14 **Abstract.** The three IASI instruments on-board the Metop family of satellites have been sounding the atmospheric
15 composition since 2006. More than 30 atmospheric gases can be measured from the IASI radiance spectra, allowing
16 the improvement of weather forecasting, and the monitoring of atmospheric chemistry and climate variables.

17 The early detection of extreme events such as fires, pollution episodes, volcanic eruptions, or industrial releases is key
18 to take safety measures to protect inhabitants and the environment in the impacted areas. With its near real time
19 observations and good horizontal coverage, IASI can contribute to the series of monitoring systems for the systematic
20 and continuous detection of exceptional atmospheric events, in order to support operational decisions.

21 In this paper, we describe a new approach for the near real time detection and characterization of unexpected events,
22 which relies on the principal component analysis (PCA) of IASI radiance spectra. By analyzing both the IASI raw and
23 compressed spectra, we applied a PCA-granule based method on various past well documented extreme events such
24 as volcanic eruptions, fires, anthropogenic pollutions and industrial accidents. We demonstrate that the method is well
25 suited to detect spectral signatures for reactive and weakly absorbing gases, even for sporadic events. Consistent long-
26 term records are also generated for fire and volcanic events from the available IASI/Metop-B data record.

27 The method is running continuously, delivering email alerts on a routine basis using the near real time IASI LIC
28 radiance data. It is planned to be used as an online tool for the early and automatic detection of extreme events, which
29 was not done before.

30 1 Introduction

31 Atmospheric composition is changing fast locally and globally, under natural and anthropogenic influences combined.
32 Fire activity and local urban pollution are likely to increase in a warming climate (Hart, 2022). With their potential
33 consequences on society and health, monitoring the events that impact atmospheric composition becomes increasingly
34 important.

35 Since the end of 2006, the IASI mission has been probing the troposphere from satellite to monitor the atmospheric
36 composition globally, onboard of 3 successive Metop satellites (Clerbaux et al., 2009). Observation records and trends
37 are available for several infrared absorbing species, such as methane (CH_4) (García et al., 2018), carbon monoxide
38 (CO) (George et al., 2009), ammonia (NH_3) (Van Damme et al., 2021), ozone (O_3) (Dufour et al., 2018; Wespes et al.,
39 2019) and dust (Capelle et al., 2014; Clarisse et al., 2019). As the first goal of this mission is to feed meteorological
40 forecast using data assimilation, radiance Level 1C (L1C) data are received in near real time, around 2-3 hours after
41 the overpass of the satellite. This makes the detection of exceptional events possible, potentially right after they occur,
42 such as large biomass burning fires (Turquety et al., 2009; R'Honi et al., 2013), anthropogenic pollution episodes
43 (Boynard et al., 2014) or volcanic eruptions (Wright et al, 2022). With more than 1.2 million of radiance spectra per
44 instrument per day, the search for local extreme events in near real time is not straightforward. A limitation is also
45 associated with the lack of data when clouds are present in the field of view, as the usual retrieval algorithms fail to
46 properly derive atmospheric concentrations for trace gases. Cloudy data are hence filtered.

47 Soon after the launch of the first IASI instrument, it has been suggested to use the principal component analysis (PCA)
48 method to reduce data volumes by reconstructing the radiances using only the leading eigenvectors (Matricardi, 2010).
49 This compression not only allows to heavily decrease the data volume but also to ease the data dissemination. Now
50 available through the EUMETSAT (EUropean organization for the exploitation of METeorological SATellites)
51 Advanced Retransmission Service (EARS-IASI), the PCA method allows meteorological centers to directly assimilate
52 the principal components (Collard et al., 2010; Matricardi et al., 2014; Guedj et al., 2015). It was also demonstrated
53 that using reconstructed IASI radiance results in a substantial reduction of random instrument noise for the analysis of
54 trace gases such as NH_3 or sulfur dioxide (SO_2) (Atkinson et al., 2010). However, it was decided to continue the
55 distribution of the entire radiance spectra (8461 spectral channels) as one of the concerns in the use of the PCA method,
56 for atmospheric chemistry studies, was the detection of spectral features associated with minor trace gases linked with
57 rare events in the reconstructed spectra. Examples are volcanic eruptions, which all differ in terms of gas and type of
58 ash emitted, and hence not enough representative cases were available in the training set. The same holds for biomass
59 burning fires releasing different amounts of specific species depending on the type of vegetation burned. With the
60 advent of the second and third IASI instrument together with the improvement of retrieval algorithms over time, a
61 number of short- and long-lived trace gases were identified in the IASI spectra above or downwind from strong
62 emission sources (Clarisse et al., 2011; De Longueville et al., 2021).

63 This paper describes the potential of the PCA applied on the IASI L1C (apodized radiance) data for the automatic,
64 near real time detection and characterization of exceptional events. The paper is organized as follows: Section 2
65 describes the IASI instrument and the dataset used in this study. Section 3 describes the PCA method. In Section 4, an
66 innovative approach based on the PCA method and IASI data granules is presented, which allows spectral
67 characterization of species in near real time. In Section 5, different case studies of exceptional past events are discussed,
68 such as volcanic, fire, and anthropogenic pollution episodes, along with industrial accidents, detected by IASI/Metop-
69 A and -B. Finally, conclusions are given in Section 6.

70 **2 The IASI radiance data**

71 IASI is a Fourier transform infrared spectrometer, which records the thermal infrared (TIR) radiation emitted by the
72 Earth and the atmosphere, between 645 cm^{-1} and 2760 cm^{-1} , with 8461 channels sampled every 0.25 cm^{-1} and a spectral
73 resolution of 0.5 cm^{-1} . An example of IASI spectrum along with the absorption band of several species is illustrated in
74 Fig. 1.

75 In this work IASI-A and IASI-B are used as a combined dataset. The IASI-A dataset is used for the study of events
76 before the launch of IASI-B and for creating the PCA training database (described here-after), and the IASI-B complete
77 dataset is used for data after 2013 to present. The two datasets have been shown to be highly consistent with no
78 significant drifts over time (García et al., 2016).

79 Each IASI instrument provides more of 1.2 million of spectra per day. IASI L1C data are disseminated by EUMETSAT
80 in 3-minute files (called “granule” hereafter) less than 3 hours after each overpass. Each granule contains 22 or 23
81 IASI scan lines with 120 pixels per line. With a wide swath width of $\sim 2200\text{ km}$, global observations are provided twice
82 a day, at 9:30 AM and 9:30 PM local time. IASI has an instantaneous field of view (FOV) at nadir with a spatial
83 resolution of $50\text{ km} \times 50\text{ km}$, composed of 2×2 circular pixels (IFOV), each corresponding to a 12 km diameter
84 footprint on the ground at nadir (Clerbaux et al. 2009).

85
86 **Figure 1: Top panel: Example of IASI spectrum. Middle and bottom panels: radiative transfer simulations for the main and**
87 **weaker infrared absorbers, respectively.**

88 The atmospheric concentrations of some species are routinely retrieved from the spectral signatures (George et al.,
89 2009; Clarisse et al., 2011; Van Damme et al., 2013) and distributed through the AERIS database (iasi.aeris-data.fr).
90 Some exceptional events have been studied in detail such as the 2010 Russian fires (R’honi et al., 2013), pollution in
91 the North China Plain (Boynard et al., 2014), and SO_2 anthropogenic pollution (Bauduin et al., 2014, 2016).

92 3 The Principal Component Analysis Method

93 **3.1 Basic concepts**

94 The PCA method for high spectral resolution sounders, such as IASI, is described in Atkinson et al. (2008). This
 95 method is well suited to efficiently represent the amount of information contained in the 8641 IASI channels. It relies
 96 on the use of a dataset of thousands of spectra representing the full range of atmospheric conditions from which the
 97 principal components are calculated, the so-called “training database”.

98 One considers an ensemble Y of n IASI radiance spectra \mathbf{y} of dimension m (where m is the number of channels and n
 99 is the number of observations). Let denote $\mathbf{N}^{-1}\bar{\mathbf{y}}$ the mean and $\mathbf{S}_\epsilon (m \times m)$ the covariance of the normalized ensemble
 100 of spectra $\mathbf{N}^{-1}Y$. \mathbf{N} is the noise normalisation matrix and is defined as the square root of $\mathbf{S}_y (m \times m)$ the instrument
 101 noise covariance matrix associated to the IASI spectra.

102 The PCA is based on the eigen decomposition of the matrix \mathbf{S}_ϵ :

$$103 \quad \mathbf{S}_\epsilon = \mathbf{E} \mathbf{\Lambda} \mathbf{E}^T \tag{1}$$

104 where \mathbf{E} is the matrix $m \times m$ of eigenvectors and $\mathbf{\Lambda}$ the diagonal matrix of their associated eigenvalues.

105 The representation of a measured spectrum \mathbf{y} in the eigenspace \mathbf{E} is obtained by:

$$106 \quad \mathbf{p} = \mathbf{E}^T \mathbf{N}^{-1}(\mathbf{y} - \bar{\mathbf{y}}) \tag{2}$$

107 \mathbf{p} (dimension m) is the vector of the principal component scores.

108 The analysis consists in representing the multidimensional IASI spectra in a lower dimensional space, which accounts
 109 for most of the variance seen in the data. This space is spanned by a truncated set of the eigenvectors of the data
 110 covariance matrix. By noise-normalizing the spectra prior to the application of the PCA, the ability to fit the data is
 111 enhanced by avoiding giving too much weight to variance caused by noise. Giving m^* the number of most significant
 112 eigenvectors of \mathbf{S}_ϵ , one can represent the spectrum in the eigenspace by a truncated vector of principal component
 113 scores, \mathbf{p}^* of rank m^* ($m^* < m$). \mathbf{p}^* is thus a compressed representation of \mathbf{y} . The reconstructed spectrum, $\tilde{\mathbf{y}}$
 114 (dimension m) is given by:

$$115 \quad \tilde{\mathbf{y}} = \bar{\mathbf{y}} + \mathbf{N} \mathbf{E}^* \mathbf{p}^* \tag{3}$$

116 where \mathbf{E}^* is the matrix of the m^* first eigenvectors or principal components. We define the noise normalized residual
 117 vector \mathbf{r} (dimension m) of the reconstruction by:

$$118 \quad \mathbf{r} = \mathbf{N}^{-1}(\mathbf{y} - \tilde{\mathbf{y}}) \tag{4}$$

119 By definition, if m^* is taken equal to m , $\tilde{\mathbf{y}} = \mathbf{y}$ and the residual is the null vector. In nominal cases if the truncation
 120 rank is carefully chosen, \mathbf{r} essentially contains noise. Several techniques exist to estimate m^* in order to keep the
 121 essential part of the atmospheric signal and to remove the eigenvectors containing mainly the measurement noise (e.g.,
 122 Antonelli et al. (2004), Atkinson et al. (2010)).

123 In the following the noise normalized residual, which is calculated for each IASI IFOV, is called IFOV-residual.

124 3.2 Construction of the training database

125 The training set includes spectra observed over different types of atmospheric/surface conditions at different scan
126 angles and for different pixel numbers to ensure that a truncated set of eigenvectors can be adequately used to represent
127 any observed spectrum. Additionally, if the training set is too small, the specific outcome of the random noise will not
128 be sufficiently uncorrelated and uniform, and will therefore have an influence on the computed eigenvectors and
129 eigenvalues. Extensive experience on IASI spectra from EUMETSAT (Hultberg, 2009,
130 <https://www.eumetsat.int/media/8306>) and additional experiments with different dataset sizes show that a number of
131 about 70000 spectra is a reasonable lower limit. For this study, around 120000 IASI/Metop-A L1C spectra were
132 selected during a full year (which was chosen as a nominal year for avoiding excessive occurrence of extreme events
133 such fires and volcanoes) on the global scale. The database contains spectra associated with a good quality flag in order
134 to only keep reliable data, acquired indifferently during the day and the night, over land and sea, and regardless of the
135 cloud cover. For each month of the year 2013 spectra were selected every five days (1, 6, 11, 16, 21 and 26 of each
136 month). To avoid over-representing high latitudes, because of the large swath of IASI (~2200 km) and frequent
137 overpasses over this area with the polar orbiting satellites, the following method was applied:

138 - between 90 and 75° only one spectrum is selected

139 - between 75 and 60°, two spectra are selected

140 - between 60 and 45°, three spectra are selected

141 - between 45 and 30°, four spectra are selected

142 - between 30 and 15°, five spectra are selected

143 - between 15 and 0°, six spectra are selected

144 To reach a sufficient but reasonable number of IASI spectra/IFOVs (1.3 10⁶ spectra per day, 4.7 10⁸ per year), 120000
145 IFOVs for year 2013 were randomly chosen to represent all atmospheric/surface situations (air masses, land/sea,
146 day/night, clear/cloudy) and acquisition conditions (IASI scan mirror position and pixel number).

147 3.3 Number of eigenvectors

148 Several techniques exist to estimate m^* in order to keep the essential part of the atmospheric signal and to remove the
149 eigenvectors containing mainly the measurement noise. Antonelli et al (2004) define a criterium based on the spectral
150 RMS reconstruction residuals, finding the optimal truncation rank when this value approach the spectral RMS of the
151 instrument noise. Other methods test directly the behavior of the reconstruction score $\sqrt{\frac{1}{m} \sum_{i=1}^m r_i^2}$ as a function of the
152 truncation rank, by looking at the second derivative of the reconstruction score as a function of the truncation rank
153 (e.g., Hultberg, 2009) or plot the principal component score (\mathbf{p}) spatial correlation as a function of eigenvector rank
154 (Atkinson et al., 2009). In this study, the estimation of m^* is based on the analysis of the eigenvalues. The eigenvalues
155 (sorted in descending order) quantify the variability explained by the corresponding eigenvectors, and the optimal

156 number of eigenvectors needed to reproduce the signal in the raw radiances can be determined by analyzing their
157 magnitude and behavior. In the present implementation of the PCA method we process the full IASI spectrum and use
158 a simple method for selecting the truncation rank. The plot of the eigenvalues was examined and PCs were selected up
159 to the point where the slope of the curve stabilized. This leads to choose the first 150 eigenvectors as done in Atkinson
160 et al., 2010. Sensitivity tests has been performed to test the impact of using different values (from 120 to 250) on the
161 reconstructed scores obtained on several atmospheric events (fires and volcanoes cases discussed in the next sections)
162 and confirm this value.

163 **4 The IASI-PCA granule-extrema (GE) based method**

164 **4.1 Granule maxima and minima**

165 The near real time detection of exceptional events is performed on the IASI granule. The choice of applying the method
166 on the granule is convenient for the near real time aspect as it represents 3 minutes of IASI data which are received
167 every few 1-2 hours by the antenna.

168 Each granule contains ~2700 radiance spectra, from which the corresponding IFOV-residuals are computed based on
169 the IASI-PCA method. For each granule, the largest positive and negative residual value for each spectral channel is
170 recorded in two arrays, called hereafter “Granule Maxima” (GMA) and “Granule Minima” (GMI). GMI and GMA are
171 defined as pseudo-residuals of dimension 8461 (the number of radiance channels) and represent the spectral envelope
172 of the statistics of residuals over the granule. Physically, the GMI (GMA) pseudo-residual is associated with
173 reconstruction errors of spectral absorption (emission) lines. Since the method is based on the granule extrema (GMI
174 and GMA), the method is therefore called: IASI-PCA-GE, with GE standing for Granule-Extrema. It is important to
175 note that these pseudo-residuals associated with a granule are different from the individual IFOV-residual associated
176 with each IFOV.

177 Figure 2 illustrates an example of GMA and GMI pseudo-residuals for an intense fire event that occurred in Australia
178 on 1 January 2020. The GMI pseudo-residual (bottom panel) is characterized by detectable spectral features associated
179 with a poor reconstruction around 700, 950, 1100 or 2100 cm^{-1} . Using spectroscopic database allows to associate some
180 of these strong peaks with contribution of different atmospheric components (see Section 5 for the identification of the
181 molecules). Similar spectral features can be seen in the GMA pseudo-residual (top panel) albeit in emission and less
182 intense.

183
 184 **Figure 2: Granule Maxima (GMA) (top) and Granule Minima (GMI) (bottom) pseudo-residuals obtained from a granule of**
 185 **IASI/Metop-B L1C data on 1 January 2020 over Australia.**

186 **4.2 Detection thresholds**

187 Two detection thresholds are defined in order to select 1) the granules associated with outliers only (which allows to
 188 gain computation time) and 2) the IFOV-residuals associated with reconstruction errors. For the definition of the
 189 detection thresholds, a dataset of 43000 IASI/Metop-B granules (21 500 granules for day-time and 21500 for night-
 190 time), containing outlier and regular spectra and chosen randomly on the first of each month between April 2013 and
 191 April 2021 is used. Note that this dataset differs from that generated for the principal component calculation as the
 192 detection method is applied on a granule basis. From this dataset, 21500 GMI and 21500 GMA pseudo-residuals are
 193 calculated for both day- and night-time conditions.

194 Figure 3 shows the statistical distribution of the largest minimum and maximum values for each of the 43000
 195 GMI/GMA pseudo-residuals for all channels. The lower and upper limit of the blue box represents the 25th percentile
 196 and the 75th percentile in the data, respectively. The red line represents the median. The black lines represent upper
 197 adjacent value (UAV) and lower adjacent value (LAV), and the red crosses have been considered as “outliers” in a
 198 first analysis of the dataset. Using UAV and LAV as thresholds was observed to be too restrictive. After several tests,
 199 it has been decided to use the 25th percentile of the data to keep granules associated with potential outliers (F₁
 200 threshold). All granules associated with GMA or GMI minimum and maximum values (in absolute values) larger than
 201 the 25th percentile of the datasets are then selected, avoiding to process granules without interesting anomalies.

202 A second threshold (F₂ threshold) was defined for each spectral channel based on the 99th percentile value of the GMI
 203 and GMA pseudo-residuals calculated from the 43000 granules (21500 for day-time conditions and 21500 for night-
 204 time conditions). This F₂ threshold is used in the processing of each granule selected after applying the F₁ threshold.
 205 It is applied only on channels of interest associated with a strong absorption of a molecule, which are identified in

206 Table 1. For those channels, all IFOV-residuals associated with values larger than the F_2 threshold values are selected.
 207 The choice of the 99th percentile as the threshold value is the result of extensive tests performed both on the ensemble
 208 of statistically representative scenes (the 43000 granules) and on specific atmospheric situations of fires and volcanoes.
 209 It corresponds to the empirical compromise allowing 1) a reasonable rate of detection of extreme events (below 4%)
 210 for the processed scenes, 2) the minimization of false positive detections in the statistically representative scenes (false
 211 positive detections are empirically identified as spatially noisy i.e. isolated IFOVs) and 3) the unambiguous detection
 212 of well-identified fire and volcanic events. Values of the F_2 thresholds used for the channels of interest are provided in
 213 Table 1. In the detection processing, for each selected IFOV-residual the spectral channel associated with the detection
 214 (and thus the corresponding spectral interval and associated molecule as defined in Table 1) is recorded, along with
 215 the corresponding IFOV-residual value, the latitude and the longitude. This step allows to localize (IFOV latitude and
 216 longitude) and characterize (spectral position and corresponding IFOV-residual value) the outliers.

217
 218 **Figure 3: Distribution of normalized GMI and GMA extrema in absolute values calculated from 43000 granules (21500 for**
 219 **day time conditions and 21500 for night time conditions). The lower and upper limit of the blue box represents the 25th**
 220 **percentile and the 75th percentile in the data. The red line represents the median. The black lines represent the upper**
 221 **adjacent values (UAV) and lower adjacent value (LAV), and the red crosses are considered as “outliers” in the dataset. The**
 222 **magenta dashed line represents the F_1 threshold.**

223
 224
 225
 226

227 **Table 1: Signal intensity thresholds (F_2) for several species for day- and night-time conditions obtained from the 99th**
 228 **percentile of the GMA or GMI pseudo-residuals. The thresholds are defined based on the more intense peaks associated**
 229 **with each molecule. Since IASI-PCA sensitivity is generally lower during night-time than during day-time, which is mainly**
 230 **due to thermal contrast, different thresholds for day and night conditions were defined.**

Molecule	Spectral range (cm^{-1})	Peak position (cm^{-1})	GMI day	GMI day	GMI night	GMA day	GMA night
HCN	711.50 - 713.50	712.50	-4.42	-4.42	-4.41	4.10	4.06
C ₂ H ₂	729.25 - 730.00	729.50	-4.01	-4.01	-3.92	3.94	3.88
C ₄ H ₄ O	744.25 - 744.75	744.50	-4.13	-4.13	-4.10	3.77	3.76

231

232 4.3 Towards a detection of extreme events in near real time

233 Right after the reception of each IASI 3-minutes granule, the two GMA/GMI pseudo-residuals are calculated as well
 234 as other statistics of the residual over the granule. Then the two different thresholds defined in Section 4.2 are applied
 235 to the GMA/GMI pseudo-residuals in order to localize the pixels potentially associated with an event and the associated
 236 channels. In case of anomalies (i.e., threshold overrun) in the GMA/GMI pseudo-residuals, an alert is set-up along
 237 with the targeted channels identified. The corresponding absorbing species with their spectral range are identified in
 238 the following together with the associated peak position of the associated channel, and the spatial distribution map of
 239 the detected pixels in the 3-minute granule is produced. This allows to visualize and further study exceptional events.
 240 The IASI-PCA-GE method was validated for past and documented events, four of which are described hereafter. It is
 241 now running continuously, delivering email alerts on a routine basis using the near real time IASI LIC radiance data.
 242 Most of these alerts are associated with fires and volcanic eruptions.

243 **5 Case studies**

244 This section presents a demonstration of the IASI-PCA-GE method for several past extreme events. The method is
 245 applied to IASI/Metop-A and the IASI/Metop-B LIC radiance data. Table 2 gives a brief description of the case studies
 246 presented hereafter.

247 **Table 2: Brief description of the four case studies analyzed in this section.**

Type	Location	Date	AM/PM orbit	Instrument	Observed molecules
Volcanic Eruption	Ubinas/ Peru	20/07/2019	AM	IASI- B	SO ₂ , HNO ₃
Fires	Australia	01/01/2020	AM	IASI-B	HCN, C ₂ H ₂ , C ₂ H ₄ , HCOOH, CO, NH ₃ , C ₄ H ₄ O, CH ₃ OH
Anthropogenic pollution	China	13/01/2013	PM	IASI-A	NH ₃ , SO ₂ , CO
Industrial accident	Iraq	24/10/2016	PM	IASI-B	SO ₂ , HNO ₃

248
 249 For each event, we identify the molecules in the outliers through analysis of the residual statistic, in order to assign the
 250 spectroscopic feature characteristic of the corresponding species, over a granule and applying the IASI-PCA-GE
 251 method. We also provide distribution maps to illustrate the spatial distribution of the target event. When available, the
 252 maps are compared to the existing retrieved IASI products (CO: Hurtmans et al., 2012; NH₃: Van Damme et al., 2021;
 253 CH₃OH and HCOOH: Franco et al., 2018; C₂H₄: Franco et al., 2022; C₂H₂: as yet unpublished; HCN: Rosanka et al.,
 254 2021; SO₂: Clarisse et al., 2012).

255 **5.1 Volcanic eruption events**

256 Volcanic eruptions have a major impact on atmospheric composition. SO₂, which has several strong absorption bands
 257 in the TIR spectral range, is the most common molecule observed in the volcanic plume (Clarisse et al., 2012). Several
 258 other species were previously observed by satellites in volcanic eruptions such as hydrochloric acid (HCl) (Clarisse et
 259 al., 2020), hydrogen sulfide (H₂S) (Clarisse et al., 2011) and sulfuric acid (H₂SO₄) (Ackerman et al., 1994; Karagulian
 260 et al., 2010), which can be injected in the stratosphere in case of high-altitude eruption (Rose et al., 2006; Millard et
 261 al., 2006).

262 **5.1.1 The Ubinas (Peru) case study**

263 The IASI-PCA-GE method was applied to several volcanic eruptions. Here, we illustrate the findings for the eruption
 264 in Ubinas, Peru on 20 July 2019 (Venzke et al., 2019). Instituto Geofísico del Perú (IGP) mentioned that seismic
 265 activity suddenly increased during June 2019 and remained high during July 2019 with important ash emissions
 266 causing the evacuation of the population in some areas affected by ashfall. Figure 4 illustrates the normalized GMI
 267 pseudo-residual obtained during this volcanic eruption corresponding to a granule taken in the area of the plume during
 268 daytime. A large difference between the reconstructed spectra and raw spectra is seen in the SO₂ v₃ band around ~1371

269 cm^{-1} and $\sim 1377 \text{ cm}^{-1}$ which is in agreement with results of Clarisse et al. (2008, 2012) showing the sensitivity of the ν_3
 270 band. Indeed, the peak found at 1371.50 cm^{-1} is associated with the presence of SO_2 plume in the upper
 271 troposphere/lower stratosphere ($\sim 14 \text{ km}$, 150 hPa) between 0.5 DU and 200 DU (saturation) (Clarisse et al., 2011).
 272 Such detection is expected in this case due to the high quantity of SO_2 emitted. It is worth noting that other peaks in
 273 the GMI pseudo-residual also show strong absorptions, which were initially associated with HNO_3 . Even if this
 274 constituent has previously been reported in volcanic plumes in some active degassing volcanoes (Mather et al., 2004),
 275 peaking in the GMI at $\sim 763 \text{ cm}^{-1}$, $\sim 879 \text{ cm}^{-1}$ and $\sim 897 \text{ cm}^{-1}$, and $\sim 1326 \text{ cm}^{-1}$ associated with ν_8 , ν_5 , $2\nu_9$, ν_3 and ν_2 nitric
 276 acid absorption bands, respectively, it has never been observed by remote sensing before. As the analysis of the IASI
 277 HNO_3 L2 products shows no HNO_3 enhancement, further investigations were performed to identify where the signature
 278 comes from.

279
 280 **Figure 4: Top: Example of GMI pseudo-residual calculated from IASI/Metop-B LIC data during a volcanic eruption in**
 281 **Ubina, Peru on 20 July 2019 in the morning (AM orbit). Bottom: HITRAN spectroscopic parameters associated with the**
 282 **absorption of HNO_3 and SO_2 are shown in blue and in orange, respectively.**

283 The HNO_3 detection by the IASI-PCA-GE method was further investigated by applying the whitening method
 284 proposed by De Longueville et al. (2021). The use of a covariance matrix, calculated from a set of IASI spectra shows
 285 similar results as those found with the IASI- IASI-PCA-GE method. However, using a covariance matrix excluding
 286 the SO_2 absorption band, no HNO_3 spectral feature was found. This suggests that no nitric acid is present in the plume.
 287 The features found in the HNO_3 absorption band by the IASI-PCA-GE method is likely related to SO_2 features given
 288 that the SO_2 ν_3 absorption band superimposes with the HNO_3 ν_3 band.

289 Furthermore, other spectral signatures remain difficult to characterize in the 1200 – 1300 cm⁻¹ spectral domain. This
290 spectral range corresponds to the absorption of different volcanic compounds such as ash, aerosols and other possible
291 volcanic molecules such as H₂S or H₂SO₄ (Karagulian et al., 2010) but is also sensible to strong H₂O absorptions.

292 After applying the threshold filters defined in Section 4.2 to the GMI pseudo-residual, the spatial distribution of the
293 pixels associated with outliers can be mapped. Figure 5 shows a plume of SO₂ (left) in Southeast America, with large
294 signal intensity values reaching around -150 in the center of the plume. The spatial distribution of the retrieved IASI
295 SO₂ L2 operational products (right) also shows the plume located in Southeast America and is in excellent agreement
296 with the SO₂ plume detected from the IASI-PCA-GE method.

297
298 **Figure 5: Left: Spatial distribution of the residual values associated with SO₂ IASI-PCA-GE detections, using IASI/Metop-**

300 **Units.**

301 5.1.2 Volcanic eruption archive for IASI/Metop-B

302 The time series of the SO₂ detections derived from the IASI-PCA-GE method is applied to IASI/Metop-B global
303 dataset over the 2013-2022 period. Figure 6 shows the comparison of the SO₂ IASI-PCA-GE signal intensity with the
304 SO₂ hyperspectral range indexes (HRI) product at 5 km (Bauduin et al., 2016). HRIs at 5 km are chosen because of a
305 good sensitivity around this altitude (Clarisse et al., 2014) compared to L2 SO₂ concentration data that are showing
306 concentration above 5 km (likely the high intensity volcanism). Only daily SO₂ extrema of both the IASI-PCA-GE
307 method and HRI product are compared. They are spatially co-located and associated with documented volcanic events
308 from the Global Volcanism Program, Smithsonian Institution (<https://volcano.si.edu/>). It is observed that both methods
309 are able to detect not only intense eruptions but also moderate or degassing volcanic events. The largest volcanic
310 eruptions detected during this period for both methods are Calbuco on 22 April 2015, Raikoke on 22 June 2019 and
311 Ubinas on 19 July 2019 (Sennert, 2015, 2019, 2019b). Furthermore, for all major events (corresponding to 2810 days
312 over 3373 days in total), an excellent correlation between HRI and IASI-PCA-GE signal intensity ($R^2 = 0.96$) is found
313 between the two datasets.

314
 315 **Figure 6: Time series of SO₂ detections from IASI-PCA-GE method (grey) and the SO₂ HRI at 5 km (orange) based on the**
 316 **IASI/Metop-B LIC data for the 2013-2022 period. Only the daily extrema are shown in the time series.**

317 In order to analyze and understand the differences between the two records, the correlation between the latitudes of
 318 both datasets shown in Fig. 6 are plotted (see Figure 7). An excellent location correlation between both HRI and IASI-
 319 PCA-GE methods is observed for high intensity detections. However, some discrepancies are found in case of low
 320 intensity events, corresponding to commonly active degassing volcanoes.

321 Some specific latitudes associated with degassing volcanoes such as Sabancaya (Moussallam et al., 2017), the Vanuatu
 322 island arc with Ambae (Ani et al., 2012), Colima and Popocatepetl in Mexico (Varley et al., 2003) and the long eruptive
 323 Kilauea volcano (Garcia et al., 2021) respectively at 15.8° S, 15.4° S, 19.5° N, 19.0° N and 19.4° N are illustrated by
 324 the black horizontal and vertical dashed lines in Fig. 7. Furthermore, some daily maxima are located around 38° S,
 325 37.5° N at 25.2° N and are respectively related to emissions from Copahue (Reath et al., 2019), Etna (Tamburello et
 326 al., 2013 ; Ganci et al., 2012) and several Chilean volcanoes.

327 The daily maxima located around 56° N have been investigated and found to be associated with Kamchatka degassing
 328 volcanoes. Disperse latitudes of IASI-PCA-GE daily maxima are not consistent with the co-registered HRI maxima.
 329 These differences between the IASI-PCA-GE and HRI methods can also be explained by the relation between plume
 330 altitude/temperature not represented in the principal components that will also affect the spectral reconstruction. As a
 331 result the location of daily maxima can be different in case of low intensity detections because of the PCA
 332 overestimation (or underestimation) of atmospheric anomalies. This also results from the non-linear relationship
 333 between retrieved concentrations and PCA intensities.

334 It is interesting to note that both IASI-PCA-GE and HRI detections observed at around 30° N and 65° N are associated
 335 with anthropogenic emissions in the region of Sarcheshmeh Copper, one of largest industrial-mining complexes for
 336 copper that is emitting about 789.9 tons of SO₂ per day (Amirtaimoori et al., 2014) and over the Norilsk city, also well
 337 known for its mining and smelting industries (Bauduin et al., 2016). That finding illustrates the capacity of both
 338 methods to detect industrial emissions.

339
 340 **Figure 7: Comparison of latitudes corresponding to the daily maxima detected for both IASI-PCA-GE SO₂ signal intensity**
 341 **and HRI product between 2013 and 2022 with IASI-B LIC data during the day. The dashed lines show location**
 342 **discrepancies.**

343 It is found that the relation between concentration and signal intensity is not linear and the PCA-based results cannot
 344 be used for an accurate quantification of SO₂ concentrations. Indeed, IASI-PCA-GE signals will be dependent on the
 345 molecule concentration but also on thermal contrast, and other surface parameters and atmospheric conditions. This
 346 is why discrepancies are found at high latitudes between the location of IASI-PCA-GE and HRI maxima, which are
 347 associated with eruptions in the Kamchatka region.

348 5.2 Fire events

349 Fires can be a significant source of trace gases and aerosols in the atmosphere and several species were specifically
 350 looked for in fire events: CO, NH₃, formic acid (HCOOH), acetylene (C₂H₂), ethylene (C₂H₄), nitrous acid (HONO),
 351 ethane (C₂H₆), acetonitrile (CH₃CN), methanol (CH₃OH), peroxyacetyl nitrate (CH₃CO(OONO₂)), hydrogen cyanide
 352 (HCN), formaldehyde (HCHO), glyoxal (CHOCHO), and CH₄ (Li et al., 2000; Goode et al., 2000; Sharpe et al., 2004;
 353 Coheur et al., 2009; Dufлот et al., 2013; R'Honi et al., 2013; Zarzana et al., 2018, De Longueville et al., 2021). The

354 IASI-PCA-GE method was applied to several case studies, but only one is presented here, selected during the fire
355 season occurring in Australia in 2019-2020.

356 5.2.1 The Australia case study

357 In Australia, fire events known as bushfires are occurring every year. Coupled with global warming and the lack of
358 rainfall in 2019-2020, the fires were particularly intense with burned areas covering more than 186000 km². It was
359 shown that pyro-convection allowed the plume to reach the lower stratosphere around 15-16 km (Khaykin et al., 2020).
360 Many species were observed by ACE-FTS during that episode (e.g., Boone et al., 2020): CO, C₂H₆, C₂H₂, HCN,
361 HCOOH, CH₃OH, PAN, acetone (CH₃COCH₃) and CH₃CN.

362 The IASI-PCA-GE method was applied to the IASI/Metop-B L1C data on 1 January 2020. Figure 8 illustrates an
363 example of a normalized GMI pseudo-residual obtained during the Australia fire event. As expected, peaks relative to
364 the CO absorption lines are found in the 2050-2200 cm⁻¹ spectral domain. Other peaks associated with the absorption
365 of molecules are also visible: HCN with a peak at 712.50 cm⁻¹, furan (C₄H₄O) at 744.50 cm⁻¹, C₂H₂ at 729.50 cm⁻¹,
366 C₂H₄ at 949.25 cm⁻¹, HCOOH at 1105.00 cm⁻¹ and 1777.00 cm⁻¹, CH₃OH at 1033.50 cm⁻¹, as well as peaks associated
367 with NH₃ at 931.00 cm⁻¹ and 967.00 cm⁻¹.

368
369 **Figure 8: Top: Example of GMI pseudo-residual calculated from IASI/Metop-B L1C data during the intense fire event in**
370 **Australia on 1 January 2020 in the morning (AM orbit). Bottom: HITRAN spectroscopic parameter associated with the**
371 **absorption of different species are shown in colors.**

372 Figure 9 (left column) shows the spatial distribution of the residual values associated with the detected species in the
373 GMI pseudo-residual. Despite their different lifetimes, the plumes for the different species are located in the same
374 region (around 180° E in the Pacific Ocean).

375 Carbon monoxide is retrieved in near real time (George et al., 2009) from IASI L1C and is used for monitoring fires
376 (Turquety et al., 2009). In Fig. 9, CO is observed both with the IASI-PCA-GE and the L2 retrieval methods. However,

377 some discrepancies are found in terms of location and intensity. A few pixels are detected by the IASI-PCA-GE method
378 in the Southeast of Australia, which is in agreement with the CO operational L2 product. However, the retrieval method
379 is able to detect a larger plume over Australia compared to the IASI-PCA-GE method. Furthermore, a large plume is
380 also detected over the Pacific Ocean but is missed by the IASI-PCA-GE method. Note that, the high intensity CO
381 peaks are clearly detected in the residuals (c.f. Fig. 10). However, most of the missing pixels, in the PCA detection
382 results, are located above sea. That could be due to the combination between the database chosen in the PCA method
383 and the high variability in this spectral domain. Indeed, a higher thermal contrast variability is observed above land
384 (Clerbaux et al., 2009), but the database contains spectra representing the natural variability without differencing sea
385 and land pixels. As a result, the spectral reconstruction above sea with the PCA method will be less sensitive to spectral
386 variations, causing a reduced sensitivity above sea. Furthermore, the spectral region between 2050 and 2200 cm^{-1} has
387 shown a large statistical distribution of extrema signals within the 21500 granules used for threshold calculation in
388 Section 4.2 allowing to set a restrictive threshold for the outlier detection for CO. That restriction will also impact the
389 number of detected pixels. The sensitivity of PCA reconstruction outliers to strong CO concentrations in fires should
390 be more deeply investigated in further studies.

391 NH_3 is also retrieved in near real time (Van Damme et al., 2017) and observed in low concentration and occurrence
392 above Australia on the 1st of January 2020 in the L2 retrievals and in low signal and occurrence in the IASI-PCA-GE
393 method. Some pixels are detected by the IASI-PCA-GE method but are not spatially correlated with the NH_3 total
394 column L2 data. A less frequent detection of NH_3 is expected since only low intensity peaks of NH_3 are found in the
395 GMI pseudo-residual but two plumes are observed above both land and sea while L2 retrievals only show many
396 isolated pixels.

397 However, for other indicators the size of the plume differs: large plumes are found for C_2H_2 , C_2H_4 and HCOOH while
398 smaller plumes are found for HCN , $\text{C}_4\text{H}_4\text{O}$ and CH_3OH . Those differences can be explained by the difference between
399 both methods. Indeed, the column maps includes the effects of radiative transfer (thermal contrast in particular), and
400 the presence of clouds can also induce differences between both products as the retrievals are highly sensitive to clouds.
401 For the IASI-PCA-GE method, the sensitivity for molecules detection highly depends on the selection of spectra to
402 construct the database and the thresholds chosen for the detection.

403
 404 **Figure 9:** Left: Spatial distribution of the residual values associated with CO, NH₃, HCN, C₂H₂, C₂H₄, CH₃OH, HCOOH
 405 and C₄H₄O detections from IASI/Metop-B L1C data during the intense fire event in Australia on 1 January 2020 in the
 406 morning (AM orbit); right: same as left for the total column L2 data. There is no map of C₄H₄O total column L2 data
 407 because there is no retrieval available.

408 **5.2.2 Fire archive for IASI/Metop-B**

409 Figure 10 illustrates the time series of the ethylene detections from IASI-PCA-GE method based on the IASI/Metop-
 410 B L1C data for the 2013-2022 period. C₂H₄ is a weak absorber often detected at 949.25 cm⁻¹ in case of high intensity
 411 fires and is able to show many high intensity peaks attributed to fire events. In the figure, the most intense fires are

412 characterized by their location (name indicated in black in Fig. 10). The presence of fires was validated by comparing
 413 C₂H₄ detection to the IASI L2 CO that is shown to be a good fire tracker (Logan et al., 1981). The seasonality of fires
 414 clearly appears during summer in the northern hemisphere mainly related to fires in Canada, Russia and Siberia and
 415 during summer in the southern hemisphere with annual Australian and Indonesian fires. One of the largest detections
 416 of the 2013-2022 period is associated with the 2019-2020 Australian bushfires discussed in section 5.2.1. Note that the
 417 highest C₂H₄ intensity, observed on 29 July 2021 with a signal of 56, could not be associated with biomass burning as
 418 no other indicators are present in the PCA-residuals. The source of this C₂H₄ enhancement is likely linked to
 419 anthropogenic activities, as well as some other maxima, all located in Iran near the Iraq border. This will be further
 420 discussed in chapter 5.3.3.

421
 422 **Figure 10: Time series of C₂H₄ detections from IASI-PCA-GE method based on the IASI/Metop-B L1C data for the 2013-**
 423 **2022 period. Only the daily extrema are shown in the time series. For clarity, the time series are separated into 2 periods:**
 424 **2013-2017 (top panel) and 2018-2022 (bottom panel). Some events (blue dots) are associated with sporadic industrial**
 425 **releases.**

426 5.3 Anthropogenic pollution events

427 5.3.1 High pollution in China

428 Boynard et al. (2014) investigated a severe pollution episode occurring in the North China Plain in January 2013. The
 429 episode was caused by the presence of anthropogenic emissions combined with low wind speed and low altitude
 430 boundary layer, leading to weak mixing and dispersion of pollutants. The ability of IASI to detect high concentrations
 431 of trace gases such as CO, SO₂, NH₃ as well as ammonium sulfate aerosol ((NH₄)₂SO₄) during night-time was
 432 demonstrated in case of large negative thermal contrast related to the winter season and the coal burning in China for

433 domestic heating. The IASI-PCA-GE method was applied on 13 January 2013 during night-time. The normalized
 434 GMA pseudo-residual obtained during the China anthropogenic pollution is illustrated in Fig. 11. In order to optimize
 435 the sensitivity of the method for a low intensity event, the F_2 thresholds were defined as $F_2 = 5$ for both day and night-
 436 time condition for the three species of interest (CO, NH₃ and SO₂). We clearly see a signal associated with CO, NH₃,
 437 and SO₂ spectral emission, with the largest signal for SO₂ (value reaching ~18). The detection of SO₂ around ~1345
 438 cm⁻¹ is less frequent compared to similar detection of SO₂ during volcanic eruptions. This result suggests that the SO₂
 439 absorption features around ~1345 cm⁻¹ also allows the detection of SO₂ during anthropogenic pollution episodes, which
 440 is in agreement with the finding of Bauduin et al. (2014, 2016). Finally, the spectral features around 1180-1200 cm⁻¹
 441 showing a low signal intensity are likely due to the IASI detector band 1 – band 2 inter-band domain that is well
 442 captured in the IASI-PCA-GE method and should not be associated to an anomalous atmospheric constituent.

443
 444 **Figure 11: Top: Example of GMA pseudo-residual calculated from IASI/Metop-A L1C data during an anthropogenic**
 445 **pollution event occurring in China on 13 January 2013 in the evening (PM orbit). Bottom: HITRAN spectroscopic**
 446 **parameter associated with the absorption of different species are shown in colors.**

447 The spatial distribution of the residual values associated with the detected species in the GMA pseudo-residual (see
 448 Fig. 11) is presented in Fig. 12 (left). The IASI-PCA-GE method allows the spectral detection of NH₃, SO₂, and CO.
 449 However only a few pixels are detected for NH₃, which is due to the very low (<5) signal intensity found for that
 450 species. We see the same behavior for CO. However, a clear SO₂ plume characterized by a signal reaching ~18 (at
 451 1345.00 cm⁻¹ - see Fig. 11) is found by the IASI-PCA-GE method.

452 Figure 12 (right) illustrates the spatial distribution of NH₃ and CO total column and SO₂ plume altitude L2 data
 453 retrieved from the IASI/Metop-A L1C data (Clarisse et al., 2012). The retrieval and IASI-PCA-GE methods shows

454 different patterns. We clearly see two plumes for SO₂ plume altitude and CO concentrations, but only few pixels of
455 detection are found for NH₃.

456
457 **Figure 12: Analysis of intense fire event in China on 13 January 2013 in the evening (PM orbit) based on IASI/Metop-A**
458 **L1C data. Left plots: spatial distribution of residual values associated with SO₂, CO and NH₃. Right plot: SO₂ plume altitude**
459 **retrievals (km), and CO and NH₃ total column retrievals (molec.cm⁻²).**

460 5.3.2 SO₂ released by a sulfur plant

461 During the period extending from 20 October to 27 October 2016, a sulfur mine burnt in d'Al-Mishraq near Mosul,
462 Iraq. This fire on the sulfur plant, which was set by Islamic state, caused a large emission of SO₂ and other sulfured
463 species in the atmosphere, which was observed from several satellite instruments (Björnham et al., 2017). Similar plant
464 fires occurred in June 2003 during four weeks with approximately 600 kt of SO₂ emitted (Carn et al., 2004). This was
465 a major health hazard (Baird et al., 2012). Nearly thousand people were intoxicated due to toxic fire plumes, and two
466 Iraqis died.

467 Figure 13 illustrates the normalized GMI pseudo-residual obtained during the Iraq industrial disaster on 24 October
468 2016 PM. The GMI pseudo-residual is characterized by an absorption peak at ~1326.00 cm⁻¹ that could be assigned to
469 HNO₃ and two absorption peaks associated with SO₂ at 1345.00 cm⁻¹ and 1371.00 cm⁻¹. The signal intensity is about -
470 14 for SO₂ which suggests that the event is of low to medium intensity. However, the SO₂ peaks found around ~1371
471 cm⁻¹ and ~1377 cm⁻¹ are mostly seen in case of intense volcanic eruptions, suggesting that the SO₂ concentrations are

472 larger than concentrations found above most of degassing volcanoes. This suggestion for an industrial origin is well
473 supported by Fig. 14 showing SO₂ total columns up to 5 DU.

474 The detection at ~1326 cm⁻¹ is not associated to HNO₃ and is due to the contribution of SO₂ and aerosols, as already
475 discussed in the case of Ubinas eruption (see section 5.1.1).

476
477 **Figure 13: Top: Example of GMI pseudo-residual calculated from IASI/Metop-B LIC data during a sulfur plant fire event**
478 **occurring in Iraq on 24 October 2016 in the evening (PM orbit). Bottom: HITRAN spectroscopic parameter associated with**
479 **the absorption of different species are shown in colors.**

480 The spatial distribution of the residual values associated with SO₂ detections is illustrated in Fig. 15. The IASI-PCA-
481 GE method allows the spectral detection of this molecule in the region of interest four days after the fire started showing
482 the transport of the plume on the east part of the country. Less pixels are detected by the IASI-PCA-GE method than
483 by the L2 retrieval method. This can be explained by the fact that SO₂ thresholds associated with the IASI-PCA-GE
484 method were empirically chosen to minimize false positive detections, and thus the detections of low intensity residuals
485 can be missed.

486

487 **Figure 14: Analysis of sulfur plant fire event in Iraq on 24 October 2016 in the evening (PM orbit) based on IASI/Metop-A**
488 **L1C data. Left plot: spatial distribution of residual values associated with SO₂. Right plot: SO₂ total column in Dobson Unit.**

489 5.3.3 C₂H₄ sporadic emission at the border of Iran/Iraq

490 In Section 5.2.2 we reported that the IASI-PCA-GE method is well suited to detect biomass burning by using the C₂H₄
491 indicator, found in conjunction with other signatures of molecules usually associated with fire activity. Among the
492 events that we detected, on a few occasions, we found intense signatures in the Iran/Iraq region with no other absorption
493 than C₂H₄, which suggests that sources other than biomass burning – likely due to anthropogenic activities – are at
494 play. The main event occurred in July 2021 and some other weaker ones are also identified in Fig. 10. By averaging
495 IASI data over time and using a super-sampling technique, Franco et al. (2022) uncovered and identified over 300
496 worldwide emitters of C₂H₄, emanating from petrochemical clusters, steel plants, coal-related industries, and
497 megacities. However, no C₂H₄ point source was formally identified in this Iran/Iraq region. But the method described
498 in this paper is well suited to also detect sporadic events, which contrasts with the continuous emissions identified by
499 Franco et al. (2022). Indeed, oversampling methods are well suited for the detection of regular, even weak,
500 anthropogenic sources, but typically miss transient sources lasting for less than 24 hours. A new analysis was therefore
501 performed on the events spotted by the IASI-PCA-GE method, which led to the identification of plumes lasting for
502 only a few hours (see Fig. 15), for specific days as identified on Fig. 10. Although visible satellite imagery and
503 independent online information indicate the presence of oil and gas activities in that area, no firm identification was
504 possible, and further investigation is needed to identify the potential sources of these sporadic emissions.

505
506 **Figure 15: Analysis of acetylene sporadic emission event in Iraq on 29 July 2021 based on IASI/Metop-A L1C data. Left**

508 **of residual values associated with C₂H₄ during the evening orbit.**

509 6 Conclusions and perspectives

510 This paper presents an innovative approach, based on a PCA method applied on the IASI radiance spectra, allowing
511 the detection and characterization of exceptional events in near real time. This new method, the IASI-PCA granule
512 extrema (GE) method, consists in focusing on extrema calculated within a given geographical region. A statistical
513 selection is made focusing on anomalous variability in IASI channels (detection of outliers) in order to identify the
514 contribution of specific molecules from different types of events. The method is applied to the standard three-minute
515 granules of IASI observations allowing the near real time detection of a series of short-lived trace gases.

516 Using a dataset representing the full range of atmospheric conditions, we show that the PCA method is well suited to
517 efficiently detect outliers. The analysis of the outliers allows the identification of spectral features exceeding the natural
518 variability of several absorbing species especially for weak absorbers, emitted during fires, volcanic, anthropogenic
519 pollution, or industrial disaster. The method is more robust than previous retrieval methods when the spectra are cloud-
520 contaminated.

521 The analysis of several case studies shows a good sensitivity of the IASI-PCA-GE method, which is able to detect
522 weak absorbers such as SO₂, HCN, C₂H₂, C₂H₄, CH₃OH, C₄H₄O and NH₃. We also showed that the method is well
523 suited to detect transient events that last only a few hours/days.

524 Our work shows that within a granule the negative part of residuals (GMI) contains more information than the positive
525 part represented by the GMA. However, the latter contains relevant information in case of negative thermal contrasts,
526 allowing the detection of specific events such as the recurrent anthropogenic pollution events occurring in China in
527 winter.

528 The IASI-PCA-GE method is better suited to detect spuriously emitted species. In this study, only species associated
529 with narrow (as Q branches of C₂H₂ and C₂H₄) spectral features have been considered. Species such as PAN,
530 CH₃COOH and CH₃COCH₃ characterized by broadband absorption features are more difficult to detect with the IASI-
531 PCA-GE method. Also, inconclusive results were obtained for CO because its variability is already well captured by
532 a truncated reconstruction due to the high variability of this species, from background conditions (50 ppb) to highly
533 polluted areas (4000 ppb). Finally, as explained above concerning SO₂ and HNO₃, the spectral coincidence of some of
534 the intense spectral features of these two species can affect the reconstruction of one when the other one is highly
535 present. In the frame of this study, this is the only identified example of confounding situations (i.e., unusual
536 perturbation in a limited number of channels impacts the reconstruction residual in other channels) leading to false
537 detection. Considering the high numbers and diversity of detections and extreme situations analyzed in this work, such
538 confounding situations are rare and PCA-based detection of atmospheric events can be effectively and efficiently
539 exploited.

540 Overall, this paper shows the capacity of PCA detection to identify different species from an event to another,
541 especially in case of fire events, which suggest the possibility to categorize fire events based on judicious combinations
542 of species. The method also proves useful to derive consistent long-term records for fire and volcanic events, and data
543 will continue to accumulate over time as the method is now routinely implemented. Further work is still needed to
544 avoid false detections, such as those associated with HNO₃ which are due to the correlation between different

545 absorption bands for the same molecule, one of them likely interfering with SO₂ present in the volcanic or industrial
546 plumes.

547 A first version of this method is currently running continuously, delivering email alerts on a routine basis using the
548 near real time IASI L1C radiance data. Although the method is still being tested, it is planned to be used as an online
549 tool for the early and systematic detection of extreme events.

550 **Data availability statement**

551 IASI L2 SO₂, NH₃ and CO data can be downloaded from the AERIS portal <https://iasi.aeris-data.fr/SO2/>
552 (<https://doi.org/10.25326/42>); <https://iasi.aeris-data.fr/nh3/> (<https://doi.org/10.25326/10>); <https://iasi.aeris-data.fr/CO/>
553 (<https://doi.org/10.25326/64>). The VOC retrievals are processed by Franco Bruno (bruno.franco@ulb.be) and Lieven
554 Clarisse (lieven.clarisse@ulb.be) at ULB, and available upon request.

555 **Competing interests**

556 The authors declare that they have no conflict of interest.
