Abstract

Distributed Acoustic Sensing (DAS) is an emerging technology for acquiring seismic data on very dense arrays of fiber optic sensors densely distributed along an optical fiber. The broadband response of the sensors along with the possibility of deploying fiber optic cables in harsh conditions and the relatively moderate cost of this sensing element gives clear perspectives for DAS in geothermal wells to contribute to the monitoring of geothermal plants. However, the technical feasibility of managing the large flow of data generated by the DAS and the suitability of the strain-rate acquisitions to monitor locally induced seismicity was yet to be assessed.

We propose a monitoring concept establishing DAS as an effective component of the seismic monitoring of the Schäftlarnstraße geothermal plant (Munich, Germany). The underlying data management system links the existing on-site infrastructure, including the fiber optic cable deployed in one of the site’s injection wells and the associated DAS recorder, to a cloud Internet-of-Things (IoT) platform designed to deliver both a secure storage environment for the DAS acquisitions and optimized computing resources for their processing. The proposed solution was tested over a period of six months and showed the feasibility of efficiently acquiring and processing the large flow of continuous DAS data. For seismic risk mitigation purposes, we additionally investigate the potential of the monitoring concept to tend towards real-time monitoring. The processing outcomes, focusing especially on two detected local seismic events, demonstrates the relevance of DAS from geothermal wells for the (micro)seismic monitoring of the geothermal site. Despite the noisy operational conditions, the applied processing workflow takes advantage of the sensors’ high spatial density for data denoising and event triggering and highlights that higher detection sensitivity than conventional seismometers can be achieved. From a different perspective, further analyses of the DAS records confirm the logging capabilities of the technology, especially regarding well completion integrity.

The 6-months test period shows that permanent DAS can be integrated as a routine seismic monitoring component of geothermal plants and advantageously complement surface seismometer-based networks, especially in urban environments.
1. Introduction

Geothermal energy has been exploited with considerable success in the Greater Munich area (Germany) since the late 1990s (Agemar et al., 2014; Dussel et al., 2016). The geological conditions in southern Bavaria are particularly suitable for extracting heat from the geothermal fluid of the Upper Jurassic layers of the Molasse basin (Schulz and Jobmann, 1989; Agemar et al., 2012). A growing number of energy companies located in the north and the south of Munich benefit from the geothermal resource to supply the district heating network with renewable energy, making it an important driver of the ecological revolution of the region (e.g. Farquharson et al. (2016)). As part of this effort, SWM GmbH, the energy provider of the Munich city, wants to cover the district heating demand with CO2-neutral resources by 2040 at the latest, predominantly from geothermal energy (Cröniger et al., 2022).

The development of the geothermal energy branch in the Munich region has resulted in a significant increase in knowledge, in particular about the geological setting of the region (Böhm et al., 2013). However, the spread of deep geothermal energy exploitation still entails its challenges. Producing heat and electricity from geothermal fluids leads to changes in the stress-state prevailing in the subsurface. Recent observations and analyses showed that these perturbations can possibly induce seismicity, even in hydrothermal systems driven by a porous matrix (Kraft et al., 2009; Megies and Wassermann, 2014; Seithel et al., 2019). Therefore, seismic monitoring outcome is a key aspect in the operation of deep geothermal reservoirs. With the on-going developments in the Munich region, the extension of the existing monitoring networks and the development of innovative monitoring strategies are important elements for seismic risk mitigation. Their full integration into the plant operation could benefit to a more secure and sustainable management of the geothermal resource, especially if the seismic monitoring results can feed numerical models aiming at forecasting the thermo-hydro-mechanical response of the geothermal system to operational conditions (e.g. Gaucher et al. (2015); Grigoli et al. (2017)).

Distributed Optical Fiber Sensors (DOFS, see e.g. Hartog (2017) for an extensive review on the technology) offer attractive perspectives to support the geothermal plant operation in a variety of contexts. The operating principle behind fiber optic sensing is based on the use of an electronic system measuring spatially resolved measurements along the optical fiber to which it is connected. Scattering effects occurring along the optic fiber make it possible to acquire various physical parameters on virtual sensors distributed along the length of the fiber, such as changes in dynamic strain (Distributed Acoustic Sensing, DAS), changes in static strain (Distributed Strain Sensing, DSS) and changes in temperature (Distributed Temperature Sensing, DTS). Hence, these technologies open up new opportunities in terms of logging, imaging and monitoring. DAS, which is the focus of this article, has developed, in the last decades, as an emerging geophysics instrument and has been applied in seismic analysis with established quality and performance (see e.g. Parker et al. (2014); Lindsey et al. (2020) or Paiz et al. (2021)). In the field of borehole seismic acquisitions, applications are as varied as production control, integrity supervision, or seismic monitoring (see Johannessen et al. (2012); Parker et al. (2014); Li et al. (2015) for reviews on possible applications). DAS technology gained early acceptance in the oil and gas industry (Baldwin, 2014) and demonstrated great potential as a long and dense seismic antenna, for instance in vertical seismic profiling (VSP) applications (Madsen et al., 2012; Mateeva et al., 2012; Harris et al., 2016; Miller et al., 2016). The potential for time-lapse monitoring of reservoirs was also demonstrated, e.g. by Mateeva et al. (2014). The imaging capabilities of the distributed measurement also benefit the identification of flow and production zones. Naldrett et al. (2018) show that DAS data can be used for the analysis of ARI entry points and gain further quantitative information about the production zone terms of seismic monitoring, the technology has shown great success in capturing signals as
varied as microseismic (Lellouch et al., 2020) or teleseismic events (Ajo-Franklin et al., 2019) in a variety of contexts and settings.

In the geothermal energy community, the potential of the technology stems in particular from its versatility and ability to acquire, along boreholes, different parameters relevant for the monitoring of the geothermal system. Hence, several fiber types in one single FOC can deliver DTS, DSS and DAS measurements. Depending on the deployment design, which remains challenging for deep (hot) boreholes, this can provide information on temperature profiles, well completion integrity, in- and out-flow zones of the geothermal fluid, induced seismicity, e.g. Koelman, 2011; Koelman et al., 2012; Van Der Horst et al., 2013). For seismic monitoring, DASs at the borehole allows sensors to be positioned much closer to the reservoir than surface seismometers, thus closer to the potential seismic source. The high spatial sampling achieved with DAS along the optical fiber also gives another perspective to the seismic monitoring, by considerably densifying the set of observations. Continuous borehole DAS may significantly contribute to the seismic monitoring, as long as the FOC is properly connected to the ground and the well is not a permanent source of noise.

In order to assess the DAS (and DTS) technology, two wells of the newly developed geothermal plant at Schäftlarnstraße (SLS), south of Munich (Germany), have been equipped with FOCs (see Fig.1a). At the SLS site, the amount of DAS data to be collected with this equipment goes up to several tens of megabytes per second. The collection and processing of this data flow can be a serious challenge, particularly when secure and fast remote access to the data is required to integrate the monitoring results into the operation of the geothermal plant. Hence, appropriate data management and processing infrastructures are necessary for the DAS system to become a real-time continuous component of the geothermal system monitoring. In this paper, we demonstrate the technical feasibility of implementing a DAS-based continuous and permanent seismic monitoring in an operational environment - the SLS site. The present study is a unique case for our knowledge and constitutes a proof of concept for future implementations. The proposed concept aims at managing the different phases of the monitoring, from the acquisition to the archiving and the processing of the DAS data. It has been developed to efficiently meet the requirements in terms of data transfer rate, amount of data, level of access to data and scalability. With regards to the data processing, screening for possible local induced seismicity was implemented, allowing us to assess the capabilities of the system in terms of seismic event detection. The opportunity to test the concept was given during a six-month continuous acquisition period, from February to July 2022.

The first part of the manuscript presents the infrastructure that was implemented on the SLS site to integrate the data storage and processing modules into a cloud based IoT platform, and which interconnects the DAS recorder and Azure, the cloud application platform distributed by Microsoft. Then, we focus on the data processing and detection workflows developed on the cloud-based platform, providing insights into the recording conditions and the denoising strategies applied to enhance the signal of interest and achieve a satisfactory level of detection. The highlights of the 6-months trial period are presented in the third part of the manuscript, focussing on two local microseismic events that have been efficiently detected by the proposed monitoring system. Finally, the results of the trial period are discussed. We first concentrate on the utilization of DAS in the routine operation of the geothermal plant, considering the logging and monitoring capabilities demonstrated at the SLS site. Then, we elaborate on the potential of the proposed concept for real-time seismic monitoring of geothermal power plants. We conclude by discussing how the monitoring concept can contribute to the development of a reservoir management system aiming at continuously guiding the operator in exploiting the geothermal resource in an efficient and sustainable manner.
Figure 1: Overview of the study site. Panel a): location of the geothermal power plant in the southern part of Munich city and projection on the surface of the 6 well trajectories. Red lines denote production wells and blue lines show injection wells. The Gauss-Kruger 4 coordinate system is used for the Northing and Easting markers. Panel b): focus on the power plant. The gray polygon shows the location of the control room in which the Febus A1-R interrogator recording system has been installed on the well site. Panel c): structure of the well TH3 along its first 900 m. The FOC is deployed from surface to 700 m (TVD). The installation allows the section to be probed repeatedly, as the interrogated fiber forms a U-loop. The well is vertical in the section of interest. The column on the left shows the stratigraphy. Numbers 1 to 6 stand respectively for Quaternary, “Obere Süßwasser Molasse” (OSM), “Süßbrackwasser Molasse” (SBM), “Obere Meeresmolasse” (OMM) “Glaukonit Sande” (OMM), “Blättermergel” (OMM), “Neuhofener Schichten”. Panel d): picture of TH3 wellhead. The red rectangle highlights the entry point of the FOC in the ground. Panel e): picture of the setup in the control room. It shows the DAS recorder, the Uninterrupted Power Supply (UPS) and the peripheral devices, which are all secured in a metallic enclosure.
2. The DAS monitoring system

2.1. On-site infrastructure and data acquisition

2.1.1. Schäftlarnstraße geothermal site

Geothermal energy plays an important role in making Munich the first major German city to produce 100% of its district heating from renewable energy by 2040 (e.g. Farquharson et al. (2016); Cröniger et al. (2022)). As part of this ambition, Stadtwerke München GmbH (SWM) developed in the Munich city, at Schäftlarnstraße (SLS), one of the largest inner-city geothermal plants in order to cover the heating needs of 80,000 citizens. Hence, from the end of April 2018 to the end of May 2020, three geothermal doublets (i.e. six wells) were drilled and tested. All wells are deviated and reach the geothermal water-bearing rock layer of the Upper Jurassic period - the Malm - at about 2500 m below sea level (Schulz and Jobmann, 1989; Böhm et al., 2013). In Figure 1a, the trajectories of the production (red lines) and injection (blue lines) wells are projected on the map of the Munich city center. Figure 1b focuses on the well site. It highlights the proximity of the wellheads that are separated by about 8 m from each other. The wells start to significantly deviate from about 800 m below surface.

The technical concept of the geothermal site of Schäftlarnstraße, based on three doublets drilled from the same pad, contributes to raising the standards of deep geothermal energy exploitation in the region.

2.1.2. On-site FOC equipment

Monitoring is a key component for the operation of geothermal plants and the SLS project goes beyond the standards in this domain. Fiber optic cables have been deployed in the TH3 and TH4 wells (see Fig. 1) in order to benefit from DOFS and the possibility to turn optical fibers into a collection of sensors. A precise description of the cable settings and their implementation can be found in Schölterle et al. (2021).

The coupling of the FOC to the surrounding medium plays a crucial role in DAS technology applications. At the SLS geothermal field, two different configurations exist (Schölterle et al., 2021). The TH3 cable has been cemented behind the casing of the well, along the vertical section extending from surface to about 700 m (see Fig. 1c). The TH4 cable is deployed inside the production well, from wellhead to total depth, using a sucker rod. Cemented cables do not interfere with well operations, and generally provide tighter mechanical coupling to the surrounding, which is favorable for the acquisition of high-quality DAS data (Reinsch et al., 2013). On the contrary, Martukanova et al. (2021) report on possible disturbing signals which may be observed with free-hanging cables in geothermal wells due to poor cable-to-well coupling. While the TH4 cable can be recovered and replaced, if necessary, this is not the case for the permanent TH3 cable, whose installation must be done carefully to avoid any damage during run-in-hole and to ensure well integrity with appropriate cementing job. In the present study, we use exclusively the FOC deployed in TH3, due to the availibility of the TH4 cable at the time of the trial monitoring period.

Figure 1c focuses on the TH3 completion over the first 700 m along which the FOC was deployed. This section is considered as being vertical, since its average deviation angle calculated from the borehole trajectory is 3°. On one side, the cemented FOC faces the shallow geological layers: Quaternary, “Obere Süßwasser Molasse” (OSM), “Süßbrackwasser Molasse” (SBM) and “Obere Meeresmolasse”
(OMM) on the well side, it faces an annulus filled with fluid, a tie-back. Beyond the tie-back flows the reinjected geothermal fluid, which enters the Malm reservoir from the open-hole section of the well (between 2571 m and 3049 m TVD).

In practice, the FOC in TH3 makes a U-loop at its end that provides redundant probing of the vertical section from surface to 700 m. Figure 1d shows the entry and exit points of the FOC at the TH3 wellhead (red square). Finally, both ends of the cable are accessible in the control room next to the well pad (gray polygon in Fig. 1b).

2.1.3. DAS set-up for the test period

For the 6-months monitoring period, a Febus Optics A1-R recording system has been connected to the sensing fiber in the control room for continuous acquisition of DAS. The device is based on the phase-coherent optical time domain reflectometry (OTDR) technique. The principle consists in measuring the phase differences in the backscattered photons from neighboring positions along the fiber. This enables recording dynamic strain data, or strain-rate (SK), over short distances called gauge-lengths (GL) and at several positions along the fiber (see Juškaitis et al. (1996)) and experimental validation of the sensing technique. An extensive description of the possible DAS settings can be found in Masoudi and Newson (2016) and in Hartog et al. (2013). Figure 1e shows the installation in the SLS control room, where the recording system (or recorder) is connected to an uninterrupted power supply (UPS). The UPS ensures the delivery of a stable alternating current to the equipment and prevents short power interruptions. All devices are stored and secured in a metallic shelter.

Considering the location of the DAS recorder relative to the well pad, the DAS records contain the signal acquired along the TH3 loop, but also the signal from the control room to the TH3 wellhead. Hence, the portions of cable at surface and in the upper part of the well are particularly subject to disturbances arising from human activity, such as circulation of heavy vehicles or operations on the well pad. The same applies to the DAS recorder installed in the control room. In Section III, we further discuss the impact of the recording conditions on the data.

The physical position of the virtual sensors distributed along the interrogated fiber has been identified from a tap test at the wellhead (Fig. 1d); this calibration procedure accounts for the acquisition parameters, in particular the fixed 10 m OTDR interval of the acquisitions. The spatial sampling is further improved using a 50% spatial overlap of the GL and benefiting from the redundant probing that results from the U-loop fiber. The analyzed DAS datasets feature thereby a 2.5 m spatial sampling, which corresponds to a distribution of 280 virtual sensors along the first 700 m of TH3. In the time domain, the sampling frequency is set at 500 Hz.

To ensure optimal signal quality, the velocity and frequency of the expected seismic waves should guide the selection of the acquisition parameters. Among these specifications, the GL is of particular importance and should minimize the so-called gauge length effect (e.g. Dean et al. (2017)). Insufficiently long gauge lengths degrade the signal to noise ratio, while, in case of excessive gauge lengths, the resolution of the measurements is degraded, and the shape of the observed wavelet is distorted. The focus of the proposed DAS monitoring is on the detection of microseismic events potentially induced at a local scale (i.e. in a radius of 5 km) during the operation of the plant, i.e. while the geothermal fluid circulates between the reservoirs within the reservoir. Hence, local seismicity is the monitoring focus which oriented the selection of the DAS acquisition parameters. Considering the surrounding environment of the fiber - apparent velocities from 1000 to 3000 m/s - and the targeted frequency range - between 5 and 40 Hz - we applied a fixed GL of 10 m, hence, the ratio of apparent wavelength to GL is expected to provide a reliable assessment of the actual wavelength (Dean et al., 2017), while the acquired datasets remain finely sampled in space.
2.2. Description of the cloud infrastructure

An inherent constraint of DAS is the possibly large amount of data it generates. This is particularly impactful in the context of continuous and permanent DAS. Hence, to guarantee stable and reliable acquisition of the data by the DAS recorder, it is recommended to externalize the processing using appropriate computational resources. Ensuring secure remote access to the stored data is another constraint which has to be managed in order to integrate the DAS system into the geothermal plant monitoring. These specifications motivated the development of a dedicated data archiving and processing cloud platform. With the acquisition set-up characteristics described previously, 5.04 GB large binary files are generated hourly by the recorder in the form of individual Historical Data Format 5 (HDFS) files. The DAS files are written on the solid-state drive (SSD) of the recorder, which behaves as a fast and efficient buffer. Besides, the Febus A1-R has been connected to the second component of the monitoring system, namely a cloud platform.

Figure 2: Panel a): schematic view of the monitoring system proposed to link the TH3 FOC, the Febus A1-R recorder, the developed IoT cloud platform and the users or developers of the infrastructure. Keys are means to highlight a secured connection. Panel b): focus on the conceptual structure of the IoT cloud platform developed to connect the Febus A1-R recorder to Microsoft’s cloud-based application platform, Azure. It is subdivided into two entities able to communicate through standardized data exchange. Azure Data Lake constitutes the data storage solution, which is organized into “Containers” and “Blobs”. The associated structure is comparable to the more common directory and file system. Azure compute instances (or cloud workstations) are used to process the datasets using scalable resources.

2.2.1. The Azure cloud application platform

Figure 2a illustrates the monitoring and data management system. The system links the onsite infrastructure (i.e. well pad and control room devices) to the Internet of Things (IoT) cloud platform developed to host specific archiving and processing modules. The setup ensures an efficient and secure data flow via the company’s intranet and enables a hierarchical remote connection of the users to both the recorder and the cloud platform.
The IoT cloud platform is described in more detail in Fig. 2b. It is based on Azure, Microsoft's cloud application platform, which bundles a set of public IaaS (Infrastructure as a Service) and PaaS (Platform as a Service) services. A detailed review of the available Azure services can be found in Soh et al. (2020a, 2020b). Two interconnected applications, namely Azure Data Lake Storage and Azure ML Studio, have been selected to fulfill the data archiving and processing tasks. These Azure services meet the data management system’s requirements in terms of amount of stored data, level of access and efficiency of IT processing.

2.2.2. Data storage solution

The storage of the hourly generated DAS binary files is ensured by the big data solution called Azure Data Lake Storage (left hand-side of Fig. 2b). The large and numerous files generated during the 6-months continuous monitoring are saved on a so-called data lake. This storage environment offers a scalable and hierarchical file system which is based on Azure Blob, a proprietary solution dedicated to storing objects in the cloud. The latter is optimized for storing large amounts of unstructured data, such as textual or binary data. In the following, the storage environment on the cloud-platform is named data lake.

Figure 2b also focuses on the structure of the data lakes, whose management is assigned to an Azure user account. The sketch distinguishes the three types of resources available to the user to organize a set of stored items. The data lake can be subdivided into so-called containers, which include themselves the blobs, i.e. the resources associated to individual data binary files generated by the recorder, or results from the data processing. The three previously mentioned structures (i.e. account, containers and blobs), can be respectively compared to file systems, folders and files, which are more familiar objects in IT.

An important aspect of the storage system is the access right management. Secured and delegated access to the resources is ensured by the use of Shared Access Signature (SAS) tokens. Every resource is therefore assigned a unique address making it possible to grant user-customized permissions and access rights. Another key feature of the chosen storage solution is the ability to manage the costs associated with the storage requirements. It involves organizing the saved data according to the frequency of access and the duration of storage, by assigning appropriate levels of access to the stored objects. Typically, the blobs located in the "Save" container (see Fig. 2b) are saved after processing and are granted with an access level which is optimized for storing infrequently accessed data. This tier provides lower storage costs but larger latency and delays in the data access. The same applies for the blobs of the “Result” container, which archives the objects resulting from the processing flow (see Fig. 2b). Hence, the properties of the data storage environment allowed all the produced resources to be stored seamlessly, including the entire 6-months long time series of DAS data. On the contrary, the blobs in the “Landing Zone”, i.e. the storage area containing files awaiting processing, are granted with tiers that are designed to achieve high performances in reading and exchanging data.

2.2.3. Data processing solution

The computing instances constitute with the cloud-based workstations the computational resources of the system (right hand-side of Fig. 2b) and are available from the Azure ML Studio. This cloud based solution allows developing, running and automating the launch of notebook-based scripts from an online workspace.

A key aspect of these workstations is their adaptability, which enables the user to scale the available resources according to its needs, in terms of supplied hardware (for example, number of physical and logical cores) and accessible services (linkage to desired tools and libraries). The system illustrated in
Fig. 2a has been designed to process the DAS data entering the “Landing Zone” on an hourly basis. Hence, the workstation has been scaled to sustain significant memory and CPU-to-memory loads, to enable the large DAS files to be loaded in the workstation Random Access Memory (RAM). Additionally, the workstation has been configured to use Python-based codes suitable for the seismic record processing and the underlying Obspy library (Beyreuther et al., 2010).

The workstation has also the advantage of providing direct access to the computational resources being queried. This feature avoids the queuing system typically associated with High Performance Computing (HPC) clusters.

3. Data processing workflows

The cloud-based processing of the acquired DAS data aims at providing a catalogue of possible induced seismicity with the associated waveforms. The Python scripts running on an hourly basis from the cloud-based workstations are intended to read and structure the DAS files landing in the Data Lake in the form of blobs and apply the seismological processing workflow.

3.1 Data structuring

The reading of the blobs of the “Landing Zone” is done from the computing instance using the dedicated Python client package. Secure access to the blobs storing the DAS acquisitions is ensured via the SSH keys assigned to the container. Once the strain-rate data of a given blob is loaded in the cloud workstation RAM, it is structured as a 2D dataset of one hour duration, extending spatially from the surface to a depth of 700 m TVD. Using the results of the tap-test carried out at the wellhead (see Sect. 2.1), we extract the 280 traces localized along TH3 and assign a physical location, i.e. a vertical depth, to each corresponding virtual sensor. The resulting 2D dataset, which has a spatial and temporal sampling of 2.5 m and 2.0 ms respectively, enters the seismological processing workflow (featuring data denoising and event detection) as an Obspy stream (Beyreuther et al., 2010).

3.2. Data denoising

Compared to conventional seismometers, seismic records obtained using DAS systems generally exhibit higher noise levels and stronger interferences (e.g. Correa et al. (2017); Olofsson and Martinez (2017)). The causes of these disturbances may be multiple and their impact on the records can vary along the cable. Lindsey et al. (2020) review several factors influencing the quality of the DAS data, from the recorder and sensor environment to the sensing method itself. DAS recordings have therefore been subject to various developments in denoising methods, benefiting notably from the higher spatial sampling of the acquired data and the spatial coherence of the observed wavefields.

While one-dimensional time-frequency Butterworth filters are effective to suppress noise in a frequency band of interest, the aforementioned characteristics of the DAS datasets allow the application of various 2D denoising approaches inherited from array processing and active seismics. Among those, spectral filtering in the frequency-wavenumber (f-k) domain (Duncan and Beresford, 1994) can be applied to suppress the energy associated with identified disturbances or incoherent noise, which may result in an enhancement of the signal-to-noise ratio (Isken et al., 2022).
Figure 3: Overview of different types of noise recorded in the target frequency band. For visual and illustrative reasons, the dataset is first filtered below 100 Hz. Panel a) focuses on the impact of the surface activity associated with the industrial operating site at which the acquisitions are conducted. From left to right, the filtered dataset is shown in the depth-time domain, then in the frequency-wavenumber (f-k) domain and, finally, back into the depth-time domain once filtered in the f-k domain. The f-k filtering consists in keeping the shaded areas (middle figure) and suppressing the energy related to known noise sources. Panel b) shows an example of a strong local signal related to operational activities carried out in a nearby well, in the depth-time domain.

Here, the one-hour strain-rate datasets are bandpass filtered in the 5 to 40 Hz frequency band, which corresponds to a typical frequency range for the detection of local induced seismicity (e.g. Maurer et al. (2020)). However, as noted in the Sect. 2.1, the geothermal power-plant activity strongly impacts the acquisitions in the target frequency band. Figure 3a illustrates two types of anthropogenic disturbances typically recorded along the fiber. First, the DAS recorder may vibrate in its rack which leads to the recording of high amplitude signals which are overprinted on all dataset traces. Such spiky signals are attributed to laser-noise (Zhirkov et al., 2019) and can lead to spurious detections. Secondly, surface activity occurring close to the well may generate acoustic waves propagating in the fluid within the tie-back (see Fig. 1c). These acoustic waves may eventually be transmitted to the fiber, resulting in the observation of down-going waves propagating at a velocity of about 1500 m/s. Consequently, to avoid numerous false detections, the datasets are additionally filtered in the f-k domain. Our approach consists in keeping, in the f-k domain, the energy of the waves propagating from the lowest part of the fiber towards the surface. This is justified by the fact that potential local seismic events should originate from deeper than 700 m. The middle panel of Fig. 3a shows the above described dataset in the f-k domain, highlighting the propagation of the previously identified waves: the ones propagating along the entire fiber at an infinite velocity, visible on the horizontal axis in the f-k domain, and those propagating from the surface at velocities typical of acoustic waves in fluids, leading to high energy components in the positive wavenumber - negative frequency domain or vice-versa (i.e. top-left or bottom-right quarter). One can also observe, in the f-k domain, a strong 50 Hz component, which is typical of noise induced by the alternating current of the electrical grid. Hence, the filtering consists in isolating the positive wavenumber - positive
frequency domain or vice-versa (i.e. the shaded part of the f-k domain). As shown on the left part of Fig. 3a, the proposed approach successfully removes the previously identified waves.

Additional strong noises, which impact the dataset locally, may not be filtered by the proposed processing flow, as shown in Fig. 3b. The spiky signals isolated here were recorded during the lowering of an electric submersible pump (ESP) in a nearby well. Hence, Fig. 3b illustrates how completion operations can also influence the recordings, especially as the inter-well distances remain short at the investigated depths. However, these types of local noise sources do not result in spurious detection, considering the workflow proposed for the event detection.

### 3.3. Event detection

Once properly structured and filtered, the dataset of interest enters the detection workflow, which is based on a recursive STA/LTA approach (Withers et al., 1998; Trnkoczy, 2012) implemented in the Obspy library (Beyreuther et al., 2010). The chosen detection parameters are given in Table 1:

**Table 1: Event detection parameters based on a recursive STA/LTA and a coincidence sum.**

<table>
<thead>
<tr>
<th>Trigger activation (STA/LTA ratio)</th>
<th>Trigger off (STA/LTA ratio)</th>
<th>Short-Time Average (STA)</th>
<th>Long-Time Average (LTA)</th>
<th>Coincidence sum</th>
</tr>
</thead>
<tbody>
<tr>
<td>2.3</td>
<td>1.3</td>
<td>0.3 s</td>
<td>3 s</td>
<td>30</td>
</tr>
</tbody>
</table>

The detection workflow uses the multiple distributed traces of the DAS datasets and includes the computation of a coincidence sum. This approach, which is commonly applied with large networks of sensors, consists in combining all single station triggers to identify possible time overlaps that will be interpreted as synchronous events. Hence, the coincidence sum gives the number of individual overlapping triggers (Withers et al., 1998; Trnkoczy, 2012). In our application, a detection occurs when the coincidence sum exceeds 30 traces (see Table 1). For neighbouring locations, this corresponds to simultaneous triggering over about 70 m of fiber. Nevertheless, no constraint was provided regarding the clustering of the single triggers over depth.

Once a 1-hour DAS dataset is processed, the detection report (i.e. list of triggers, including detection time, triggered traces, etc.) is appended and saved in the “Results” container together with the corresponding waveforms, i.e. six-seconds long data subsets centred on each detection and written in minised format. On average, the full processing of a one-hour long DAS file (5.04 GB) takes 11 minutes with 8 processors (2.7 GHz Intel Xeon® Platinum 8168) on the cloud workstation.

The detection results are occasionally downloaded locally for quality control and post-processing, which includes the picking of the seismic phases. The results of the post-processing of two microseismic events are presented in Sect. 4.

### 4. Monitoring results

During the survey, 4122 files have been acquired, saved and processed following the described procedure. Over the 6-months period, the DAS recorder recorded continuously except for short periods during which the GPS signal was lost. This section presents the results obtained in terms of detections and dataset characterisation.
4.1. Spectral content of the DAS records

As an initial evaluation of the collected DAS data, we analyze the frequency content using probabilistic power spectral densities (or PPSP, see e.g. McNamara (2004)). PPSP is commonly used to assess statistically the noise levels at different frequencies. To obtain noise levels representative of the day and night fluctuations, we analyze 48 hours of strain-rate data collected. At each sensor, the PPSP is computed from 192 data segments of 30 minutes. The median of each PPSP is calculated and a stack of all the resulting frequency profiles is presented in Fig. 4. The target frequency band of this analysis, 5 to 40 Hz, is delimited by dashed lines. The image shows a strong impact of anthropogenic activities at shallow depth, over the first 50 m, in this frequency domain.

![Spectral content of the DAS records at the study site. Panel a): Evolution with depth of the frequency content of strain-rate data acquired on two consecutive days. The probabilistic power spectral density (PPSP) is computed from each time-series, using 192 data segments of 30 minutes. The colour scale indicates the median PPSP at the sensor depth. The target frequency band, from 5 to 40 Hz, is bounded by the dashed lines. Panel b): Evolution with depth of the spectral energy (the integral of the PPSP) in the 5 - 40 Hz frequency range (black curve). Panel c): Same as panel b, but for the energy below 0.1 Hz (black curve). In panels b) and c), the amplitude of TH3 cement bond log (CBL) is shown over depth in red and the lithological changes are highlighted by the coloured background (see Fig. 3c) for the corresponding units). Note that the spectral energy curve and the CBL amplitude have been filtered with a moving average filter of 10 m.

This shallow influence is highlighted in the central part of the figure, which focuses on the evolution with depth of the spectral energy between 5 and 40 Hz (black curve). Below 100 m, the curve shows that the noise conditions do not significantly improve with depth anymore. The right part of the figure focuses on the lowest frequencies of the shown spectra, below 0.1 Hz. The variation in depth of the spectral energy has similar fluctuations in this low frequency range than in the target frequency band.
In both frequency bands, we highlight local fluctuations which affect the entire spectrum. The origin of these noise sources can be multiple. A specific attention is given to the topic in Sect. 5.1, especially with regard to the cement bond log (CBL) acquired in TH3 and shown in red in Fig. 4.

### 4.2. Local seismic event analysis

#### 4.2.1. Seismic event detection

During the monitoring period, several regional and a couple of local seismic events have been detected. To assess the capability of the DAS to monitor induced local seismicity, we focus in this paragraph on the two detected local seismic events. The first one, of local magnitude M, 1.5, occurred on February 2022, the 9th and has been extensively recorded by the surface seismic stations operated locally, in a radius of 10.4 km (see Azzola et al. (2021) or Azzola et al. (2022)). The second one occurred on April 2022, the 22nd. Its characteristics have not been evaluated yet. Besides the DAS measurements presented here, this second event was hardly identified by a three-component seismometer deployed in a nearby well and was not observed from the surface network. This suggests that the event has a magnitude lower than the completeness of the surface network magnitude, i.e. Mw -0.7 (Azzola et al., 2021).

Figure 5 shows the bandpass- and f-k filtered strain-rate data associated with the February (panel a) and April (panel b) events. The bandpass-filtered datasets are additionally shown in Appendix A (see Fig. A1) to emphasize the effect of the denoising strategy in the f-k domain on the spatial coherence of the strain-rate acquisitions. The left panels of Fig. 5 give an overview of the multiple arrivals that can be identified in the DAS records. The middle and right panels focus on the first P- and the first S-waves, respectively. Both wave types are clearly discriminated from their apparent velocities along the fiber, which are larger for the P-wave than for the S-wave. Interestingly, one can also observe that the S-wave maximum amplitude is larger than for the observed P-wave. The figure also highlights the distinctive characteristics of both events. In Figure 5a, i.e. for the February event, successive scattered P- and S-waves can be observed in the 3-second data-window, and the first S-wave is dominant at a frequency of 8 Hz, lower than the P-wave frequency, around 25 Hz. The higher frequency content of the April event captured in Fig. 5b), the lower delay between the P- and S- waves, and the lack of multiple scattered waves are characteristics of a nearby event.

In addition, multiple phases with different polarizations, including the first P- and S-waves, have been clearly recorded for both events (Fig. 5). This shows that the insensitivity of the TH3 fiber to horizontally polarized waves is not a major constraint to properly identify onset times of local events.
Figure 5: Strain-rate of the local February (panel a) and April (panel b) seismic events detected on the entire interrogated fiber. The left panels show the multiple arrivals including the first P- and S-waves. The middle and right panels focus on the first P- and first S-arrivals, respectively. The plain curves show the results of the semi-automatic first arrival picking approach. Panel a): the February event is located about 10 km away from the SLS geothermal site and has a magnitude of $M_s$ 1.5. The horizontal axis indicates seconds after 2022.02.09 05:51:30.7 (UTC). Panel b): April event. The horizontal axis shows seconds after 2022.04.22 13:26:11.8 (UTC).

4.2.2. Onset-time picking

For both local events, we display in Fig. 5 the evolution with depth of the P- and S- waves arrival times (see continuous black curves). The onset times have been obtained using a semi-automated picking procedure applied – for the time-being – outside the cloud. The reason for the non-automation of the procedure is the necessary ad-hoc definition of a picking guide function supported by three user-defined picks. The procedure follows standards applied in active borehole or surface seismic processing. For each analyzed time-series, it consists in finding the break time (zero-crossing) in a search window defined around the guide function.
Figure 5 shows that the first P-wave arrivals have been consistently identified over the entire fiber for both events. Nevertheless, although the automatic picking for the S-wave is correct along most of the fiber, this is not true for the shallowest, nor the deepest part of the fiber. For the first 100 m (respectively 200 m) associated with the April (February) event, the origin is likely the larger background noise evidenced at these depths, which is not totally discarded by the applied filtering. For the February event, the strongest, the interference between the S-wave and the multiple P-waves comes in addition to the effect of the surface activity.

The automatic picking technique was applied trace by trace and was not exploiting the array properties of the DAS, in particular the signal coherency recorded along the fiber. This characteristic, which is well-known and used in VSP-processing, offers perspective to improve the seismic event processing sequence.

4.2.3. Preliminary event and site characterization

A precise location and characterization of both local events from the DAS data will be the focus of future work. However, for preliminary characterization, Wadati diagrams (Wadati and Oki, 1933) have been computed using the most consistent part of the P- and S-arrival times. The corresponding Wadati diagrams are presented in Appendix B (Fig. B1). Approaches based on Wadati diagrams have their limitations, especially as the isotropy and homogeneity of the propagation medium may be an irrelevant hypothesis depending on the location of the events with respect to the sensors. However, the diagram can provide a first estimate of the April 22 origin time, which compensates for the lack of additional seismic observations. Hence, the estimated origin time is 2022-04-22 13:26:11.77 (UTC). When accounting for the period of the analyzed phases, an error of 0.02 s can be attributed to the estimate. Furthermore, the vertical antenna formed by the DAS allows partial localization of the event, using the travel distances computed along the fiber from the aforementioned origin time. Considering an average P-wave velocity of 3000 m/s leads to an origin at a depth of 1700 m TVD (1180 m under mean sea level) with a horizontal offset of 500 m from the DAS antenna. Hence, this April event likely has its origin in the Tertiary sedimentary cover, rather than in the geothermal reservoir (Malm-Jurassic formation).

The Wadati diagram is also used to analyze changes in the apparent P- to S-wave velocity ratio (VP/VS) along the fiber. The diagram highlights two distinct trends, with an inflection point at approximately 500 m, at the end of the so-called “Obere Süßwasser Molasse” formation (OSM). The observed apparent VP/VS ratios are of 2.5 and 2.2 respectively for the superficial and the deeper parts.

For both events, the vertical profile of the P- and S-wave arrival times can also be used to characterize the variations along the FOC of the apparent velocity of the identified seismic phases. The result is illustrated in Fig. 6. Each apparent velocity profile is computed by filtering the associated arrival time profile and by applying a moving average filter of 100 m and 15° for the P- and S-waves respectively. The profiles obtained for both events are consistent in terms of spatial location of the local minima and maxima, for both P- and S-waves. These apparent velocity variations may be positioned along the lithological column, as displayed in the figure as different shades of yellow. All profiles highlight strong variations, notably inside the thick OSM formation, which is mainly composed of clay marl, sand and gravel layers. The apparent velocity changes observed may indicate variations of the geomechanical properties, and outline the layered structure of the formation, at a local scale.

In terms of absolute amplitudes, the profiles calculated for the S-waves show a difference of 200 m/s at their maximum, which is reached at the interface between the layers “3” and “4”. However, the absolute velocity estimates observed for both events should be compared carefully, considering that Fig. 6 focuses on apparent velocities measured along the vertical FOC. The February event originates from the Malm reservoir several kilometres away from TH3 while the April event occurred much closer
and shallower. Considering the location of both events, the P- and S-waves will intersect the FOC with distinct incidence angles, which subsequently impacts the amplitude of the analyzed velocity component.

Figure 6: P- and S-wave arrival times (left panels, black curve) and slopes (right panels, red curve) for the February (Event 1, top) and the April (Event 2, bottom) events. A moving average filter whose period corresponds to the local wavelength is applied on the raw slope profile before plotting. The background colour shows the lithological changes and the numbers of the top-left panel refer to the column presented in Fig. 1c). For each event, the right hand side panel shows the VP/VS ratios computed from the slope profiles.

For both events, VP/VS ratio profiles have been computed from the derived velocities. The computed ratios show local variations within the investigated depths and a decrease of the ratio is observed for both events around 500 m. The absolute values and the location of the apparent decrease in VP/VS are consistent with the Wadati diagram computed from the February record. In addition, the strong variations observed below 700 m (TVD) and the VP/VS ratio measurements are consistent with analysis at the study site (e.g. Wawrzinek et al. (2021)).
5. Discussion

At the light of the results of the 6-month continuous monitoring period, we now evaluate the usability of DAS in the routine operation of the geothermal plant.

5.1. Logging and monitoring capabilities of DAS along well

While the logging capabilities of DTS and DSS have been applied since decades ( Förster et al., 1997; Hurtig et al., 1994), previous studies have shown that DAS can also provide insight into the well and surrounding structures, in particular when focusing on their lower frequency content. For example, Bruno et al. (2018) reported on the effectiveness of DAS technology for measuring the hydromechanical response caused by fractures in a reservoir. At the Reykjanes geothermal field (Iceland), Raab et al. (2019) show that variations and patterns in a cement bond log (CBL) are correlated with the average strain-rate DAS data acquired behind casing and under noisy well drilling and testing conditions. CBL is generally used to check the casing cementation job, which constitutes one aspect of the well integrity assessment. Correlation of DAS background noise and CBL indicates the possibility to monitor - continuously - the well cementation from DAS data. This aspect is investigated at SLS in well TH3 (Fig. 4d and 4c). Hence, the evolution with depth of the average DAS spectral energy below 0.1 Hz, or between 10 and 40 Hz (black curve), is plotted next to the CBL acquired in TH3 in December 2019 (red curve). Usually, amplitudes of CBL are smaller with a good cement bond than with a partial bond, or no bond at all (free pipe). Out of the shallowest part above 50 m where surface noise has a significant impact on the presented energy profile (see dotted part of the black curve), the DAS and CBL curves present similarities, especially around 200 and 600 m. At these depths, both profiles show very similar variations, which suggest that a poorer cement bond and fiber coupling may explain the higher noise level observed in the strain-rate data. However, a perfect match between the profiles cannot be demonstrated along the entire fiber. In particular, the high energies observed locally at 350 and 400 disturbing the spectra over the whole frequency range (Fig. 4a), cannot be associated with a particular cementation zone, according to the CBL. On the other hand, the present CBL delivers a directional but unoriented measure of the cement bond and does not allow the analysis of potential azimuthal variations of the cement quality nor channelling effects. The mechanical coupling of the fiber could therefore be locally weaker without noticeable evidence on the CBL. The plant operation may also contribute to the observation of local disturbances. The various datasets presented in the time domain (Fig. 3 and 5) show short depth intervals of higher strain-rate. The changing location of the noisy intervals over time suggests that the underlying source is not static and cannot be attributed to the well structure.

Besides the logging capabilities of the DAS, the detection of the two local microseismic events presented in Sect. 4 also supports the relevance of monitoring using DAS along wells. In addition, the intrinsic linear array-type nature of DAS provides advantageous insight into the seismic source. Hence, DAS advantageously complements standard monitoring approaches of geothermal fields from-surface (e.g. Baisch et al. (2014)):

- For both events, multiple P- and S-phases could be identified along the vertical section of the well, which proves the capacity of DAS to consolidate the records delivered by three-component seismometers and opens promising perspectives in terms of localization and characterization of the event. Lior et al. (2021) showed in particular the ability of DAS-based approaches to resolve source parameters using P-waves on horizontal ocean-bottom fibers. The utilization of the DAS waveforms for the further characterization of the seismic source is currently investigated.
In addition, the level of detection achieved for the April event demonstrates the capability of the technology to monitor a geothermal field in an urban area. The FOC cemented behind the well casing acts effectively as a long string of sensors deployed closer to the monitoring target, which eventually detect weak events whose low magnitude prevents surface seismometers from identifying them.

For the April event, the characteristic functions of the recursive STA/LTA (Fig. 7) show concomitant P- and S-waves triggers and give evidence of satisfactory signal-to-noise ratios, despite the apparent low magnitude of the event (Sect. 4.2.1). Figure 7b shows in particular that the STA/LTA ratio exceeds three for the S-waves in the deepest levels. The figure highlights as well that fewer and sparser traces are triggered between surface and 200 m, which was previously identified as an interval strongly perturbed by anthropogenic noise (see Sect. 4.1).

Figure 7: Characterization of the level of sensitivity in the detection of the April event. Panel a): characteristic functions of the recursive STA/LTA algorithm which has been applied to each strain-rate time-series. Red and blue dots show respectively the coordinates at which the trigger turns on and off, provided the parameters shown in Table 1. Panel b): evolution with depth of the maximum STA/LTA ratio measured along the characteristic functions presented in panel a).

To some extent, the aforementioned monitoring and logging capabilities can be compared to those of a string of geophones. However, DAS prevents from locating an event using one single monitoring well because of the broadside insensitivity of the current set-up. Although offset and depth of the event could be determined, the back azimuth would remain unknown. This limitation could be minimized for FOC deployed along deviated wells. Besides, technological solutions are currently investigated to overcome the broadside insensitivity of DAS, using in particular helically wound fibers (Hornman, 2017). Hence, unless several sites or wells would be instrumented with FOCs for DAS, the latter needs to be complemented by other equipment (e.g. surface seismometers) to be able to reach seismic monitoring objectives (e.g. location capabilities), but possibly at the cost of a higher magnitude...
of completeness. Nevertheless, the previously mentioned logging capabilities of DAS are enhanced by
the high spatial sampling achievable along large distances. Furthermore, these logging capacities are
enriched by the possibility delivered by one single sensing element to monitor various physical
parameters. Indeed, a FOC is usually made of several single and multi-mode fibers that can be used
for a variety of applications. This potential has been evidenced and leveraged by the oil and gas
industry for around one decade (Koelman et al., 2012; Koelman, 2011; Van Der Horst et al., 2013).

5.2. Towards real-time seismic monitoring of geothermal plants

The use of DAS for monitoring geothermal plant operations requires a degree of sensitivity in detecting
events, which has been demonstrated in Sect. For mitigation purposes, the monitoring system
must also provide the results, i.e. seismic activity, as fast as possible. The implementation
of a DAS system into the monitoring strategy of the geothermal plant calls therefore for efficient
transfer of large amounts of data in addition to fast and secure data access for optimized processing.
These needs were met with the Azure cloud platform, which offered a unified service that combined
storage, accessibility and data processing. During the 6-months monitoring period, processing of 1-
minute long DAS acquisitions, besides the 1-hour long datasets, was also carried out to move towards
real-time processing. During the dataset formatting, each file was concatenated with 10 seconds of
the preceding one to avoid missing events at the edge of the datasets (due to filter initiation). The
processing of each file, according to the workflow described in Section 4, took on average between 9
and 10 s, which is significantly less than the file duration and thus avoids the occurrence of overflows.
To tend towards real-time processing of the acquired datasets, two limiting factors are identified:

- the buffering of the files on the recorder. In its current operating condition, the system needs
an HDF5 file to be fully written to the A1-R recorder’s buffer to be pushed towards the Data
Lake. Such a technical limitation could be overcome by adapting the recorder’s software with
the goal of streaming the data towards the IoT cloud platform on a real-time basis.
- the file transfer through the wired connection. The band-pass of the wired connection being
limited, this necessarily adds a lag time in the data processing. For short files, this limitation is
much less restrictive than the files buffering: with the observed uploading rate of 36 MB/s,
less than three seconds are theoretically necessary to upload one-minute-long files on the
Data Lake.

In practice, these two factors delayed the data processing by about 10 more seconds. Hence, the
processing flow allowed to deliver automatic detection results with a maximal delay of approximately
1 min 20 s after the event onset time, which shows great potential for real-time monitoring.

5.3. Outlook for a Reservoir Management System

In order to minimize risks and optimize operational parameters, the real-time integration of
monitoring outcomes and associated forecasts into the exploitation of geothermal sites is a critical
aspect for the geothermal operators. At the SLS geothermal plant, work on this issue has recently led
to the development of a concept of what would constitute a reservoir management system (RMS)
(Gauch er et al., 2022). By merging observations and forecasts, the system should be able to propose
the geothermal field operator alternative production scenarios to mitigate immediate or forecasted
risks.

The system is composed of three main modules, which are linked and interact with each other
(Gauch er et al., 2022). A database is designed to store the monitoring observations acquired in the
field, the results of their processing and the risk projections. The database is in interaction with the
processing centre, which is necessary to update the results of the observations and numerical
modelling. Finally, the dashboard synthesizes all available information with a finite number of key
indicators and interfaces with the operators. The latter aims to facilitate decision making based on the
observations and modelled predictions.

The monitoring system tested at the SLS geothermal site during the 6-months period demonstrates,
with respect to the described RMS, the technical feasibility of acquiring, processing and archiving large
amounts of passive seismic data, as encountered with DAS. The supporting IoT platform routinely used
by the field operator proved to be a viable solution, which moreover features scalable processing and
archiving resources in addition to user-dependent access authorizations to guarantee data
confidentiality. Hence, the DAS monitoring system could be seen as a prototype linking the monitoring
outcomes to the central database and using some of the features of the processing centre, while
operating in a real operational environment.

Conclusion

In this work, we describe the monitoring concept that has been developed to establish DAS as an
effective component of the seismic monitoring of the Schäftlarnstraße geothermal plant, located in
the inner city of Munich. The described monitoring system links the on-site infrastructure, which
includes the interrogated fiber and the DAS recorder, to a cloud IoT platform designed to deliver both
a secured storage environment for the DAS acquisitions, and optimized IT resources for their
processing. The 6-months testing period and the related outcomes can be seen as a proof of concept,
showing the viability of the proposed monitoring system and, thereby, the feasibility of acquiring
continuous DAS data in geothermal wells under operational conditions, while efficiently managing and
processing the large and continuous flow of DAS records.

The technical characteristics of the cloud platform supporting the monitoring concept, which features
scalable and performant storage and processing resources, open interesting perspectives for the
densely sampled DAS acquisitions to be used in quasi-real time assessment of induced seismicity. For
mitigation purposes, we demonstrate the usability of the proposed concept to report on seismic event
detections with low latency while processing minute-long data blocks.

The integration of DAS into the monitoring operations requires occasionally a degree of sensitivity in
detecting events. The relevance of using DAS in the seismic monitoring operations is demonstrated by
the observations collected during the 6-months testing period. In particular, the level of detection
achieved for a low magnitude event occurring near the geothermal boreholes demonstrates the
capability of the technology to monitor a geothermal field under high anthropogenic noise conditions.
The quality of the DAS data is evidenced by the high spatial coherence observed for both P- and S-
waves over the entire FOV, as well as the measured signal-to-noise ratio, especially for S-waves. The
demonstrated level of sensitivity results mainly from the proximity of the borehole DAS sensors to the
assumed location of induced seismicity, and from the application of advanced detection (network
coincidence) and denoising (f-k filtering) techniques that take advantage of the high spatial and
temporal sampling of the acquisitions. Hence, DAS advantageously complements standard monitoring
approaches based on surface deployments, allowing the detection of events that individual
seismometers may fail to record.

Our study also highlights the possible dual use of DAS from the detailed analysis of two local seismic
events, using in particular the measured onset-time of P- and S-waves. On one hand, DAS allows dense
sampling of the P- and S-waves arrival times along the fiber. This set of observations supports the
further evaluation and analysis of spatial variations of P- and S-waves apparent velocities along the
fiber. The variations in apparent velocities and apparent VP/VS ratios presented for the two local
seismic events highlight local structural changes in the medium surrounding the TH3 fiber. Beside site characterization, the arrival times contribute to the preliminary characterization of the seismic event using Wadati diagrams, giving access to the time, depth and offset of the seismic event origin. On the other hand, the broadside insensitivity of the applied DAS technology can restrict its capabilities for extensive seismic source characterization. The monitoring based on one single vertical DAS antenna cannot be considered as a stand-alone solution to meet the requirements associated with the seismic monitoring of the SLS site, as complementary viewpoints would be necessary for a precise evaluation, in particular, of the seismic source back-azimuth.

However, the present study demonstrates that the deployment of FOC in geothermal wells opens perspectives that extend beyond seismic monitoring. Benefiting from the broadband sensitivity and high spatial sampling of DAS, we show a correlation between the CBL and the spatial evolution of the spectral energy of DAS strain-rate. The measurement suggests that higher noise-levels observed in the DAS data may be associated with a weaker mechanical coupling of the fiber and a weaker cement bond, leading to interesting prospects for the continuous well surveillance. More generally, DOFS provide a cost-effective sensing element to implement logging, imaging and monitoring capabilities all over the lifetime of a borehole, in an operational environment (e.g. Li et al. (2015)). The interest of the geothermal energy industry in DOFS lies therefore in the potential of a single sensing element to provide information on temperature profiles, in- and out-flow zones of the geothermal fluid along the well (Schölderle et al., 2021), well integrity (cement bond log, leakage through casing) and, as discussed, advantageous seismic monitoring perspective.
Appendix

Appendix A

Figure A1: Same as Fig. 5, without denoising the strain-rate datasets in the f-k domain. Here, we only apply a bandpass filter between 5 and 40 Hz to the data. In comparison with Fig. 5, this figure highlights the effect of the f-k filtering on the spatial coherence of the upwards-traveling wavefronts.
Figure B1: Wadati diagrams computed using the P- and S-wave arrival times associated with the February (left) and the April (right) events. The colormap shows the depth (TVD) of the virtual DAS sensors along the TH3 fiber.
Author contributions
JA designed the algorithms, performed the analysis and wrote the initial draft.
EG contributed to the discussion and extensively reviewed the article.
KT coordinated, for the geothermal operator (SWM GmbH), the 6-month monitoring test and reviewed the article.
