Abstract
In this paper, we review observational and modelling results on the upwelling in the inner tropical Atlantic. We focus on the physical processes that drive the seasonal variability of surface cooling and upward nutrient flux required to explain the seasonality of primary productivity. We separately consider the equatorial upwelling system, the northern coastal upwelling system of the Gulf of Guinea and the tropical Angolan upwelling system. For the equatorial regime, we discuss the forcing of upwelling velocity and turbulent mixing as well as the underlying dynamics responsible for thermocline movements and current structure. The coastal upwelling system in the Gulf of Guinea is concentrated along northern boundary and is driven by both, local and remote forcing. The particular role of the Guinea Current, nonlinearity and the shape of the coastline are emphasized. For the tropical Angolan upwelling, we show that this system is not wind-driven, but instead results from the combined effect of coastally trapped waves, surface heat and freshwater fluxes, and turbulent mixing. Finally, we review recent changes in the upwelling systems associated with climate variability and global warming and address possible responses of upwelling systems in future scenarios.

Short summary
Tropical upwelling systems are among the most productive ecosystems globally. The tropical Atlantic upwelling undergoes a strong seasonal cycle that is forced by the seasonal cycle of the zonal wind along the equator and the near-coastal wind field off Africa. Besides the wind forcing that lead to an up- and downward movement of the nitracline, turbulent diffusion results in upward mixing of nutrients. Here, we review the different physical processes responsible for upward nutrient supply.

1 Introduction
The tropical oceans are important to the Earth system for several reasons. The ocean receives a large part of shortwave radiation from the sun arriving at the Earth surface that must be redistributed horizontally and vertically. Similar important exchanges of carbon dioxide, oxygen and other trace gases occur at the interface between tropical ocean and overlying atmosphere. Tropical marine ecosystems are among the most productive ones, with high relevance for global fisheries (Longhurst 1993). They are associated with a substantial carbon flux from the near surface into the deep ocean (Kiko et al. 2017). At the same time, the tropical oceans are affected by modes of natural climate variability that have reverberations around the globe, e.g., including the Pacific El Niño or the Atlantic Niño. Climate warming and change are thought to profoundly affect the tropical oceans. On the one hand, they impact natural climate variability via an intensification of climate extremes or changing of natural variability.
(Cai et al. 2018; Crespo et al. 2022; Prigent et al. 2020b). On the other hand, they are thought to enhance stratification thereby impacting subduction, upwelling, and air-sea gas exchange with consequences for acidification and deoxygenation (Oschlies et al. 2018) and marine ecosystems.

The zonal extend of the tropical Atlantic is similar to that of the Indian Ocean and about three times smaller than that of the Pacific Ocean. The difference in size between Pacific and Atlantic oceans seems to be the main reason for the dominance of interannual climate variability in the tropical Pacific, while the tropical Atlantic has largest variability on seasonal time scales (Burls et al. 2011; Keenlyside and Latif 2007). A geographical peculiarity of the tropical Atlantic Ocean is the existence of the Gulf of Guinea which, in addition to its eastern boundary, also has a northern boundary extending approximately along 5°N from 10°W to 10°E. There are several major rivers running into the tropical Atlantic including the Amazon, Congo and Niger rivers (Fig. 1).

Based on satellite data, Longhurst (1993) provided a first systematic overview of the different open ocean and coastal upwelling systems in the tropical Atlantic. Today, mean satellite chlorophyll concentration (Fig. 1) reveals strongly enhanced productivity in the region of the Amazon River and the Congo River mouths. In the region of the Niger River mouth no comparable signal of enhanced productivity is found likely due to its much-reduced discharge (Fig. 1). Besides the impact of river discharge on the mean chlorophyll concentration, high productivity is found near the coasts in the Gulf of Guinea upwelling system (GGUS), and the tropical Angolan upwelling system (tAUS). The equatorial Atlantic upwelling system (EAUS) is instead characterized by albeit enhanced but in comparison to the coastal upwelling systems relatively weak chlorophyll concentration (note the logarithmic scale for the chlorophyll concentration in Fig. 1) (Grodsky et al. 2008). Nevertheless, the EAUS is still of major importance for the overall productivity in the tropical Atlantic due to the large oceanic area covered.
Upwelling in the eastern tropical Atlantic is supplied by thermocline waters transported in different eastward currents. Tropical Atlantic upwelling is an element of the shallow overturning circulation, the subtropical cells (STCs), and is connected to the subduction in the eastern subtropics via equatorward thermocline flow and poleward Ekman transport in the surface layer (Fu et al. 2022; Schott et al. 2004; Tuchen et al. 2020). At the equator, the Equatorial Undercurrent (EUC) transports thermocline waters eastward, toward the EAUS. Due to the presence of the Atlantic meridional overturning circulation, these waters are almost exclusively of southern hemisphere origin (Johns et al. 2014; Schott et al. 1998; Tuchen et al. 2022a). Part of the waters recirculates into the westward current branches of the South Equatorial Current, the northern and the central South Equatorial Current, or contributes to supply the southward flow along the eastern boundary within the Gabon-Congo Undercurrent and the Angola Current (Kolodziejczyk et al. 2014; Kopte et al. 2017). The GGUS is supplied by the Guinea Current and the Guinea Undercurrent. While the waters of the Guinea Current mostly originate in the North Equatorial Countercurrent, a similar connection between the North Equatorial Undercurrent and the Guinea Undercurrent is less obvious (Bourlès et al. 2002; Djakouré et al. 2017; Herbert et al. 2016).

The tropical Atlantic undergoes a strong seasonal cycle associated with the meridional migration of the Intertropical Convergence Zone (Fig. 2). During boreal summer, the Intertropical Convergence Zone migrates northward resulting in strongly enhanced easterly winds along the equator and the establishment of the Atlantic cold tongue (ACT) in the eastern basin centred around 10°W (Fig. 2c). At the eastern boundary between equator and 15°S, the lowest sea surface temperatures (SST) near the coast are found between July and September. At the northern boundary of the Gulf of Guinea, winds strengthen as well during boreal summer in accordance with the development of the West African Monsoon resulting in upwelling favourable westerlies along the Ghanaian coast. Lowest SST near the coast is found in July-August (Fig. 2c). The equatorial Atlantic is warmest in March/April (Fig. 2b) corresponding to a seasonal cycle with a fast cooling during the onset phase of the ACT and slower warming after it has reached its maximum spatial extent (Brandt et al. 2011; Caniaux et al. 2011).

**Fig. 2** Monthly mean sea surface temperature (SST, colour shading), sea level anomaly (contour lines, unit is cm), and wind stress (arrows) during (a) January, (b) April, (c) July and (d) October. SST data are from OI-SST (https://www.esrl.noaa.gov/psd/data/gridded/), surface wind stress from ERA5.
In the tropical Atlantic, the thermocline depth often can be associated with the depth of the nitracline. An upward movement of the thermocline thus marks upward vertical advection of nitrate fuelling biological productivity (Radenac et al. 2020). Besides local wind forcing, the propagation of equatorial and coastally trapped waves (CTWs) along the equatorial and coastal waveguides, respectively, contributes to the vertical movement of the thermocline/nitracline. Such wave propagation can result in dynamic upwelling far away from the wave generation sites (Bachelery et al. 2020; Hormann and Brandt 2009; Illig et al. 2018a; Illig et al. 2018b). The Hovmöller diagrams of SST and winds as well as chlorophyll concentration and sea surface height show the seasonal development along the equatorial and coastal waveguides in the northern (Fig. 3) and southern (Fig. 4) hemispheres, respectively. Primary cooling along the equator can be identified following the enhancement of upwelling-favouring easterly winds in May-June (Weingartner and Weisberg 1991). A secondary cooling occurs in November-December (Jouanno et al. 2011a; Okumura and Xie 2006). In the GGUS, where SST reaches minimum values in August (Fig. 3a), upwelling-favouring westerly winds contribute to local cooling (Djakouré et al. 2017). Contrary, the southerly winds in the Angolan upwelling region are particularly weak during phases of coldest sea surface (Fig. 4a) (Körner et al. 2022; Ostrowski et al. 2009). Biological productivity marked by enhanced chlorophyll concentration is generally enhanced during periods of depressed sea surface height or correspondingly during periods of elevated thermocline (Fig. 3b).

In this review, we focus on the upper-ocean seasonal cycle in the three eastern-basin upwelling systems of the inner tropical Atlantic, the physical forcing driving the upwelling, the upward nitrate supply, and the resulting biological productivity. Section 2 focuses on equatorial upwelling, section 3 on the Gulf of Guinea coastal upwelling and section 4 on the tropical Angolan upwelling. In section 5, we discuss implications of longer-term changes and global warming for the seasonal cycle, and, finally, in section 6, we provide a conclusion and outlook.
Fig. 3 Seasonal cycle of (a) sea surface temperature (shading) and wind stress (arrows) and (b) chlorophyll concentration (shading) and sea level anomaly (contour lines, unit is cm) along the equatorial (left of the vertical black lines) and Gulf of Guinea coastal waveguides (right of the vertical black lines). Marks at the lower x-axis give geographic coordinates and marks at the upper x-axis give a scale for the distance and geographic locations along the waveguides. Also included in (a) are contours of the 25°C and 26°C isotherms to highlight equatorial and coastal upwelling. Positive and negative sea level anomaly in (b) are marked by solid and dashed contour lines, respectively; mean sea level anomaly is removed. SST data are from the Microwave OI SST product averaged for 1998-2022, wind data are from ASCAT and QSCAT averaged for 1991-2021, chlorophyll data are from Copernicus-GlobColour averaged for 1997-2022, sea level anomaly data are from Copernicus DUCAS averaged for 1993-2020.
2 Equatorial upwelling

The equatorial upwelling transports cool, nutrient-rich waters toward the surface of the equatorial Atlantic. Its influence at the surface is more pronounced in the eastern part of the basin, where it gives rise to the development of the ACT. Its intensity is modulated by a seasonal cycle composed of an annual and a semiannual component, with a primary SST minimum in July-August and a secondary minimum in November-December (Fig. 3) (Jouanno et al. 2011a; Okumura and Xie 2006). First insights into the seasonal evolution were obtained from observational studies in the 1980s, revealing a close link between seasonal surface cooling and vertical movements of the thermocline (Merle 1980; Voituriez et al. 1982). Indeed, periods of surface cooling in the eastern equatorial Atlantic (Fig. 3) are in phase with the thermocline upwelling in May-June and November (Fig. 5). By using forced ocean models, Philander and Pacanowski (1981) have revealed variations of the equatorial thermocline as forced by the seasonal cycle of the wind stress; stronger easterlies result in a stronger uplift of the thermocline in the eastern equatorial Atlantic. These authors discussed the response of the Atlantic Ocean to the seasonal wind forcing as an equilibrium response that can be understood as a succession of steady states. However, such an equilibrium response requires the dominance of low baroclinic mode equatorial Kelvin and Rossby waves that propagate fast enough to adjust the thermocline to the wind forcing within the seasonal cycle (Ding et al. 2009; Hormann and Brandt 2009; Philander and Pacanowski 1981; Philander and Pacanowski 1986).

Fig. 4 Same as Fig. 3, but along the southwest African coastal waveguide (right of the vertical black lines).
the eastern thermocline uplift, the equatorial easterlies force a strong eastward thermocline
flow, the EUC, that supplies the upwelling in the eastern equatorial Atlantic (Johns et al. 2014;
Schott et al. 1998).

The equatorial upwelling is an integral part of the STCs that are driven by the easterlies away
from the equator. The equatorial divergence in the Atlantic calculated from the Ekman
transports at about 10°S and 10°N, which defines the upwelling transport in the inner tropics,
is about 20 Sv (Schott et al. 2004; Tuchan et al. 2019). Easterlies at the equator additionally
result in equatorial upwelling that is part of the tropical cells (Perez et al. 2014). Tropical cells
are similar overturning circulations as the STCs, but confined only to the upper 100 m with
upwelling at the equator and downwelling at about ±3-5° latitude. In the Atlantic the mean
tropical cells are found to be asymmetric with respect to the equator; the northern cell extends
into the southern hemisphere. This behaviour can be explained by the presence of southerly
winds peaking during boreal autumn that drive a cross-equatorial northward surface flow at the
equator (Heukamp et al. 2022). This circulation feature, often referred to as the equatorial roll,
has maximum southward return flow at about 50 m depth and upwelling and downwelling
slightly south and north of the equator, respectively. The different forcing terms of the
upwelling velocity in the equatorial Atlantic are numerous and are discussed in detail in
Giordani and Caniaux (2011).

Over the past decade, several studies have revealed that turbulent mixing helps to define the
spatial distribution and temporal variability of equatorial surface cooling (e.g., Jouanno et al.
2011a). Turbulent mixing at the base of the mixed layer that drives heat flux out of the mixed
layer into the deeper ocean is dominantly induced by the vertical shear of the zonal equatorial
currents, that is the westward South Equatorial Current at the surface and the eastward EUC at
the thermocline level (Hummels et al. 2013). Different processes such as the seasonal variability
in strength and core depth of the zonal currents, vertical shear associated with intraseasonal
waves, the seasonal varying meridional circulation, and the deep-cycle turbulence contribute to
the spatial and temporal variability of equatorial mixing (Heukamp et al. 2022; Moum et al.
2022). Using the diapycnal heat flux derived from observations, the seasonal mixed layer heat
budget at the equator could be closed to a large extent and the seasonal development of the
mixed layer temperatures reasonably well explained (Hummels et al. 2014).

An important consequence of upwelling is the increase in biological production that is primarily
dependent on nitrate supply (Herbland and Voituriez 1979; Loukos and Memery 1999; Radenac
et al. 2020). There is a strong similarity between the seasonal cycles of phytoplankton
concentration and SST in the cold tongue area (Fig. 3) (Jouanno et al. 2011b), suggesting that
the same physical processes control the downward heat flux out of the mixed layer and the
upward supply of nitrate to the euphotic layer. This was confirmed by the analysis of repeated
sections of PIRATA and outputs from a coupled physical-biogeochemical model (Radenac et
al. 2020). Surface chlorophyll concentrations in the ACT peak in July-August and show a
secondary maximum in December-January (Fig. 5a). Radenac et al. (2020) showed that the
primary phytoplankton bloom in July-August is due to a strong vertical nitrate input in May-
July, and the secondary bloom in December is due to a shorter, moderate input in November-
December (Fig. 5b). Analysis of the nitrate balance in the upper ocean suggests that vertical
advection controls nitrate input to the equatorial euphotic layer and that vertical diffusion allows
nitrate to reach the mixed layer (Figs. 5c, d). However, already noted by Monger et al. (1997),
the phytoplankton concentration levels remain high beyond the primary bloom period in July-
August, despite the thermocline/nitracline has dropped back to pre-uplift depth in September.

Upwelling slightly south of the equator associated with southerly winds or turbulent mixing
between EUC and South Equatorial Current were discussed to account for the enhanced nitrate
concentration found above the EUC core during that period (Monger et al. 1997; Oudot and
Morin 1987).
Fig. 5 Seasonal cycle of vertical profiles of (a) chlorophyll, (b) nitrate, (c) vertical advection, and (d) vertical diffusion in 1.5°S–0.5°N, 20–5°W. The depths of the mixed layer (upper solid line), of the EUC core (dashed line), and of the 20°C isotherm (dotted line) are indicated.

Analysis of the PIRATA sections and model outputs in Radenac et al. (2020) shows that waters transported eastward by the EUC has in general relatively low nitrate concentrations compared to nearby water bodies to the north and south. This is most likely due to the source waters of the EUC that arrive from the oligotrophic layers of the subtropical South Atlantic (Johns et al. 2014; Schott et al. 1998; Tuchen et al. 2022a). The model simulations by Radenac et al. (2020) also revealed that the EUC core does not follow the thermocline depth (as defined as the 20°C...
isotherm, Figs. 5, 6). While in the eastern equatorial Atlantic, the vertical migration of the thermocline undergoes a semiannual cycle in accordance with the local wind forcing, the EUC core depth has a dominant annual cycle (Brandt et al. 2014). This non-equilibrium response of the equatorial Atlantic to the seasonal wind forcing could be explained by resonant equatorial basin modes composed of eastward and westward propagating equatorial Kelvin and Rossby waves, respectively (Brandt et al. 2016). As the thermocline depth is a good proxy of the nitracline (Fig. 5b), the EUC transports enhanced nitrate and phytoplankton concentrations when the EUC core is close to or deeper than the thermocline or nitracline, which is the case during July-August and to a lesser extend in December (Figs. 5a, b).

Measurements along the equator during two cruises in boreal autumn (Fig. 6a) and boreal spring (Fig. 6b) reveal the basin-wide character of the up- and downward movement of the EUC core relative to the thermocline depths. During boreal autumn, the EUC core closely follows the thermocline, while during boreal spring, it is located clearly above the thermocline. This behaviour can be associated with the resonant equatorial basin mode of the 4th baroclinic mode showing an annual cycle with maximum eastward velocity in the near-surface layer in boreal spring and maximum westward flow in boreal autumn (Brandt et al. 2016). A specific consequence of the relative movement of EUC core and thermocline depth is that the thermocline and thus the nitracline during part of the year vertically migrates into the shear zone above the EUC core. As the upper shear zone of the EUC supports strongly elevated turbulent mixing (Hummels et al. 2013; Hummels et al. 2014; Jouanno et al. 2011b; Moum et al. 2022), enhanced upward nutrient flux occurs during those periods. This was confirmed by the model study of Radenac et al. (2020) showing maxima in the diffusive nitrate flux into the mixed layer in July-August and December (Fig. 5d).

Beside a seasonal cycle, the productivity on the equator shows elevated intraseasonal and shorter-term variability. In particular, tropical instability waves (TIWs) and wind-forced
intraseasonal waves play an important role in stimulating locally productivity due to both meridional advection of nitrate and chlorophyll as well as due to events of enhanced vertical advection and mixing (Athie and Marin 2008; Jouanno et al. 2013; Menkes et al. 2002). TIWs are found to be associated with strong mixing events (Moum et al. 2009) or the generation of fronts (Warner et al. 2018) that both can drive upward nutrient supply. Resulting high productivity events could be observed during the boreal autumn cruise that took place shortly after the seasonal maximum of the TIW activity (Sherman et al. 2022).

3 Gulf of Guinea upwelling

In the Gulf of Guinea, coastal upwelling occurs seasonally along the northern coast, between 10°W and 5°E, from Côte d’Ivoire to Nigeria (Hardman-Mountford and McGlade 2003). It plays a key role in primary production and local fisheries and is therefore of large socio-economic importance for the bordering countries (Amemou et al. 2020; Koné et al. 2017). SST variability in the GGUS is suggested to modulate the amplitude of the African monsoon and thus has influence on regional climate (Caniaux et al. 2011; Djakouré et al. 2017). The GGUS is constituted of two main upwelling cells, an eastern cell east of Cape Three Points (4°44’N, 2°05’W) and a western cell east of Cape Palmas (4°22’N, 7°43’W), that are clearly marked by regions of reduced SST near the coast in satellite data (Wiafe and Nyadjro 2015).

Different physical processes have been proposed to explain the presence of the coastal upwelling in the GGUS. In early studies, the coastal upwelling has been related to the strengthening of the geostrophic coastal current. Indeed, the seasonal strengthening in the eastward-flowing Guinea Current contributes to enhance the meridional tilt of the thermocline, thereby bringing cooler subsurface waters near to the coast closer to the surface (Bakun 1978; Colin et al. 1993; Ingham 1970). The link between SST and wind stress curl in the GGUS was first suggested by Katz and Garzoli (1982) and Garzoli and Katz (1983). By using a model of the tropical Atlantic, Philander and Pacanowski (1986) showed the influence of both wind components and the wind stress curl on the upwelling in the GGUS. Additionally, Marchal and Picaut (1977) analysed isotherm displacements between Ghana and Côte d’Ivoire and suggested that vertical pumping by cyclonic eddies generated downstream of the capes could explain upwelling of cool waters. However, modelling results by Djakouré et al. (2014) did not confirm that the cyclonic eddies generated downstream of the capes contribute to the upwelling. Instead, Djakouré et al. (2014) and Djakouré et al. (2017) suggest that the upwelling downstream of Cape Palmas is associated with the nonlinear dynamics of the Guinea Current and its detachment from the coast. It is worth noting that the thermocline depth, the strength of the coastal current, and thus the upwelling, are all under the seasonal remote influence of the equatorial ocean through the propagation of equatorial Kelvin and CTWs (Adamec and Obrien 1978; Clarke 1979; Moore et al. 1978; Picaut 1983; Servain et al. 1982). Such remote influence is also indicated by the seasonal cycle of the sea level anomaly along the equatorial and coastal waveguides (Fig. 3b) and was found for intraseasonal wave propagation as well (Imbol Kougoue and Brandt 2021; Polo et al. 2008).

By using a model of the tropical Atlantic with an embedded high-resolution nest for the Gulf of Guinea, Djakouré et al. (2014) and Djakouré et al. (2017) performed sensitivity experiments to identify the dominant processes driving the seasonal upwelling in GGUS. The sensitivity includes experiments with a changed coastline without the capes (Djakouré et al. 2014) and with the nonlinear terms responsible for the advection of momentum removed (Djakouré et al. 2017). The spatial distribution of the mean SST for the major upwelling season (July-September) is shown for their reference simulation in Fig. 7. A comparison of the sensitivity experiments with the reference simulations (Fig. 8) shows that the sea surface during boreal summer is still colder than the 25°C (chosen as a threshold for the presence of coastal upwelling (Bakun 1978)), when the capes are removed (Fig. 8b). The western upwelling cell disappears...
only when the nonlinear terms are removed and the Guinea Current is trapped at the coast (Fig. 8c).

The thermocline depth, superimposed on the SST in Fig. 8, is in each of these configurations closest to the surface during the upwelling season. During this period, in the simulation without capes, the thermocline has a structure almost identical to that of the realistic configuration. However, the thermocline depth is always larger than 20 m in the simulation without capes and thus deeper than in the reference simulation. In the simulation without nonlinear terms, while generally deeper than in the reference simulation, the thermocline is closer to the surface in the western upwelling cell than in the eastern upwelling cell (west and east of Cape Three Points, respectively). The sensitive experiments demonstrated that advection of momentum is the main contributor to the vertical pumping of the western upwelling cell while the cooling of the eastern upwelling cell is mainly associated with the wind-induced coastal divergence (Djakouré et al. 2017).

**Fig. 7** Mean SST (°C) for the major cold season (July - September) for the reference experiment by Djakouré et al. (2017). The dashed line represents the 1000 m isobath.

**Fig. 8** Hovmöller diagrams of SST (°C) along the coast of the GGUS from 9°W to 6°E of (a) the reference experiment, the idealized experiments (b) without capes and (c) without inertial terms. The thermocline depth (20°C isotherm) is superimposed (thin contour lines, unit is m). The vertical dashed black lines represent the longitude of Cape Palmas and Cape Three Points, see Fig. 7. The time axis in months extends from November to February of the following year. The 25°C isotherm is additionally marked to highlight the coastal upwelling (thick contour lines).

In the eastern part of the GGUS that is dominantly wind-driven, coastal cooling weakens toward the east while approaching the Niger River mouth (Fig. 9). Earlier studies have shown that onshore geostrophic flow can compensate wind-driven offshore transport, thus reducing...
upwelling in some regions (Marchesiello and Estrade 2010; Rossi et al. 2013). Using a realistic regional model configuration, dynamical Ekman and geostrophic coastal upwelling indices were compared to coastal vertical velocities along the northern Gulf of Guinea coast, during the boreal summer season (Alory et al. 2021). Indeed, the upwelling indices were able to explain a large part of vertical velocity variations all along the coast. They also showed that wind-forced coastal upwelling is reduced by about 50% due to onshore geostrophic flow east of 1°E (Fig. 9a). Note that the Ekman index shown in Fig. 9a only takes into account the Ekman transport, as Ekman pumping has little influence in this region (Wiafe and Nyadjro 2015). The onshore geostrophic flow is associated with a sea level slope increasing toward the east. It is driven by density differences along the coast, from relatively cool and salty waters in the upwelling core east of Cape Three Points (Fig. 7) to warm and fresh waters in the Niger River plume and largely compensates offshore Ekman transport and therefore reduces upwelling (Fig. 9a).

The comparison of a reference simulation with a simulation in which river run-off is removed, revealed that the Niger River discharge contributes to induce an onshore geostrophic surface flow, but additionally causes a thinning of the mixed layer. Overall, there is no net effect of the river discharge on the near-surface geostrophic transport from which the geostrophic upwelling index is derived. Nevertheless, the Niger River discharge induces a coastal warming reaching 1°C near 2°E (Fig. 9b), which is found to be the result of a weakening of turbulent mixing by the enhanced salt stratification (Alory et al. 2021). The summer upwelling season corresponds both to a maximum thinning of the mixed layer and maximum surface chlorophyll concentration along the coast (Toualy et al. 2022). Riverine nutrient inputs may be more or less compensated by a reduced upward nutrient flux due to discharge-driven increased stratification as there is no strong chlorophyll signal in the plume region (Fig. 1).

4 Tropical Angolan upwelling

The Angolan waters host a highly productive ecosystem: the tAUS. Located in the southern hemisphere between the Congo River mouth at 6°S and the Angola-Benguela frontal zone at 15°S, the tAUS is of great socio-economic importance for local communities. Fishing supplies about 25% of the total animal protein intake of the Angolan population and is critical for economic security (FAO 2022; Hutchings et al. 2009; Sowman and Cardoso 2010). The productivity in the tAUS undergoes a distinct seasonal cycle (Fig. 4). In the tAUS during austral winter, maximum productivity is observed at the same time as the lowest SST and the strongest cross-shore temperature gradient are present (Awo et al. 2022; Körner et al. 2022; Tchipalanga et al. 2018). In contrast to other eastern boundary upwelling systems, the seasonality of the productivity in the tAUS cannot be explained by local wind forcing (Ostrowski et al. 2009).

Prevailing southerly winds in the tAUS are generally weak throughout the year (Fig. 4a). Neither the seasonal cycle of alongshore wind stress nor of the wind stress curl are in phase with the seasonal cycle in productivity suggesting that other mechanisms drive the productivity seasonality in the tAUS (Körner et al. 2022).

One of the key dynamics modulating the tAUS on different time scales is the passage of CTWs (Awo et al. 2022; Bachèlery et al. 2016b; Illig et al. 2018b; Kopte et al. 2017; Körner et al. 2022; Tchipalanga et al. 2018). CTWs that propagate poleward along the eastern boundary are forced remotely by wind fluctuations along the equator or locally by winds at the eastern boundary. Sea level satellite observations reveal the seasonal passage of four remotely forced CTWs throughout the year (Fig. 4b) (Rouault 2012; Tchipalanga et al. 2018). A downwelling CTW arrives at the Angolan coast in March followed by an upwelling CTW in June/July. A secondary downwelling CTW propagates along the Angolan coast in October followed by a secondary upwelling CTW in December/January. The main component of the eastern boundary circulation in the tAUS is the poleward Angola Current (Kopte et al. 2017; Siegfried et al. 2019). Its variability is linked to equatorial ocean dynamics via the propagations of CTWs at different time scales (Imbol Koungue and Brandt 2021; Kopte et al. 2018; Kopte et al. 2017). On seasonal time scales the southward velocities of the Angola Current peak in October with a secondary maximum in February (Kopte et al. 2017).

The hydrographic conditions in the tAUS undergo distinct seasonal changes (Fig. 10). Conductivity, temperature, depth (CTD) data from fifteen years of biannual research cruises of the Nansen program (Tchipalanga et al. 2018) illustrate the seasonal differences between the primary downwelling phase in austral summer and the primary upwelling phase in austral winter (Fig. 10). In austral summer (February-April) the cross-shelf section derived from data averaged between 10°S and 12°S shows warm surface waters and a subsurface salinity maximum. The subsurface salinity maximum is absent in austral winter (June-August). The isopycnals show evidence of down- and upwelling as they bend downward towards the shore in austral summer and upward in austral winter. Furthermore, the isopycnals undergo a vertical displacement between the seasons (the 26.2 kg m$^{-3}$ isopycnal moves vertically by about 50 m).

The vertical displacement of the permanent thermocline can be attributed to the passage of CTWs. The seasonal passage of four CTWs induces a semiannual cycle in the vertical isopycnal movements (Kopte et al. 2017; Rouault 2012).
Fig. 10 Hydrographic conditions between 10°S and 12°S during main downwelling phase, February-April (a,c) and main upwelling phase, June-August (b,d) inferred from the Nansen CTD dataset (Tchipalanga et al. 2018). CTD data is projected on mean topography (GEBCO) between 10°S and 12°S. Panels a and b show the temperature field, panels c and d the salinity field. Black contour lines mark potential density.

To understand the changes in SST in the tAUS, one has to account for other processes than the passage of CTWs. The SST which shows an annual cycle is dominantly driven by the surface heat fluxes. The advection of warm water by the Angola Current plays only a minor role (Körner et al. 2022). In the tAUS, lower SST are found directly along the coast compared to further offshore (Fig. 2). The resulting negative cross-shore SST gradient has a semiannual cycle and is strongest between April and September, with a secondary maximum in December/January. The cross-shore SST gradient can neither be explained by surface heat fluxes which act to dampen the spatial SST differences nor by the weak horizontal heat advection. Ocean turbulence data revealed that turbulent mixing across the base of the mixed layer is strongest in shallow waters and capable of setting up the negative cross-shore SST gradient. The semiannual cycle of the gradient can be explained by turbulent mixing acting upon seasonally different stratifications (Körner et al. 2022) as discussed below.

In contrast to SST, sea surface salinity (SSS) in the tAUS undergoes a semiannual cycle. Fresher water is found in the northern part of the tAUS in October/November and in February/March (Fig. 10) (Awo et al. 2022; Kopte et al. 2017; Lübbecke et al. 2019). An important source of freshwater in the tAUS is the Congo River discharge at 6°S, with a maximum discharge into the ocean in early December (Martins and Stammer 2022). The observed freshwater in the tAUS is controlled by meridional advection via the Angola Current and peaks in phase with the strengthening of the Angola Current (Awo et al. 2022). Indeed, the Angola Current displaces the freshwater from the Congo River plume toward the tAUS, leading to elevated stratification with low-salinity water at the surface above a subsurface salinity maximum. This strong stratification favours the subsurface advection of high salinity water counteracting surface freshening via vertical salt advection and mixing at the base of the mixed layer (Awo et al. 2022).

Turbulent mixing is an important mechanism in the tAUS for the near-coastal cooling, upward salt flux, and upward nutrient supply (Awo et al. 2022; Körner et al. 2022; Ostrowski et al. 2009). Ocean turbulence data from six research cruises is used to analyse the distribution of vertical eddy diffusivity at a cross-shelf section at 11°S (Fig. 11). The vertical eddy diffusivity is elevated near the bottom at the continental slope and shelf. Additionally, waters shallower
than 75 m show enhanced diffusivities over nearly the whole water column. This finding suggests a dependence of mixing on bathymetry in the tAUS with stronger mixing occurring in shallow waters, similarly to other upwelling systems (Perlin et al. 2005; Schafstall et al. 2010).

![Fig. 11 Vertical eddy diffusivity calculated from microstructure observation as a function of depth and distance to coast. Measurements are taken at a section at about 11°S. Eddy diffusivity is calculated for each profile individually before profiles are binned together in groups of 20 profiles.](https://doi.org/10.5194/egusphere-2022-1354)

The elevated mixing rates in shallow waters of the tAUS can be explained by the interaction between onshore propagating internal waves and topography. The main energy source of the internal wave field is assumed to be internal tides, which are generated by the interaction of the barotropic tide and the continental slope (Hall et al. 2013; Lamb 2014). By applying a numerical model, Zeng et al. (2021) found that in the tAUS a substantial part of the tidally generated internal wave energy propagates onshore and dissipates in shallow waters. Resulting enhanced near-shore mixing agrees well with observations. The seasonality of the spatially-averaged generation, onshore flux, and dissipation of internal tide energy is weak. This means that throughout the year, roughly the same amount of energy is available for mixing in shallow waters. However, the energy available for mixing acts on seasonally different background stratifications leading to different effects of mixing on temperature (Körner et al. 2022; Zeng et al. 2021). Associated with the passage of CTWs as well as with changes in surface heat fluxes and SSS, the stratification in the tAUS undergoes a semiannual cycle (Kopte et al. 2017). Zeng et al. (2021) showed how cooling in the near coastal area is stronger during phases of weak stratification.

The productivity season in the tAUS is in phase with the propagation of CTWs (Fig. 4). The chlorophyll concentration peaks around one month after the passage of the seasonal upwelling CTW in austral winter. Similarly, a secondary chlorophyll peak is visible after the passage of the secondary upwelling CTW in December/January. However, the exact process of how the passage of the CTWs leads to an increase in primary production remains an open question. The seasonal varying effect of mixing on SSTs shows that a reduction in stratification can lead to more effective cooling near the coast during the upwelling phase (Körner et al. 2022; Zeng et al. 2021). The upward nutrient supply additionally depends on the change in the background distribution of nutrients. Higher upward nutrient fluxes could be achieved by increasing the nutrient gradient during phases of upwelling CTW in areas of high mixing. Such changes in background conditions associated with the onshore advection of nutrients during the passage of CTWs might be able to ultimately explain the seasonal productivity signals in the tAUS.

5 Relation between upwelling seasonality and longer-term variability

The seasonal upwelling has important consequences on the expression of the interannual variability at the sea surface of the tropical Atlantic. It is the area and season most impacted by
the upwelling that show marked interannual variability, whether in terms of SST (Keenlyside and Latif 2007) or phytoplankton concentration (Chenillat et al. 2021).

The dominant climate mode in the tropical Atlantic is the Atlantic Niño (Hisard 1980; Lübbecke et al. 2018; Ruiz-Barradas et al. 2000). It is most pronounced in the equatorial cold tongue east of 23°W and peaks during boreal summer. Anomalous warm or cold events are thus associated with anomalous deep or shallow thermocline and correspondingly with reduced or enhanced upwelling, respectively. The Atlantic Niño is associated with SSS variability as well (Awo et al. 2018) suggesting an additionally forcing of the equatorial and eastern boundary upwelling in the eastern tropical Atlantic by the impact of precipitation and river discharge on near-surface stratification. Besides the interannual variability, decadal variability can impact the equatorial upwelling. Such variability might be associated with a changing strength of the STCs forced by off-equatorial easterlies (Rabe et al. 2008; Tuchen et al. 2020). Similarly, Brandt et al. (2021) found an intensification of the EUC for the period 2008-2018 that was linked to enhanced trade winds in the tropical North Atlantic likely associated with the Atlantic multidecadal variability (Knight et al. 2006). Other mechanisms that are suggested to impact the strength of equatorial cooling on decadal time scales include the decadal variability of TIWs. A decadal strengthening of TIWs was found to be associated with enhanced warming of the equatorial cold tongue by lateral eddy fluxes (Tuchen et al. 2022b). Coupled climate simulations also suggest the importance of surface heat fluxes in driving interannual to decadal cold tongue SST variability (Nnamchi et al. 2015). As discussed by Jouanno et al. (2017), such heat flux forcing is likely overemphasized due to large upper ocean temperature biases commonly found in climate models. Chang et al. (2008) analysed the impact of a changing Atlantic meridional overturning circulation (AMOC) on the tropical Atlantic using simulations with a climate model. These simulations showed that a weakened AMOC results in a warmer equatorial Atlantic with reduced seasonal cycle and interannual variability. Similarly, a weakening of interannual variability is projected under a global warming scenario (Crespo et al. 2022). However, the impact of global warming or reduced AMOC on seasonal or interannual variability of productivity is highly uncertain as even the impact on upper ocean stratification is not coherent between different models and datasets, which is partly due to the fact that first decadal trends in stratification or productivity are just emerging (Hammond et al. 2020; Roch et al. 2021; Sallee et al. 2021).

In the GGUS, interannual variability is generally stronger in regions of strong seasonal variability as has been documented from satellite and in situ data (Sohou et al. 2020; Wiafe and Nyadjro 2015). Potential drivers of interannual variability are similar to drivers of seasonal changes. They include changes in the wind forcing and turbulent mixing, and remote forcing associated with the Atlantic Niño (Jouanno et al. 2017; Wade et al. 2011). Processes involved in the 2012 cold anomalies in the GGUS, the coldest event observed over the last 30 years, have been investigated through a model heat budget (Da-Allada et al. 2021). Results revealed that the surface cooling at Cape Palmas was driven by changes in zonal advection and increased turbulent mixing due a strengthening of the Guinea Current and associated vertical shear, while east at Cape Three Point, it was driven by a strengthening of the zonal wind stress that increased the offshore Ekman transport.

Benguela Niños and Niñas are the dominant mode of interannual climate variability in the tAUS (Shannon et al. 1986). Contrary to the variability in the EAUS and GGUS, seasonally interannual variability does not reach its maximum during the main upwelling season, but during the main downwelling season from March to May (Lübbecke et al. 2019). During a Benguela Niño or Niña, SST can be up to 2°C higher or lower than the climatology in the tAUS (Imbol Kougue et al. 2021; Imbol Kougue et al. 2019; Rouault et al. 2007; Rouault et al. 2018). These extreme events have drastic consequences for the marine ecosystem (Gammelsrød et al. 1998) through modulations in coastal upwelling intensity, nutrients and oxygen content along the continental shelf (Bachélery et al. 2016a). It can be assumed that forcing mechanisms...
of Benguela Niños and Niñas are similar to those of the seasonal upwelling variability. On one hand, winds at the equator can generate equatorial Kelvin waves (Illig et al. 2004) that continue southward along the southwest African coast as CTWs and produce locally thermocline displacements (Bachélery et al. 2016b; Bachélery et al. 2020; Imbol Koungue et al. 2017; Polo et al. 2008). On the other hand, fluctuations of local alongshore winds (Richter et al. 2010) and other local processes such as freshwater inputs (Lübbecke et al. 2019) further generate SST anomalies in the tAUS. For the satellite era, Prigent et al. (2020a) showed a weakening of interannual SST variability in the southeastern tropical Atlantic between 2000-2017 relative to 1982-1999. However, since 2018, two consecutive extreme coastal warm events have been recorded in the tAUS in 2019/2020 (Imbol Koungue et al. 2021) and in 2021. The recent decades demonstrate a strong warming trend in the tropical Atlantic SST with the largest warming observed in the coastal upwelling regions off southwestern Africa including the tAUS (Tokinaga and Xie 2011). Moreover, using observational data, Roch et al. (2021) discovered a change in upper-ocean stratification from subtropical to tropical conditions associated with a warming and freshening of the mixed layer between 2006 and 2020 in the southeastern tropical Atlantic (10°S-20°S; 5°W-15°E). Such changes in stratification are assumed to particularly impact the mixing-driving nitrate supply in the tAUS.

6 Conclusion and outlook

Here we have reviewed the physical processes in three major upwelling systems of the inner tropical Atlantic, the EAUS, the GGUS, and the tAUS, that drive the upwelling seasonality. Among them are the processes that locally impact the thermocline depth - often used as a proxy of the nitraline - such as zonal wind along the equator, alongshore wind and wind stress curl in coastal upwelling regions or the detachment of the boundary current. Remote processes associated with the propagation of equatorial Kelvin and CTWs affect the thermocline depth in the different upwelling regions on intraseasonal, seasonal and interannual timescales as well. The processes affecting the thermocline depth can be summarized under locally and remotely driven vertical advection which is able to transfer colder and nutrient-rich waters upward to the surface during active upwelling. Additionally, diffusive fluxes associated with turbulent mixing at the base of the mixed layer and within the thermocline transport heat downward and nutrients upward.

The EAUS can be characterized as a wind-driven upwelling system forced by different wind components at the equator and off the equator. Wind changes generate upwelling and downwelling equatorial waves propagating along the equator and adjust the equatorial thermocline to reach an equilibrium with the wind forcing. The zonal velocity field instead is dominated by the equatorial basin resonance of the 2nd and 4th baroclinic modes resulting in an EUC that vertically migrate largely independent of the thermocline (Brandt et al. 2016). During periods, when the thermocline depth is shallower than the EUC core, turbulent mixing in the shear zone above the core of the EUC is essential for the downward heat flux and upward nitrate flux out and into the mixed layer, respectively (Hummels et al. 2014; Jouanno et al. 2011b). In the GGUS different processes define the two upwelling centres, east of Cape Palmas and east of Cape Three Points. East of Cape Palmas, the nonlinear detachment of Guinea Current from the coast plays the most important role, while east of Cape Three Points, upwelling is mainly associated with the wind-induced coastal divergence (Djakouré et al. 2017). The upwelling in the tAUS, which is characterized by weak winds, is dominantly driven by a combination of remotely forced CTWs and locally induced turbulent mixing (Körner et al. 2022; Rouault 2012; Tchipalanga et al. 2018).

Climate warming and change might impact the upwelling in the different regions and its seasonality (amplitude and phase) differently. Most obvious are probably future changes in the wind field, e.g., a strengthening of the winds in a warming world or poleward shifts of the main
Changes in the stratification and mixed layer depths are highly uncertain with recent studies suggesting an increase of the stratification at the base of the mixed layer together with a mixed layer deepening likely due to enhanced wind-driven upper-ocean turbulent mixing (Sallee et al. 2021). However, other processes such as lateral mixing, responsible for reducing nitrate concentrations in upwelling regions, or surface heat fluxes, might contribute as well. Recently, the multidecadal increase in the strength of TIWs and associated equatorward eddy heat flux was suggested to warm the EAUS (Tuchen et al. 2022b). Such eddy fluxes generally oppose the Ekman transport in upwelling systems. Air-sea heat and buoyancy fluxes were identified to modulate such compensation in idealized model simulations (Thomsen et al. 2021), suggesting that in a warming climate also changes in heat and freshwater fluxes have the potential to impact the upwelling strength via its impact on lateral eddy fluxes. The identification of climate changes in upwelling systems is a major goal that requires the maintenance and further development of the tropical Atlantic observing system (Foltz et al. 2019). In particular, coastal upwelling regions show a sparse data coverage and the strengthening of the near-coastal observing system has a high priority. This requires a close cooperation with the coastal communities to jointly develop the research agenda according to collective interests and needs. Main questions regard the often-competing role of changes in wind forcing and stratification and the role of changing eddy fluxes and buoyancy forcing. What will be the consequences of changing upwelling amplitude and/or timing for biogeochemistry and biology? Overall, future upwelling studies require a close cooperation between different research disciplines focusing on the interaction between the physical, biogeochemical and biological systems and allowing an improved assessment of ecosystem management and fisheries.

Publicly available datasets were used for this study. Chlorophyll data are from the Copernicus-GlobColour dataset (https://doi.org/10.48670/moi-00021). The sea level anomaly data were accessed via the Copernicus Server (https://doi.org/10.48670/moi-00148). Microwave OI SST and wind data from ASCAT and QSCAT are available under https://www.remss.com. Also used are surface wind stress from ERA5 (https://cds.climate.copernicus.eu/). Hydrographic sections in Angolan waters have been produced using the Nansen CTD Dataset (https://doi.pangaea.de/10.1594/PANGAEA.887163).

PB outlined and wrote the manuscript. MK, RI, JJ, SD, GA produced the figures. All co-authors contributed to and reviewed the manuscript.

List of abbreviations.

**AMOC** Atlantic meridional overturning circulation

**ACT** Atlantic cold tongue

**CTD** conductivity, temperature, depth

**CTW** coastal trapped wave

**EAUS** equatorial Atlantic upwelling system

**EUC** Equatorial Undercurrent

**FAO** Food and Agriculture Organization

**GGUS** Gulf of Guinea upwelling system

**tAUS** tropical Angolan upwelling system
