM from measurements and estimations along the**
412 **altitude. (Bottom right) Flight tracks during KORUS-AQ.**

413

414 **A2 Aerosol Extinction Calculation in GEOS-Chem**

415 Extinction (Ext) of radiation by aerosols is represented as the sum of extinction due to each of the aerosol components
416 using the following equation:

$$Ext_k = \frac{3Q_{ext,k}M_k}{4\rho_k R_{eff,k}} \quad \text{Eqn. (3)}$$

417 where subscript k indicates the property for the kth component. R_{eff} is the effective radius defined as the area weighted
418 mean radius. Q_{ext} is the area-weighted mean extinction efficiency. M is the aerosol mass loading per unit volume. ρ is
419 the aerosol density. Aerosol optical depth (AOD) is the integral of aerosol extinction across the vertical domain.

420 For each component, extinction is calculated for assumed log-normal size distribution with corresponding dry
421 geometric mean radius R_g and geometric standard deviation σ , hygroscopicity, refractive index (RI), and density (ρ)
422 for individual aerosol components, as listed in Table A1. Sulfate, nitrate, and ammonium are grouped into SNA for
423 convenience. R_{eff} and Q_{ext} are calculated using Mie Theory (Mishchenko et al., 1999, 2002) based on assumptions in
424 aerosol size and RI. Hygroscopicity for SNA and OM is represented using a κ -Kohler hygroscopic growth scheme
425 (Kreidenweis et al., 2008) as implemented by Latimer & Martin (2019).

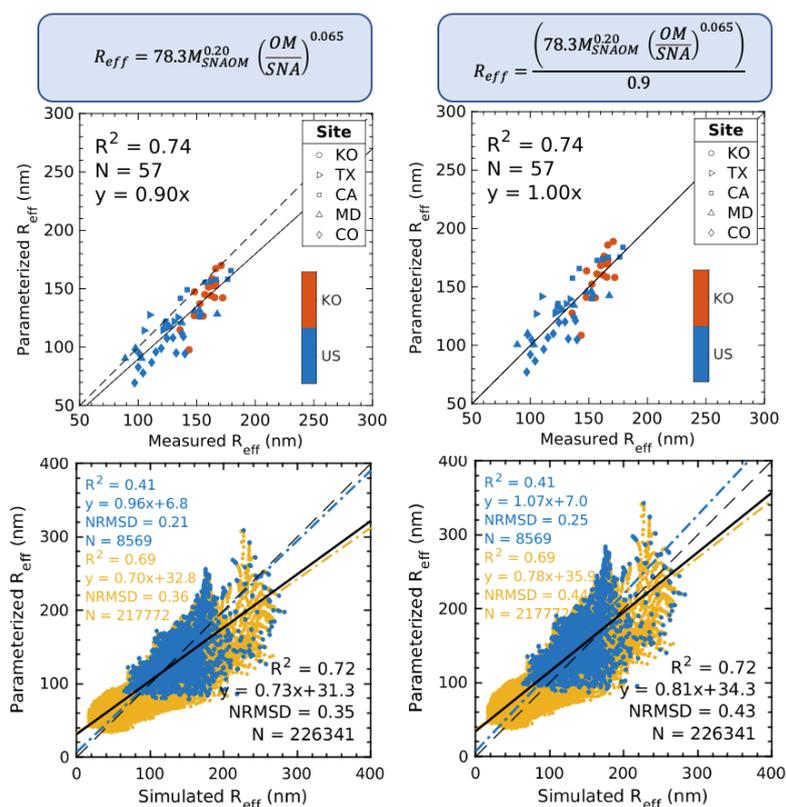

426 **Table A1. Dry aerosol properties in GEOS-Chem bulk model**

Aerosol components	R_g , μm	σ	Hygroscopicity	Refractive Index (dry, 550 nm)	ρ , g cm^{-3}	R_{eff} , μm	Q_{ext}
SNA	0.058	1.6	$\kappa = 0.61$	$1.53 - 6.0 \times 10^{-3}i$	1.7	0.101	0.603
OM	0.058	1.6	$\kappa = 0.1$	$1.53 - 6.0 \times 10^{-3}i$	1.3	0.101	0.603
