Abstract. The subsurface dissolution of soluble rocks, ~~also called subrosion~~, can affect areas over a long period of time and pose a severe hazard. We show the benefits of a combined approach using P-wave- and S_H -wave reflection seismics, electrical resistivity tomography, transient electromagnetics, and gravimetry for a better understanding of the ~~subrosion~~ process. The study area, 'Esperstedter Ried' in northern Thuringia, Germany, located south of the Kyffhäuser hills, is a large inland salt marsh that developed due to dissolution of soluble rocks at approximately 300 m depth. We were able to locate buried ~~subrosion~~ structures, ~~subrosion~~ zones, faults and fractures, and potential fluid pathways, aquifers and aquitards based on seismic and electromagnetic surveys. Further improvement of the ~~subrosion~~ model was accomplished by analyzing gravimetry data that indicates ~~subrosion~~-induced mass movement as shown by local minima of the Bouguer anomaly for the Esperstedter Ried. Forward modelling of the gravimetry data, in combination with the seismic results, delivered a cross section through the inland salt marsh from north to south. We conclude that the tectonic movements during the Tertiary, which led to the uplift of the Kyffhäuser hills and the formation of faults parallel and perpendicular to the low mountain range, were the initial trigger for subrosion. The faults and the fractured Triassic and Lower Tertiary deposits serve as fluid pathways for groundwater to leach the deep Permian Zechstein deposits, since ~~subrosion~~ is more intense near faults. The artesian-confined salt water ascends towards the surface along the faults and fracture networks, and formed the inland salt marsh over time. In the past, ~~subrosion~~ of the Zechstein formations formed several, now buried, sagging and collapse structures, and, since the entire region is affected by recent sinkhole development, ~~subrosion~~ is still ongoing. From the results of this study, we suggest that the combined geophysical investigation of ~~subrosion~~ areas can improve the knowledge of control factors, ~~risk~~ areas, and thus local ~~subrosion~~ processes.

1 Introduction

Subrosion, the subsurface dissolution/leaching of soluble rocks, poses a major geohazard, especially if it occurs in urbanized areas (Gutiérrez et al., 2014; Parise, 2015). In particular the sudden formation of sinkholes, also called dolines, can cause

building and infrastructure damage and life-threatening situations (Beck, 1988; Waltham et al., 2005). Therefore, to gain a better understanding of the **subrosion** process, its controlling factors and the resulting structures is of high importance.

The **subrosion** process requires the presence of soluble rocks (e.g. evaporites), unsaturated groundwater or meteoric water, and fractures, joints or faults which may serve as fluid pathways (Waltham et al., 2005). The process leads to mass movement and forms cavities that may migrate upward over time (Davies, 1951; White & White, 1969). It results in a continuous sagging of the surface that generates a depression, or a sudden collapse, which generates a sinkhole (Waltham et al., 2005; Gutiérrez et al., 2008).

Several studies have dealt with the understanding of the processes and the imaging of subrosion structures, such as cavities, sinkholes, and depressions, using different types of methods. The most suitable methods for the monitoring of sinkhole development are aerial photos, differential GPS, and radar interferometry (Yechieli et al., 2002; Abelson et al., 2003; Vey et al., 2021). For the detection of cavities and mass movement, gravimetric methods have shown to be useful (Neumann, 1977; Butler, 1984), but they also deliver information about possible cavity fills, as do electrical resistivity tomography (ERT), and various electromagnetic methods (Militzer et al., 1979; Bosch & Müller, 2001; Miensopust et al., 2015). To get an image of the subsurface the most common techniques are ground-penetrating radar (Kaspar & Pecen, 1975; Batayneh et al., 2002) and reflection seismics (Steeple et al., 1986; Miller & Steeples, 2008; Krawczyk et al., 2012; Wadas et al., 2016). Several studies in karst regions using P-wave reflection seismics have been carried out (Evans et al., 1994; Keydar et al., 2012), but investigations using S_H -wave reflection seismics that enable high-resolution imaging of the near-surface (Krawczyk et al., 2012; Wadas et al., 2016, 2017; Polom et al., 2018), or even in combination with P-waves, are sparse or missing. Since **subrosion** and the development of its corresponding structures are a complex phenomenon, a combination of various methods (e.g. Malehmir et al. (2016); Al-Halbouni et al. (2021); Ezersky et al. (2021)) is needed to better understand the components and controlling factors associated with it. The more boundary conditions that influence the processes and the structures that can be determined, the better, e.g., dynamic models (Augarde et al., 2003; Shalev et al., 2006; Al-Halbouni et al., 2019) can be adapted in order to make better predictions of risk areas.

In this study, we show the benefits of a combined approach using P- and S_H -wave reflection seismics including ERT (Doetsch et al., 2012; Wiederhold et al., 2013; Ronczka et al., 2017; Nickschick et al., 2019; Tanner et al., 2020), transient electromagnetics (TEM; Rochlitz et al. (2018); Steuer et al. (2011)) and gravimetry (Eppelbaum et al., 2008; Ezersky et al., 2013b; Flechsig et al., 2015) to better understand the local subrosion of an inland salt marsh in Thuringia, Germany. We analyze depressions and collapse structures and determine the vertical and lateral fluid pathways and areas of subsurface mass movement. Furthermore, we recommend a workflow for geophysical investigations of subrosion areas to determine control factors and risk areas.

2 Geology

Germany suffers from a widespread sinkhole problem, because soluble deposits are close to the surface in many areas. One of the main **subrosion** areas is located along the Kyffhäuser-Southern-Margin-Fault (KSMF) in Thuringia. The Esperstedter Ried to the south of the Kyffhäuser hills is part of this **subrosion** area. It is a 5 km² wide sink and it is the largest inland salt

marsh of Thuringia (Fig. 1). It developed due to leaching of salt-bearing rocks at approximately 300 m depth (Schriel & Bülow, 1926a, b).

2.1 Geological evolution

The Kyffhäuser hills have a N–S extension of 6 km, a W–E extension of 13 km, and they are one of the smallest low mountain ranges in Germany. To the south, the hills are bounded by the northward-dipping, W–E striking KSMF, a major thrust fault (Schriel & Bülow, 1926a, b).

An epicontinental ocean, the Zechstein Sea, covered the area during the Permian, and due to sea level changes, conglomerates, carbonates, sulfates, and salt were cyclically deposited (Richter-Bernburg, 1953). As a result, the central part of the Kyffhäuser hills consists of sandstones and conglomerates, and the southern part consists of gypsum and anhydrite. The main Zechstein Formations south of the hills are the Werra-, Staßfurt- and Leine Formations (z1–z3). Anhydrite and gypsum of z1 to z2 formations represent the main subrosion horizon in the research area (Schriel & Bülow, 1926a, b). The erosion of the Variscan Orogen at the Permian–Carboniferous transition led to deposition of eroded material in the Molasse Basin, and today these clastic sediments form the central part of the Kyffhäuser hills (Schriel, 1922; Knoth & Schwab, 1972). Triassic deposits are only found at isolated locations, and Cretaceous and Jurassic rocks have been completely eroded (Schriel & Bülow, 1926a, b; Reuter, 1962). During the Upper Cretaceous and the Tertiary, the low mountain range was uplifted and tilted, which resulted in the formation of a fault scarp to the north and a southward-dipping terrain (Freyberg, 1923). Tertiary deposits are found near Bad Frankenhausen and Esperstedt, and Quaternary sediments, such as silt and loess, cover a large area (Schriel & Bülow, 1926a, b).

The presence of salt springs and the occurrence of sinkholes and depressions in the near-surface indicate soluble rocks in the underground such as the Zechstein formations, and they show that Bad Frankenhausen and Esperstedt are affected by subrosion (Reuter, 1962).

2.2 Stratigraphy

Five boreholes are used for the later correlation of seismic reflectors and stratigraphy (Figs. 2 & 3). The Zechstein formation (z) is the oldest one drilled. In the research area, the Zechstein consists of the Werra-, Staßfurt- and Leine Formations (z1–z3). North and south of the Esperstedter Ried, the Zechstein formations are much closer to the surface than in the central part of the salt marsh. The Permian is followed by deposits of the Triassic Lower Buntsandstein (su). In two boreholes (94/1962 and 15/1952) the base of the Triassic and the top of the Permian deposits could not clearly be determined and borehole 01/1971, with a drilling depth of ca. 180 m, did not reach the Triassic sandstones. Tertiary (t) sediments are found in borehole 15/1952 with 1.70 m of silt and brown coal, and in borehole 01/1971 with 157.50 m of sand, gravel, clay, silt, and brown coal. Quaternary (q) deposits, like gravel, sand, and silt are found in all five boreholes. The thickness varies between 1 m in the northeast to 100 m in the center to 20 m in the southwest. The first increasing and then decreasing thickness of sediments from north to south is an indicator for a basin-like structure in front of the mountain range.

Figure 1. Geological map showing the Esperstedter Ried (modified after Schriel & Bülow, 1926a, b). The red box marks the investigation area.

3 Data acquisition methods

East of Bad Frankenhausen in the Esperstedter Ried, P- and S_H -wave reflection seismic surveys as well as ERT, fixed loop TEM and gravimetric measurements were carried out along several profiles (Fig. 3).

3.1 P-wave reflection seismic

The aim of the P-wave reflection seismics was to image the large-scale geological structures to about 300 m depth. For the survey we used a hydraulically-driven vibrator (HVP-30) as seismic source, which excited compressional waves in a sweep frequency range of 20 Hz to 140 Hz at 10 m spacing, and 360 one-component vertical geophones planted in the ground at 5 m spacing (Fig. 4).

3.2 S_H -wave reflection seismic

The purpose of the S_H -wave reflection seismics was to image the subsurface at higher resolution compared to P-waves, and thus detect small-scale features associated with local geology and **subsrosion**. In case of water-saturated soft sediments, which are found in the Esperstedter Ried, the velocity of the S_H -wave is significantly slower compared to the P-wave velocity, and this results in high-resolution images of the near-surface (e.g. Dasios et al., 1999; Inazaki, 2004). For data acquisition, we used a hydraulically-driven vibrator (MHV-4S) that excited horizontally-polarized shear waves in a sweep frequency range of 10 Hz to 80 Hz at 4 m spacing, and 120 one-component horizontal geophones at 1 m spacing combined in a landstreamer as receivers

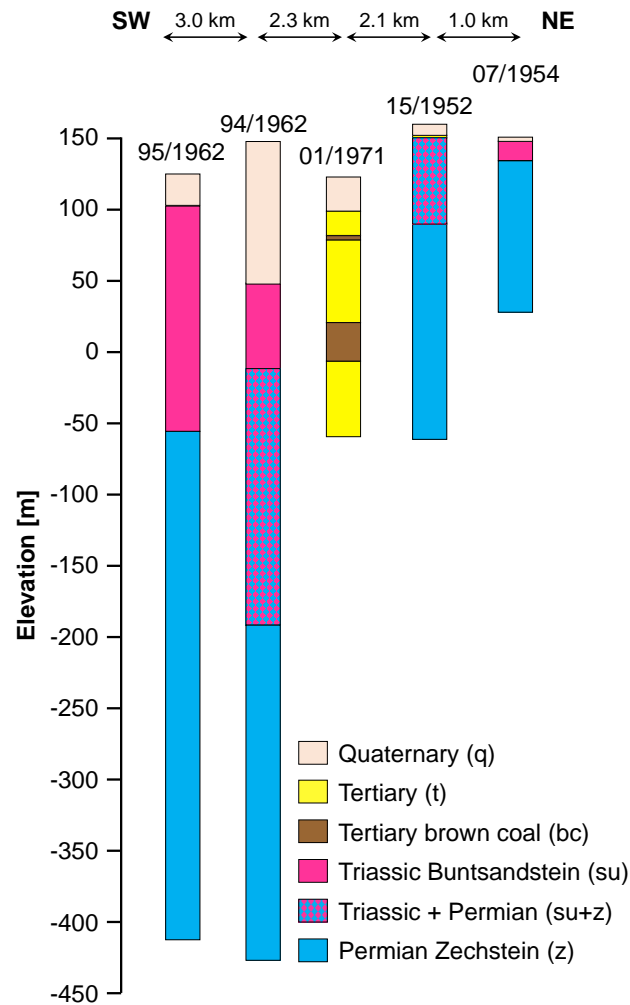

Figure 2. Stratigraphy of five boreholes in and around the Esperstedter Ried. The locations can be found in Fig. 3. The stratigraphic units were used for the interpretation of the seismic profiles.

(Fig. 4). The main advantage of this source-receiver combination on paved ground is the suppression of surface Love waves (Polom et al., 2010, 2013; Krawczyk et al., 2012, 2013).

3.3 ERT & TEM

105 The goal of the electrical resistivity tomography (ERT) and the transient electromagnetic (TEM) surveys was to investigate the subsurface resistivity distribution to determine zones of subrosion and areas of potential saltwater ascension. Whereas the large-scale direct current measurements provide robust information about the general resistivity structure, but with comparatively

Figure 3. Esri ArcGIS map showing the locations of the P-wave (light blue lines) and the S_H -wave (red lines) reflection seismic profiles, the gravimetric profile (dark blue line), the ERT profile (pink line), the TEM profiles (yellow lines) and the boreholes (orange dots). The thrust fault (KSMF) is marked by a dashed black line with triangles on the hanging wall.

poor resolution, TEM is especially suited to resolve good conductors down to a few hundred metres depth (Milsom & Eriksen, 2011). The ERT survey was conducted with a dipole-dipole configuration using 26 pairs of electrodes with approximately 200 m spacing along the 4.5 km N–S profile. The transmitter provided up to 30 A of source current, voltages were recorded with nine remotely-controlled data loggers (Fig. 4) developed at LIAG (Oppermann & Günther, 2018).

The ERT was restricted by power lines, roads and a gas pipe. By choosing a fixed-loop setup for the TEM survey, it was possible to cover parts of the profile that are nearly unaffected by strong artificial electromagnetic noise. Receiver positions had 50 m spacing in N–S direction and are placed across four large transmitter loops with 250 m × 250 m dimensions. For more information about the survey and specific details of sensors and data analysis we refer to Rochlitz et al. (2018).

Figure 4. Seismic (a-d) and ERT (e-g) equipment of LIAG used during the field campaigns. For the seismic surveys hydraulic P-wave and S-wave vibrators (a) were used as active seismic sources, vertical/horizontal geophones (b & d) were used as receivers, and a Geometrics Geode recording system (c). For the ERT surveys, a mobile power source consisting of a generator (e), electricity power inputs plugged into the ground (f), and an adapted recording system (g; photo taken from Oppermann & Günther (2018)) were utilized.

3.4 Gravimetry

The gravity survey (TLUBN, 2017), ~~which~~ was carried out by the company Geophysik GGD mbH in 2013 on behalf of the Thuringian State Institute for Environment, Mining and Conservation (TLUBN). Its aim was to complement information from the reflection seismic surveys by imaging density contrasts in the subsurface of the Esperstedter Ried and to facilitate 2D forward modelling, where structural information from reflection seismic interpretation is available as a constraint. The focus was more on the regional basin structure than on local, surface inhomogeneities. The gravity survey was carried out along a profile with a station spacing of 100 m, using a Scintrex CG-5M quartz gravimeter with nominal ± 0.005 mgal standard deviation of repeated measurements. The positions and elevations were determined by differential GNSS or by total station surveys with a standard deviation of ± 0.02 m. To enable a map-based qualitative interpretation, supplementary gravity data from the regional survey of Thuringia, acquired in the second part of the 20th century, with a mean point distance of 1 km to 2 km and standard deviations between ± 0.01 mgal and ± 0.06 mgal (Conrad, 1996) completed the dataset.

4 Data processing

4.1 P-wave reflection seismic

The processing of the P-wave data was carried out using the processing software SeisSpace by Halliburton. The first processing steps of the P-wave data were quality control, 3-fold vertical stack, geometry assignment, and muting of surface waves. This was followed by spectral balancing and an automatic gain control (AGC) using a 500 ms window to improve the signal-to-

noise ratio (S/N ratio). Short wavelength refraction statics and residual statics were applied and after velocity analysis an initial velocity model was calculated. A Kirchhoff pre-stack depth migration was carried out, and the velocity model was iteratively improved by residual moveout (RMO) analysis. Finally, additional spectral balancing, trace mute, and a frequency-wavenumber filter (F-K filter) were used to further improve S/N ratio and resolution. For detailed explanations of the processing algorithms, see Hatton et al. (1986); Lavergne (1989); Yilmaz (2001).

4.2 S_H -wave reflection seismic

The processing of the S-wave data was carried out using the processing software VISTA Version 10.028 by Gedco (now Schlumberger). The first processing steps of the S_H -wave data were vibroseis correlation, geometry assignment, amplitude balancing, frequency filtering, and 2-fold vertical stack to improve the S/N ratio. This was followed by a top mute and a F-K filter to eliminate noise and harmonic distortions. The datasets were sorted by Common Mid Point (CMP) following interactive velocity analysis, normal-moveout (NMO) correction, and residual statics correction. A stacked seismic section in time domain was created, bandpass- and F-K filters removed remaining noise, and spectral balancing was applied. A finite-difference (FD) migration moved the dipping reflectors to their true position and finally, the sections in time domain were converted to depth. For detailed descriptions of the processing algorithms, see Hatton et al. (1986); Lavergne (1989); Yilmaz (2001).

4.3 ERT & TEM

The ERT surveys yielded time series of 27 current injections and for each of them 26 potential difference measurements with GPS base. The resistances were determined using a lock-in algorithm, where the potential difference is extracted from the noisy time series by using the known time-dependence of the injected current signal (Oppermann & Günther, 2018). The apparent resistivities were calculated by multiplication of the resistance with a geometric factor, which depends on the distances between the potential and current electrodes. From these apparent resistivities a pseudosection was created. The true resistivities were then reconstructed using the BERT inversion algorithm (Günther et al., 2006) based on a triangular model discretization that is able to take topography into account. For regularization, we used a geostatistical operator (Hermans et al., 2012; Jordi et al., 2018) with a correlation length of 800 m for the horizontal direction and 70 m for the vertical direction, in order to account for the predominant layering of the geological strata.

Processing of TEM data mainly includes noise removal by selective stacking and logarithmic gating. 1D inversion of the processed data was challenging due to affection by strong atmospheric and anthropogenic noise. The two obtained resistivity distributions based on the coil and SQUID receivers are overall similar, but the inversion results based on the SQUID receiver exhibited a higher consistency between neighboring stations, greater penetration depths and less artifacts caused by anthropogenic noise (Rochlitz et al., 2018). Nevertheless, using resistivity constraints from ERT and structural information from seismics, the reliability of inversion results could be evaluated.

4.4 Gravimetry

The processing of the gravity data (densely sampled stations along a profile in the Esperstedter Ried and sparse stations from regional surveys nearby) consisted of a uniform conversion of gravity observations to Bouguer anomalies. The calculation refers to common geodetic and geophysical reference systems (ETRS89, DHHN92, and IGSN71), a standard Bouguer density of 2670 kg m^{-3} , and a maximum radial distance of 166.70 km for the calculation of a spherical Bouguer cap and terrain effects. The formulas used comply with international standards (for details, see e.g. Hinze et al. (2005)): normal gravity by closed form formula of Somigliana (Somigliana, 1929); atmospheric correction to normal gravity; free air correction by a series expansion to the 2nd order; Bouguer correction by closed formula for the gravity effect of a spherical cap of 166.70 km radius. Spherical terrain corrections were calculated in two steps: step 1 considered the near field terrain between 0 km and 25 km distance from a station using a DEM with 1 arcsec (ca. 25 m) cell size; step 2 considered the far field terrain between 25 km to 166.70 km distance using a DEM with 10 arcsec (ca. 250 m) cell size. The resulting complete Bouguer anomaly is the difference between the observed gravity and the sum of all correction terms. The regional data surrounding the Esperstedter Ried (12 km x 12 km area) has been gridded using kriging. This grid of Bouguer anomalies was subject to spectral filtering, to enhance the visibility of regional density contrasts and potential faults. The anomalies along the local profile in the Esperstedter Ried served as input for iterative forward modelling. This quantitative interpretation step was realized using IGMAS+ (Interactive Geophysical Modelling Application System; Schmidt et al. (2011)). This software, originally designed for 3D gravity data, gravity gradient and magnetic modelling, enables the definition of bodies with constant or varying densities on polygonal cross sections (2D vertical planes) with finite strike length, thus enabling 2.5D forward modelling. A 2.5D model allows the rapid verification of hypotheses about the mass distribution in the subsurface, in cases where structural information is available only along profiles. As structural constraints, the interpreted sections of the seismic profiles P2 and S2 and a cross section through the geological map (Schriel & Bülow, 1926a, b) were used.

5 Results

5.1 Interpretation of seismic profiles P1 & S1 (W–E)

The reflection seismic profiles P1 and S1 were carried out across the Esperstedter Ried from west to east. P-wave profile P1 is of 2.98 km length and S_H -wave profile S1 is of 1.04 km length. Profile S1 was surveyed after P1 and covers a selected area of P1.

In P1 and S1 (Fig. 5a, d) from the surface down to ca. 100 m depth and between ca. 1.20 km and 1.50 km profile length, mostly horizontal and continuous reflectors with partly high amplitudes are imaged, which represent Quaternary and Tertiary deposits (Fig. 5). These impedance contrasts represent layer boundaries. The high-amplitude reflector at ca. 10 m to 25 m depth, which is visible in both sections and traceable throughout the entire profile of S1, represents the boundary between the Quaternary gravel and silt, and the Tertiary clay. In section P1 (Fig. 5a), in about 100 m depth, within the Tertiary deposits, another high-amplitude reflector is imaged. It is mostly continuous and traceable throughout the entire profile, which we interpret as Tertiary

brown coal and use as a marker horizon (Fig. 5b). In S1 (Fig. 5d), the brown coal shows no distinct reflector, but instead the
195 internal structures of the Quaternary and Tertiary deposits can be observed in more detail compared to the P-wave section (for
details see section 5.3 and Fig. 7). Below the top Triassic, at ca. 250 m depth in P1, a horizontal reflector showing a partly strong
impedance contrast is imaged in the east of both sections between 1 km and 2.40 km profile length, especially in P1 (Fig. 5a, b).
This is interpreted as the boundary between the Lower Triassic sandstones, and the Permian evaporites. The sandstones of the
Lower Triassic show almost no internal structures and the area below the top of the Permian contains only poor reflections,
200 probably due to limited penetration depth of the seismic waves and the resolution limits.

To the west of P1 and S1, between 0 km and ca. 0.75 km profile length, shallowly-dipping reflectors form a bowl-shaped
structure ca. 0.70 km in length at 100 m to 300 m depth within the Tertiary, Triassic and Permian deposits (Fig. 5a, c, d). The
brown coal marker horizon was used to support the interpretation, since no boreholes are available in this area. Profile S1
shows only the eastern margin of this structure, but it gives more detailed information on the internal features of the formations
205 with respect to the P-wave profile (Fig. 5d, e). Onlapping silt and clay layers of the Tertiary are observed above the coal, and
further above are horizontal Tertiary and Quaternary deposits. Between ca. 0.80 km and 0.90 km profile length at ca. 100 m to
280 m depth V-shaped reflectors are observed in P1 (Fig. 5c). The same zone is characterized by synclinal reflectors and low
reflectivity in S1 (Fig. 5d).

The Triassic sediments show local thinning and a general decrease in thickness from east to west. Numerous faults and
210 fractures in the Tertiary, Triassic and Permian formations are imaged (Fig. 5f). In P1 steeply-dipping normal and reverse faults,
which transverse the seismic profile, are identified, and in S1 not only the faults of P1 are imaged, but also other steep faults
and many nearly vertical fractures within the bowl-shaped structures, which are not all drawn in the interpretation (Fig. 5).
These are not observed in P1 since their scale is below the resolution limit of the P-wave profiles (Fig. 5e).

We interpret the large bowl-shaped structure (Fig. 5b, e, f) to be a former sinkhole that opened during the Tertiary ~~due to~~
215 ~~subrosion~~. The nearly vertical fractures within and below the depression that crosscut the Triassic and the Permian indicate
collapse of an underground cavity. Since the brown coal layer dips and is crosscut by some of the fractures, the sinkhole must
have occurred after the deposition of the organic material. This is supported by the onlapping Tertiary and the horizontally-
layered Quaternary sand and gravel above. The small structure more to the east seems to be a second collapse with steep
margins (Fig. 5e, f).

220 5.2 Interpretation of seismic profiles P2 & S2 (S–N)

Reflection seismic profiles P2 and S2 were carried out from south to north. P-wave profile P2 is of 5.10 km length, but only
the first 4.50 km are analyzed, because of poor reflectivity in the most northern part. The S_H -wave profile S1 is of 0.67 km
length. Profile S2 was surveyed after P2 and covers a selected area of P2. The profile lengths of P2 and S2 were adapted so
that they match the gravimetric profile to enable better comparability of interpretations, thus e.g. P2 starts at 2.10 km and ends
225 at 6.60 km.

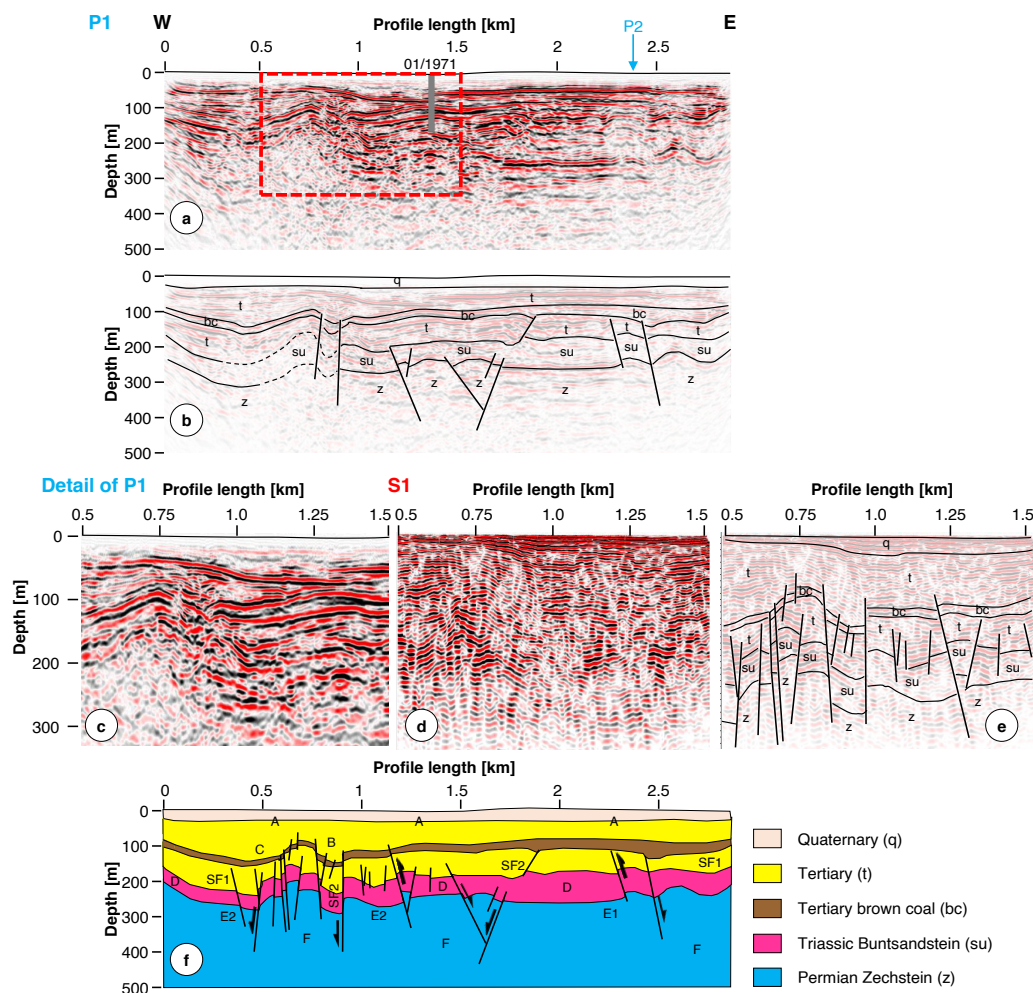

Figure 5. Seismic profiles P1 and S1 uninterpreted (a, c, d), with interpreted stratigraphy (b, e) and combined interpretation with seismic facies and seismic features (f). The red box in (a) marks the detail of P1 in (c) and the position of the S_H -wave profile shown in (d) and (e). The seismic facies (A–F) and the seismic features (SF1–SF2) are exemplarily marked and are explained in section 5.3 and Fig. 7. The vertical exaggeration is 2:1 and the reference datum is 126 m a.s.l. for P1 and 124 m a.s.l. for S1.

The most northern part of P2 between ca. 6.35 km and 6.60 km profile length from the surface down to about 400 m depth (Fig. 6a, b) shows irregular and discontinuous reflectors of low amplitudes. They represent the Permian Zechstein formations of the Kyffhäuser hills. This area is separated from the south by a steep, northward-dipping thrust fault, the KSMF.

South of the KSMF, at 50 m to 100 m depth (Fig. 6a, b), a continuous, high-amplitude reflector is imaged, which is traceable throughout almost the entire profile. Just as in P1 and S1, this impedance contrast is interpreted as the boundary between the Quaternary and Tertiary deposits. A second, mostly continuous reflector with high impedance contrast is visible between ca. 2.90 km and 6.35 km profile length at 100 m to 200 m depth, which is interpreted as the top of the brown coal (Fig. 6a, b, d, e),

and is further used as a marker horizon. The thickness of the Tertiary formation decreases from north to south. The Triassic sandstones below show no internal structures, but at ca. 250 m depth, a discontinuous, high-amplitude reflector is imaged. This is interpreted as the top of the Permian Zechstein, which is traceable throughout the entire profile P2 (Fig. 6a, b). Repeatedly, between 3.20 km and 6.35 km profile length the reflector shows low reflectivity, but between ca. 2.40 km and 3.20 km profile length it is continuous and has even higher amplitudes. These two areas are separated by a steep northward-dipping normal fault (Fig. 6b, e, f).

Directly south of the KSMF, between 5.10 km and 6.35 km profile length, dipping reflectors that form a bowl-shaped structure within the Quaternary to Permian deposits are imaged (Fig. 6a, b, f). In contrast to the two structures observed in P1 and S1, the Quaternary is affected too. The deepest point of the bowl-shaped structure is at ca. 400 m depth and coincides with a low reflectivity zone in the Permian Zechstein. Another 0.30 km wide depression was identified to the south between 2.10 km and 2.40 km profile length at 200 m to 350 m depth within the Quaternary to Permian sediments (Fig. 6a, b). A third bowl-shaped structure was imaged at shallow depth, in the near-surface between 3.30 km and 3.45 km profile length at ca. 40 m to 100 m depth. This was pointed out as the area of interest for the S_H -wave reflection seismic survey S2 (Fig. 6c, d, e). The high-amplitude reflectors of the top of the Tertiary are also observed in S2, but the impedance contrast is weaker than in P2. In S2 details of the internal structure of the different formations can be recognized (for details, see section 5.3 and Fig. 7).

Besides the KSMF, other steep faults are identified below the northern depression and below the near-surface depression to the south (Fig. 6f). The profiles P2 and S2 reveal that the fault below the near-surface depression, between 3.30 km and 3.45 km profile length at ca. 40 m to 100 m depth, is not a single fault, but instead is a fault zone and nearly vertical fractures within the Lower Tertiary sediments are also imaged in S2.

The low reflectivity areas of the top Permian are assumed to be the result of leaching processes, similar to the bowl-shaped structures, which are interpreted as a near-surface sinkhole due to cavity collapse and syn-sedimentary sagging of the surface ~~due to slow mass movement of material induced by subrosion~~. In contrast to the leached Permian to the north, it is less affected by subrosion to the south, as indicated by strong impedance contrasts, which are probably the result of unimpaired evaporite sequences. The steep fault, at ca. 3.20 km profile length, may serve as a barrier for groundwater flow coming from the Kyffhäuser hills.

5.3 Seismic facies analysis

The procedure of the seismic facies analysis is based on Roksandic (1978). A total of six seismic facies types (A–F) and four seismic features (SF1–SF4) can be identified in the P- and the S_H -wave seismic data on the basis of configuration, continuity, amplitude, and frequency content (Fig. 7). A comparison of P-wave and S-wave was not possible for all facies and feature types, because for some locations only P-wave data was available.

The three facies A–C are characterized by continuous to semi-continuous reflectors and represent more or less undisturbed layers. Facies A consists of Quaternary and Upper Tertiary with continuous, horizontal, and parallel reflectors. Compared to the S-wave sections, the P-wave sections show low amplitudes in the uppermost part due to resolution limits. As a result, the silt, sand and gravel layers of the Quaternary are not imaged, and the deeper parts are of high amplitudes. The S-wave

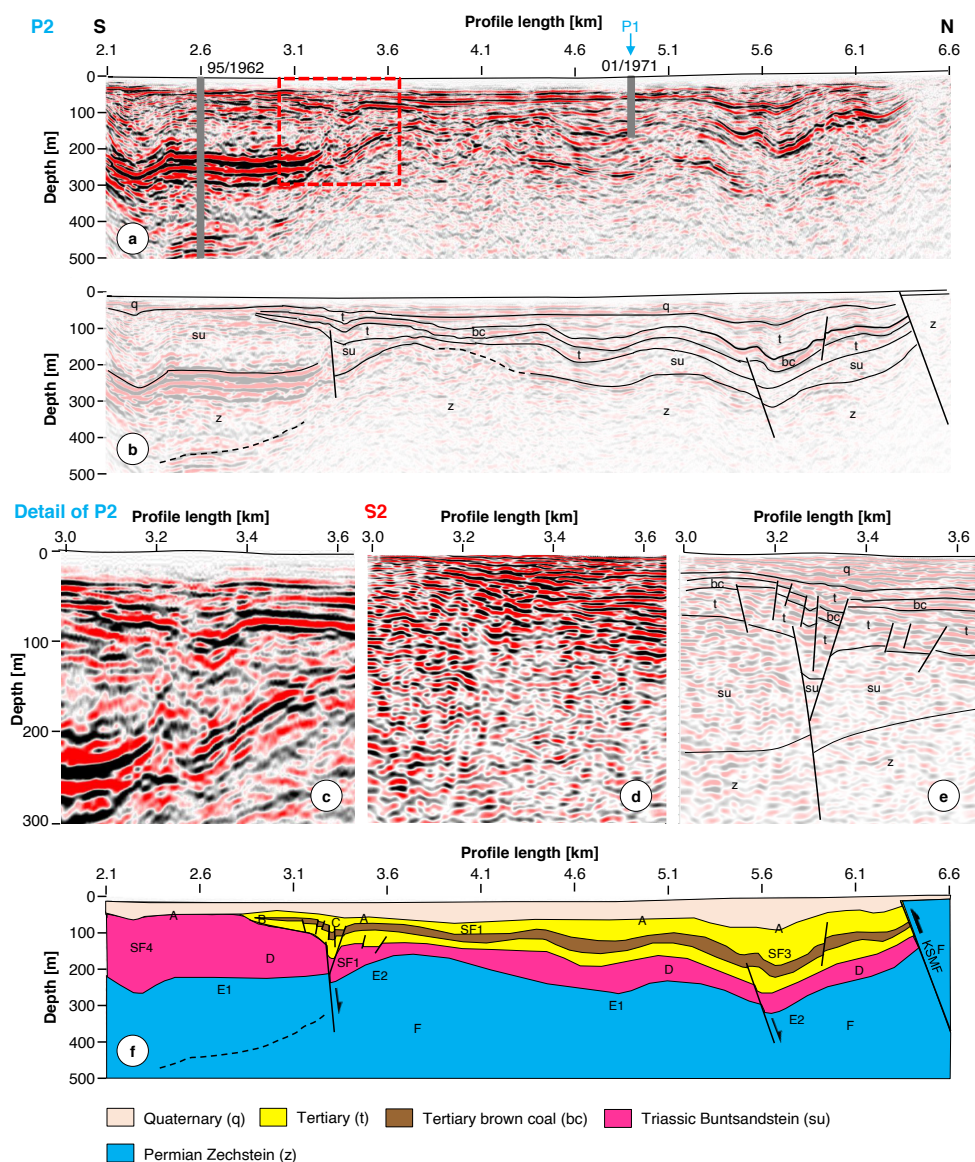

Figure 6. Seismic profiles P2 and S2 uninterpreted (a, c, d), with interpreted stratigraphy (b, e) and combined interpretation with seismic facies and seismic features (f). The profile lengths of P2 and S2 were adapted so that they match with the gravimetric profile to enable better comparability of interpretations, thus e.g. P2 starts at 2.10 km and ends at 6.60 km. The red box in (a) marks the detail of P2 in (c) and the position of the S_H -wave profile shown in (d) and (e). The seismic facies (A-F) and the seismic features (SF1-SF4) are exemplarily marked and are explained in section 5.3 and Fig. 7. The borehole 01/1971 was projected onto the seismic profile over a distance of 1 km, the borehole 15/1952 was projected over a distance of 430 m, and the borehole 95/1962 is located directly beside the seismic section. The vertical exaggeration of the seismic sections is 2:1 and the reference 150 m a.s.l. for P2 and 121 m a.s.l. for S2.

data, however, shows generally high amplitudes with a high frequency content and the differentiation of individual reflectors within the two formations is more detailed, because of the improved resolution. Facies A might be a good water conduit for horizontal water flow, due to the permeable gravel and sand layers, but noticeable vertical fluid pathways, which are important for subrosion, were not found. Facies B shows the internal structures of the lower Tertiary silt, gravel, sand, and clay, and it has semi-continuous, wavy to sigmoid-parallel reflector patterns. Both P- and S-wave data show a high frequency content, but the amplitudes in the S-wave are higher for this facies and the reflectors are thinner and more detailed compared to the P-wave data. Facies B, with its semi-continuous reflector patterns, could favour vertical water flow. Facies C shows the Tertiary fill of a subrosion-induced depression with oblique to parallel reflectors. P-wave and S-wave data show slightly different images. In the P-wave data the Tertiary fill is visible as semi-continuous reflectors of medium amplitudes and medium frequency content, and in the S-wave data an onlap fill is observed with continuous reflectors, high amplitudes, and medium frequency content. In contrast to the Tertiary deposits of Facies B, the depression fill does not seem to be strongly fractured.

The three facies D-F are characterized by mostly discontinuous reflectors and represent disturbed layers. Facies D consists of Lower Triassic sandstones of the Buntsandstein, and the pattern configuration can be described as hummocky-clinoforms. In the P-wave data this facies is discontinuous, of low amplitudes and low frequency content, and in the S-wave data semi-continuous reflectors of medium amplitudes and medium frequencies are observed. The sandstones are disturbed and no internal structures are identified for both wave types, as a result it is most likely that the fractured, permeable sandstones serve as fluid pathways for vertical and lateral groundwater flow. Facies E shows the different types of the top Permian horizon, which are identified in the seismic sections. Facies E1 shows the undisturbed case with continuous, mostly horizontal and parallel reflector patterns. Two differentiations for the undisturbed evaporite can be made. High amplitudes might indicate thicker salt layers that generate a stronger impedance contrast against the Triassic sandstones above, compared to medium amplitudes of possibly evaporite (anhydrite, gypsum) that would generate a weaker impedance contrast. Facies E2 shows the disturbed case with discontinuous, hummocky to chaotic reflection patterns, low amplitudes, and low frequency content. Both P- and S-wave data show the same characteristics and this facies is interpreted as fractured and leached Zechstein formations, and are used for the determination of subrosion zones. Facies F images the interior of the Permian Zechstein formations. Just like for Facies E2, P- and S-wave data are very similar showing discontinuous and chaotic reflectors with no internal structures.

The seismic feature SF1 consists of semi-continuous reflector patterns that form a bowl-shaped structure in both P- and S_H -wave data, although the amplitudes in the S_H -wave data are generally higher, as is the frequency content. It is interpreted as a broad sinkhole with more or less horizontal layers above. In the S-wave data a divergent fill and a fractured underground beneath the sinkhole are identified. Seismic feature SF2 shows different characteristics in P-wave and S-wave. In the P-wave data, discontinuous reflectors form V-shaped troughs of medium amplitudes and medium frequency content, whereas in the S_H -wave data semi-continuous reflectors form parallel, synclinal structures of low amplitudes and low frequency. It is interpreted as another subrosion-induced, steeper sinkhole. Seismic feature SF3 consists of multiple troughs of continuous to semi-continuous reflectors of high and low amplitudes and medium to low frequency content. It is interpreted as a subrosion-induced depression and the sagging is either still ongoing or was active until recent times, which is supported by the fact that all formations from the Permian to the Quaternary are affected. Seismic feature SF4 is similar to SF3, but in contrast only a U-shaped trough

Seismic facies	Example	Description	Interpretation
A		a) sub-parallel, horizontal b) continuous c) low to high d) medium	P: undisturbed Quaternary and Upper Tertiary deposits
		a) sub-parallel, horizontal b) continuous c) high d) high	P: the uppermost layers with silt, sand and gravel were not imaged
B		a) wavy, sigmoid-parallel b) semi-continuous c) medium d) high	disturbed Tertiary deposits with possible fluid pathways
		a) wavy, sigmoid-parallel b) semi-continuous c) high d) medium	
C		a) oblique to parallel b) semi-continuous c) medium d) medium	P: Tertiary fill of a subrosion-induced depression; the top of the depression is visible as oblique layering
		a) oblique to parallel b) continuous c) high d) medium	S: Tertiary onlap fill of a subrosion-induced depression
D		a) hummocky-cliniforms b) discontinuous c) low d) low	P: Lower Tertiary Burundstein; internal structures are poorly imaged
		a) hummocky-cliniforms b) semi-continuous c) medium d) medium	S: disturbed Lower Tertiary Burundstein with possible fluid pathways
E1		a) parallel, mostly horizontal b) continuous c) high to medium d) low to high	undisturbed top Zechstein
E2		a) chaotic to hummocky b) discontinuous c) low d) low	disturbed and fractured top Zechstein due to subrosion processes
F		a) chaotic b) discontinuous c) low d) low	interior of the Zechstein evaporite; no internal structures can be identified
		a) chaotic, hummocky b) discontinuous c) low d) low	

Figure 7. Six different seismic facies (A–F) and four seismic features (SF1–SF4) were identified in the study area. Four seismic reflection parameters were used to classify the different types: a) configuration, b) continuity, c) amplitude, and d) frequency. The P-wave and S-wave facies are marked with 'P' and 'S'. Comparison of P- and S_H-wave data could not be carried out for all facies and feature types, because for some locations only P-wave data is available.

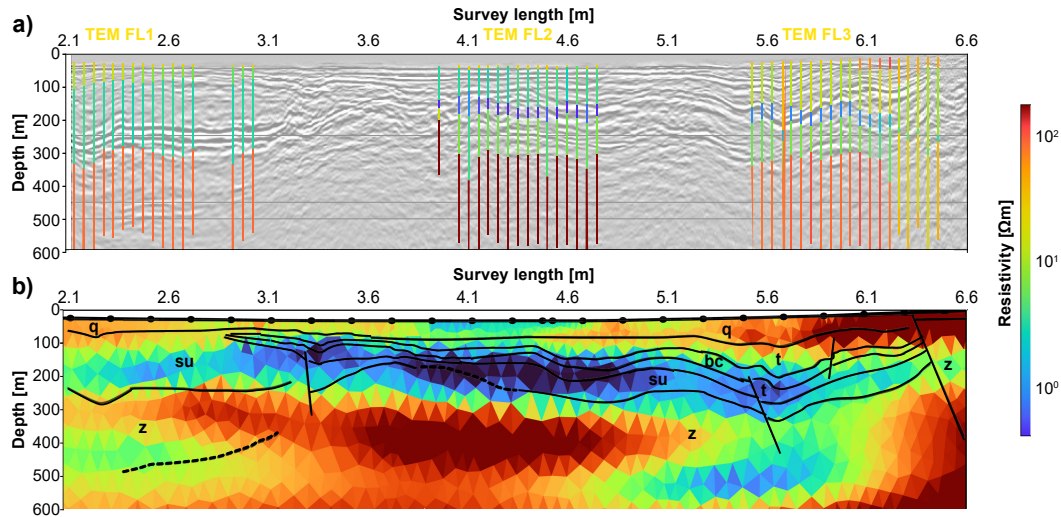

Figure 8. TEM profiles (a) on seismic profile P2 and ERT profile (b) with interpreted seismic structures in black. The profile lengths were adapted so that they match with the gravimetric profile to enable better comparability of interpretations, thus, e.g., the ERT profile starts at 2.1 km and ends at 6.6 km. The vertical exaggeration is around 2:1 and the reference datum is 150 m a.s.l. for the ERT and TEM data.

is observed in SF4. Just like SF3 all formations from the Permian to the Quaternary are affected, which is interpreted as a ~~subrosion-induced depression, where~~ sagging is ongoing.

Although P- and S_H -wave reflection seismic data image the same subsurface structures, the seismic facies imaging can be different due to the variations in penetration depth and resolution of the seismic waves types, which can influence the interpretation of the reflection pattern. Therefore, we suggest a combined analysis of P-wave and S_H -wave seismic data.

5.4 Interpretation of ERT & TEM

Fig. 8 shows the inversion results of TEM and ERT in combination with the interpreted geological structures of seismic profile P2. The target depth of the TEM method is between 300 m and 600 m, depending on the subsurface conductivity characteristics (Rochlitz et al., 2018), and the target depth of the ERT is of ca. 400 m. For the TEM survey at the fixed loop positions 2 and 3, a five-layer model instead of the original four-layer model by Rochlitz et al. (2018) was evaluated to be more suitable to explain data as well as subsurface resistivities. The profile length annotations were adapted to match with the gravimetric profile to enable better comparability of interpretations, thus e.g. the ERT profile starts at 2.10 km and ends at 6.60 km.

In the near-surface within the Quaternary deposits the electrical resistivity ranges from ca. $10 \Omega\text{m}$ to $40 \Omega\text{m}$ between 2.10 km and 5.80 km profile length down to 30 m depth. In the north, the KSMF is located and due to the thrust fault, leached Zechstein is found only a few meters below the surface showing resistivities of several hundreds of Ωm . North of the KSMF, the salt is completely dissolved/eroded.

Below ca. 100 m and 300 m depth a broad zone of low resistivity with less than $10 \Omega\text{m}$ between 2.30 km and 6.10 km profile length is observed. This zone corresponds with Tertiary and Triassic deposits, as interpreted in the seismic sections P2

and S2. Within this zone is an extremely conductive thin layer of approximately 1 Ωm , which is in particular resolved by the TEM data. The boundaries of this layer coincide well with main seismic reflectors. It is interpreted to match with saline aquifers between the lignite and Triassic Buntsandstein. Unfortunately, there are no continuous TEM-soundings across the entire profile available. In contrast, the ERT inversion data smears this layer over greater thickness due to limitations of resolution, but proves its continuity.

From 3.10 km to 2.10 km profile length the extremely conductive layer vanishes and resistivities between 100 m and 300 m depth increase slightly, as shown by the ERT and TEM FL 1, which is probably related to the fault zone at 3.20 km. The fault might hamper the lateral groundwater flow, and therefore, the lateral distribution of the salt water coming from the leached Permian deposits, which migrated upward along the faults and fractures to the north due to artesian-confined groundwater conditions.

The top Permian at 250 m to 300 m depth, as indicated by seismic interpretation, correlates with the top of the TEM basement layer with high resistivities of more than 100 Ωm . This is also visible in the ERT result, but the contrast is smoother and does not reveal a unique basement depth. At 5.50 km profile length, the ERT shows lower electrical resistivities reaching depths of 500 m. This coincides well with the interpreted fault. This area correlates also with the position of ~~subrosion-induced structures, like~~ the sinkholes above. Therefore, it is an indicator for salt-water ascension, due to dissolution of Zechstein evaporites and artesian-confined groundwater conditions. The ascending salt water is the reason for the development of the inland salt marsh. A similar low-resistivity area at such great depths is located at 2.10 km to 2.50 km on the profile. However, since the profile ends there, detailed interpretation is speculative.

Overall, the ERT and TEM results are in very good agreement with the seismic interpretation, although no joint inversion was carried out, which would improve the quality of the datasets and their interpretation.

5.5 Interpretation of gravimetry

The prominent features on the Bouguer map (Fig. 9a) are in remarkably good agreement with the near-surface strata on the geological map (Fig. 1). The contours of the central positive Bouguer anomaly of +18 mGal (1 Gal = 0.01 m/s^2) clearly follow the outline of the Carboniferous (Kyffhäuser Formation) and Permian (Zechstein) rocks. The roundish negative anomaly of -8 mGal to the SW correlates with outcropping Triassic (Muschelkalk) formations, whereas the WNW–ESE strike direction of an elongated, central gradient zone matches the geometry of Tertiary and Quaternary sediments in the Esperstedter Ried.

Several spectral domain filters were applied in order to locate possible sources of gravity anomalies and to highlight fine changes in the gravity field. As an example, Fig. 9b shows the result of the so called 'tilt derivative' or 'tilt angle' filter (Miller & Singh, 1994), which is defined as

$$\Theta = \tan^{-1} \frac{\text{VDR}}{\text{THDR}},$$

where VDR is the first vertical derivative of the gravitational potential, which describes the vertical gravity component, and THDR is the total horizontal derivative, which describes the combined horizontal gravity components of the field vector in x-

and y-direction. This filter process generates maxima centered above the source of the anomaly. Its zero crossing is located close to the edges of source bodies. All amplitudes are restricted to values between $+\pi/2$ and $-\pi/2$ ($+90^\circ$ and -90°), thus suppressing strong amplitudes and amplifying weak amplitudes. The tilt-angle filter reveals an elongated source beneath the Kyffhäuser hills and a local low in the southern part of the Esperstedter Ried. In general, negative values correlate well with the location of Quaternary fluvial sediments of low density and areas with presumed mass loss due to dissolution of soluble rocks, while the majority of positive values surround Triassic, Permian and Carboniferous outcrops.

Quantitative interpretation was accomplished by iterative 2.5D forward modelling of the gravimetric profile GR (Fig. 9c, d). This simplified approach is suitable for the S–N profile, since the Bouguer anomalies depict an elongated structure of roughly 10 km length. It strikes nearly perpendicular to the profile, and therefore exhibits, as a first-order approximation, a 2D character. The modelling relies on the seismic interpretation of profiles P2 and S2 (Fig. 6). Additional structural information was obtained from a geological section of the region (Schriel & Bülow, 1926a, b). The densities used in the modelling are mean values from geophysical textbooks (e.g. Hinze et al. (2013)) and from forward modelling of adjacent areas (e.g. Gabriel et al. (2001), and references therein). The measured anomalies (red curve in Fig. 9c) show a strong positive anomaly of +18 mGal in the northern part of the profile, and decreasing values towards the south, reaching a minimum of 0.4 mGal. Three small-scale (short wavelength) minima and one large-scale (long wavelength) minimum are observed in the southern part.

The large-scale positive anomaly in the north results from the uplifted Kyffhäuser hills and the KSMF, a reverse fault, which is represented by high density Permian and Carboniferous strata, and the absence of low density rock salt in this region. The Kyffhäuser hills have only a thin cover of unconsolidated material, but consist of dense bedrock (e.g. conglomerate, anhydrite) close to the surface. The generally lower Bouguer values in the southern part result from a thicker cover of unconsolidated sediments, damage zones within the bedrock as observed in the seismic sections, the presence of low density material, especially Tertiary brown coal and Permian salt, and possible formation of open or filled cavities. Especially, the latter is interpreted as a result of the subrosion processes in ca. 300 m depth. South of the KSMF, three local small-scale minima are identified (Fig. 9c & d), which are not well explained by the modelling approach (blue curve in Fig. 9c) using constant densities for each layer. These minima correlate with subrosion-induced depressions and collapse structures imaged on the corresponding seismic profiles P2 and S2 (Fig. 6), therefore locally-varying densities are plausible, e.g. the Permian Zechstein of an area that is strongly affected by subrosion has a higher density (2600 kg/m^3) than in areas with less or no subrosion (2150 kg/m^3), due of the absence of salt, which has a low density (see, e.g. Müller et al. (2021)). Furthermore, between the two southernmost local minima (at ca. 3 km profile length), a weak positive local maximum is detected, which correlates with a high amplitude reflector of the top Permian in the seismic profile P2. This indicates less or no subrosion in this area compared to the northern part of the Esperstedter Ried. The observed misfit in the forward modelling, e.g. the difference between measured and calculated anomalies, suggests that locally limited areas with varying densities must be located in depths of e.g. 150 m to 250 m. Further to the north of the inland salt marsh one large-scale minimum is observed, which correlates with a basin-like structures identified in seismic section P2 (Fig. 6). Based on our results, we assume that it developed because of syn-sedimentary sagging due to

low mass movement induced by subrosion. The syn-sedimentary development enabled the accumulation of higher amounts of

Figure 9. Bouguer anomalies (a) show a positive anomaly for the Kyffhäuser hills and the tilt derivative (b; e.g. Miller & Singh (1994)) shows a negative anomaly for the Esperstedter Ried because of mass movement due to subsrosion and the accumulation of, e.g., Quaternary sediments with lower density. In the local Bouguer anomalies of the profile GR (c) three small-scale and one large-scale local minima are observed (d), which correlate with subsrosion-induced mass loss identified in the seismic sections P2 and S2. The legend contains the description of the modelled formations and their assumed densities taken from literature. The blue line in (a) and (b) is the gravimetric profile GR. The vertical exaggeration is 2:1.

unconsolidated Quaternary sediments and also Tertiary deposits with lower densities, compared to the surrounding areas. As a result, a large-scale minimum is seen in the gravity data at this location.

The results show that even large-scale gravimetry can help to identify possible areas affected by subrosion-induced mass movement.

6 Discussion

6.1 Conceptual subrosion-model of the Esperstedter Ried

To better understand the local subrosion-processes of the Esperstedter Ried the geological evolution of the region has to be first reconstructed. This includes the sedimentary depositional history and the development of large-scale geological structures, like faults or basins (McCann & Saintot, 2003), which can be identified directly using seismic and indirectly using gravimetric methods (Conrad, 1996; Hinze et al., 2013). These structures can have an influence on past and recent subrosion-processes, e.g., enhanced subrosion at faults (Closson & Abou Karaki, 2009; Del Prete et al., 2010; Ezersky & Frumkin, 2013a; Wadas et al., 2017). After reconstructing the general geological evolution of the Esperstedter Ried, the factors controlling the local subrosion will be outlined and a conceptual model will be presented.

In the Esperstedter Ried the P- and S_H -wave reflection seismics and the gravimetric investigation revealed large- and small-scale structures, like faults, fractures and thickness variations, delivering a structural model of the area. With regard to the fault development, it is known that from the Upper Cretaceous to the Lower Tertiary, the Kyffhäuser hills were upthrust and the KSMF developed (Freyberg, 1923; Seidel, 2003). This fault has a Hercynian strike, which can be observed in the geological map of Bad Frankenhausen (Schriel & Bülow, 1926a, b) and in the gravimetry data (Fig. 9). This preferred Hercynian strike direction of northern Germany can also be observed in the formations shown in the reflection seismic profiles P2 and S2 (Fig. 6), in which other faults were identified that transverse the profiles, cut the Lower Tertiary, and show approximately a NW–SE strike. It has to be noted that the Bouguer anomaly maps shown in this study have a resolution limit of 1 km and therefore cannot image this scale of faulting.

Furthermore, we assume that the uplift of the Kyffhäuser hills led to flexural isostasy (Watts, 2001) in the southern foreland and therefore regional, large-scale subsidence, which has to be distinguished from the local subrosion-induced subsidence.

After Weber (1930), subrosion-induced sagging/subsidence can be subdivided into three phases: (1) dissolution of salt, (2) hydration of anhydrite and transformation into gypsum, and (3) leaching of gypsum. During the first phase, planar cavities are formed along the salt layer resulting in local sagging and during the third phase funnel-shaped cavities are formed and after collapse they form a sinkhole. These three phases can be identified in the Esperstedter Ried, utilizing the seismic sections (Figs. 5 & 6) and the gravimetric modelling results. They enabled the identification of large sagging structures, e.g. visible by thickness variations (explained in more detail below) and salt water ascension that represent the first phase, and mass movement and collapse structures that represent the third phase. These structures can be correlated with local minima of the Bouguer anomaly (Fig. 9), which is evidence of mass movement and mass removal. Altogether this proves the assumption of subrosion-induced subsidence at the Esperstedter Ried.

Overall, the Permian, Triassic and Tertiary formations show thickness variations across the study area. Except for local variations, a general decrease in thickness from south to north, towards the KSMF, is observed for the Permian and Triassic

deposits. The thickness variation of the Triassic is probably a result of erosion after deposition and a varying accommodation space during deposition, but the thickness variations of the Zechstein are mostly the result of ~~subrosion~~. Since faults are able to enhance ~~subrosion~~ (Closson & Abou Karaki, 2009; Del Prete et al., 2010; Ezersky & Frumkin, 2013a; Wadas et al., 2017), the leaching process is more intense close to the KSMF and more salt and gypsum are dissolved leading to mass movement and a decrease in thickness of the Zechstein formation. Other reasons, such as active diapirs and salt movement, as reasons for the Zechstein thickness variations can be excluded. According to the geological map, the top Carboniferous is found in ca. 550 m depth and the thickness of the Permian is expected to be between ca. 350 m to 400 m. The salt in the Permian deposits needs to be much thinner, so even if the top Carboniferous varies in depth it is highly unlikely that the salt layer would be thick enough to form active diapirs (Schultz-Ela et al., 1993; Jackson et al., 1994). Salt movement due to increased differentiated load is also unlikely, because areas with a thicker Triassic Buntsandstein do not correlate with areas of thinner Permian deposits (Schultz-Ela et al., 1993), instead the opposite is observed. However, the thickness of the Triassic sandstones does have an influence on the formation of ~~subrosion~~-induced structures. Great thicknesses of a compact rock are relatively stable against ~~subrosion-induced~~ subsidence and collapse, because even when cavities are formed in the Zechstein formations beneath, the sediments above the cavity would form a structural arch (Waltham et al., 2005), which prevents collapse and subsidence. Whereas low thicknesses of the Triassic sandstones increase the possibility of cavity collapse and local subsidence, which is the case in the Esperstedter Ried. Further evidence for the long lasting subsidence is given by the Tertiary brown coal that was deposited during the Oligocene, and which shows a varying thickness and a dip variation of 10° to 60° (Frank, 1845). It is unlikely that the brown coal was deposited with such a high dip, so we assume that the brown coal thickness variations are a result of continued ~~subrosion-induced~~ sagging during deposition, with thinner brown coal at the basin margins and thicker brown coal at the basin centre.

A better understanding of ~~especially~~ the recent local ~~subrosion~~ processes, however, also requires detailed knowledge about the fluid pathways and the localization of ~~subrosion~~ zones. This was accomplished using ERT/TEM, and seismic facies analysis of P- and S_H -waves. The top of the soluble Permian rocks was detected at 250 m to 300 m depth, so near-surface ~~subrosion~~, as it is the case for the town of Bad Frankenhausen, north of the KSMF (Wadas et al., 2016; Kobe et al., 2019), is not possible. The unsaturated groundwater needs to reach greater depths in order to leach the evaporites such as salt and anhydrite. One of this groundwater levels is detected in 150 m to 200 m depth according to the TEM data, which shows a low resistivity zone in this depth. Regarding this, downward water flow through a fracture network is required for ~~subrosion~~ (Billi et al., 2007). Although this process takes place mostly at shallower depths, a correlation between fractures and ~~subrosion~~ features is observed for the Esperstedter Ried from the seismic facies analysis. The low resistivity zone of the TEM data is connected with the soluble rocks through a fractured seismic facies of the Triassic and Lower Tertiary, as shown in the S-wave data (Fig. 7). Faults are also very important for vertical water flow, and this is shown by the ERT data. At faults the water can migrate downwards and dissolve the deeper soluble rocks, as observed in seismic profile P2 and the ERT (Figs. 6 & 8), where below the sagging structures steep faults crosscut the Tertiary, Triassic and probably Permian deposits, and serve as large fluid pathways. The water can also migrate upward along the fault planes (Legrand & Stringfield, 1973) and fractures (Pusch et al., 1997; Westhus et al., 1997), mostly due to artesian-confined groundwater flow towards the surface, as is the case for the Esperstedter Ried.

The ERT identified an area of low resistivity at the surface between 3.9 km and 4.7 km profile length, which is the centre of the inland salt marsh (Fig. 8). Besides the fluid pathways, possible ~~subrosion~~ zones have also been identified by the P-wave reflection seismic profiles and the ERT. Areas affected by ~~subrosion~~ show a less pronounced top Zechstein reflector, and a lower resistivity. The leaching and the mass movement destroy the layer boundary and the layering of the Zechstein, therefore no continuous reflector can be observed (e.g. below the large sagging structure to the north of P2). The opposite is visible in the south of P2, where a strong impedance contrast without a low resistivity zone is imaged for the top Zechstein, indicating less ~~subrosion~~.

Altogether, the tectonic and depositional history indicate that ~~subrosion was~~ probably triggered by tectonic movements and fault development and therefore, ~~was~~ probably most active during and after the tectonic phases of the Tertiary, but ~~it is~~ still ongoing, as ~~it is~~ evidenced by continuous salt water ~~ascension~~ at the Esperstedter Ried (TMLNU, 2008) and recent subsidence and sinkhole development (Jankowski, 1964; Wadas et al., 2016; Kobe et al., 2019).

6.2 Workflow for ~~geophysical investigations of subrosion areas~~

Based on the results of this study, we propose that our combined geophysical approach is suitable to generally investigate ~~subrosion~~ areas and to create conceptual models that describe the factors controlling ~~subrosion~~-induced subsidence and sinkhole formation, which also help to identify ~~risk~~ areas. Our recommended workflow (Fig. 10) will be explained in the following, including conditions and limitations of the proposed methods that have to be kept in mind.

Reflection seismics is the preferred method to identify sagging- and collapse structures, and also faults and fractures, even in urbanized regions, as other studies have shown for P-waves (e.g. Steeples et al. (1986); Evans et al. (1994); Miller & Steeples (2008); Keydar et al. (2012)) and for S-waves (e.g. Miller et al. (2009); Pugin et al. (2013); Polom et al. (2016); Wadas et al. (2016); Polom et al. (2018)). Especially the combined approach of using P- and S_H -waves in this study improves the understanding of local ~~subrosion~~ structures. With the P-wave reflection seismics large-scale and with the S_H -wave reflection seismics small-scale structures can be identified. But since ~~subrosion~~ results in strong vertical and lateral variations of the underground, a densely-spaced seismic survey has to be acquired in order to image these variations. Furthermore, the penetration depth of the seismic waves has to be considered. Shear-waves can image the underground at higher resolution than P-waves in the case of water-saturated and unconsolidated sediments, but the penetration depth is lower. As a result, with the equipment used in this study, shear-wave reflection seismics is able to image the underground down to ca. 300 m depth and the P-wave reflection seismics delivers images from ca. 30 m below surface to ca. 400 m to 500 m depth. Another seismic source with a higher energy transmission might solve this problem, and to detect smaller ~~subrosion~~ features at the near-surface higher sweep frequencies, and at least a smaller source and receiver spacing should be used. The seismic facies analysis has shown that one and the same facies unit can have different characteristics, depending on the wave-type applied, but both, P- and S_H -wave reflection seismic methods combined, can give valuable information about ~~subrosion~~ and fracture zones, and therefore potential fluid pathways. With a combined approach the advantages of both methods can be used to create a structural model covering a wide range of scales from deep and large-scale structures to near-surface and small-scale features. Based on such a sophisticated structural model, the sedimentary depositional history can be reconstructed.

Another type of geophysical methods are geoelectric (e.g. ERT) and electromagnetic (e.g. TEM) techniques. ERT has shown to be useful in identifying aquifers and fluid pathways in karst regions (e.g. Militzer et al. (1979); Bosch & Müller (2001); Miensopust et al. (2015)), especially in combination with seismic methods that deliver structural constraints (e.g. Sandersen & Jørgensen (2003); Bosch & Müller (2005); Tanner et al. (2020)). The advantage of TEM over ERT is the improved resolution in the near-surface down to ca. 300 m depth, but without ERT the information about the electrical resistivity in greater depths e.g. 400 m to 500 m would be missing, where ~~subrosion~~ at faults may occur at greater depths. In general, ERT is better suited to detect lateral resistivity variations, whereas TEM is highly sensitive to conductive structures. Similar to seismic methods, the source and receiver spacing is the determining factor for the possibility to detect aquifers, fluid pathways, or ~~subrosion~~ zones. In this study, the spacing of 200 m for the ERT and of 50 m for the TEM survey was sufficient to recover larger ~~subrosion~~ features (e.g., the low resistivity zone at the fault in profile P2 at 5.60 km profile length), but targeting near-surface, small-scale ~~subrosion~~ zones would require survey layouts with denser source and receiver spacings. It is also necessary to note, that ERT has a restricted applicability in urban areas due to disturbances by electromagnetic noise. In contrast Rochlitz et al. (2018) demonstrated that the inversion results of a SQUID-based TEM exhibits a higher consistency between neighboring stations and less artifacts caused by anthropogenic noise compared to classical coil-based TEM. The identified aquifers and salt-water bearing areas combined with the structural model can ~~than~~ be used to derive a hydrological model. From this ~~hydrological model~~, together with the reconstructed sedimentary facies and depositional history of the region, the fluid pathways and ~~subrosion~~ zones can be derived.

Both reflection seismic- and electromagnetic methods do not deliver information about local mass movements or cavities ~~induced by subrosion~~. For this gravimetry is the preferred method for near-surface investigations in order to depict density contrasts and local gravity anomalies (e.g. Butler (1984); Kersten et al. (2017); Kobe et al. (2019)). In our study, we show that structures and zones affected by ~~subrosion~~ as identified by the reflection seismic- and electromagnetic methods correlate with local minima of the Bouguer anomaly due to reduced densities. Therefore, the gravity data together with the structural model can be utilized to get a density-distribution model of the subsurface from which the local mass movement can be deduced. The station spacing for the gravimetry profile in this study was 100 m, which was appropriate to detect mass movement on a larger scale (e.g. the near-surface collapse structures producing local minima had a lateral extent of at least ca. 100 m), but in case of the detection of small-scale ~~subrosion~~, as it is necessary for urban environments, we suggest to use a smaller station spacing (e.g. < 50 m).

By combining all the models/results the local control factors of ~~subrosion-induced~~ subsidence and sinkhole formation can be determined and ~~risk~~ areas can be identified (Fig. 10).

7 Conclusions

The initial trigger of ~~subrosion~~ at the inland salt marsh of the Esperstedter Ried were the tectonic movements during the Tertiary, which led to the uplift of the Kyffhäuser hills and the formation of faults parallel and perpendicular to the low mountain range. The faults and the fractured Triassic and Lower Tertiary deposits serve as fluid pathways for groundwater to leach the deep

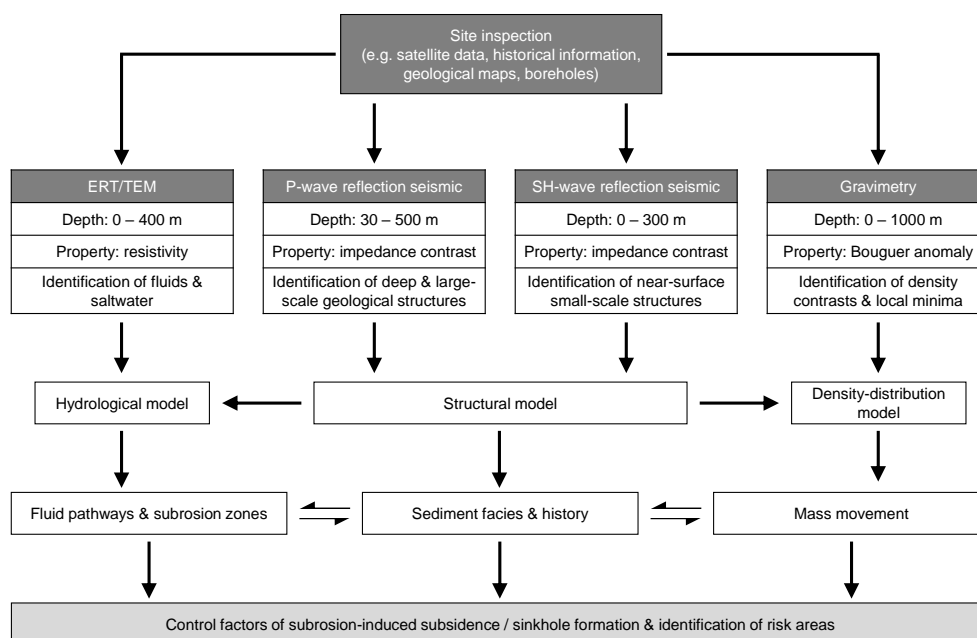

Figure 10. Recommended workflow for geophysical investigations of subrosion areas to determine controlling factors and risk areas.

Zechstein deposits, since subrosion is more intense near faults. The artesian-confined salt water ascends towards the surface along the faults and fracture networks, which formed the inland salt marsh over time. In the past, subrosion of the Zechstein formations formed, now buried, sagging and collapse structures, but subrosion features are also found near the surface and, since the entire region is affected by recent sinkhole development, subrosion must be still ongoing.

We show that the combined analysis of P-wave and S_H -wave reflection seismics is well suited to develop a structural model and locate buried subrosion structures, subrosion zones, faults and fractures, and potential aquifers and aquitards, on the basis of seismic facies analysis. To get a better insight into the hydrological conditions of an investigation area, ERT/TEM are effective in identifying and characterizing aquifers, aquitards, fluid pathways and subrosion zones. Further improvement is accomplished by including gravimetry to identify density contrasts and to detect subrosion-induced mass movement. Based on our results, we suggest a combined geophysical investigation of subrosion areas to identify controlling factors and risk areas to better understand the subrosion processes.

In a next step, the structural and physical and geological constraints derived from our proposed geophysical investigation workflow described above, could be used as input parameters for numerical modelling. Numerical modelling is widely used to better understand, e.g., physio-chemical or mechanical processes. In the context of subrosion, numerical modelling is applied to, e.g., simulate the time-dependent dissolution processes and the collapse mechanisms of sinkholes (Parise & Lollino, 2011; Salmiet al., 2017; Al-Halbouni et al., 2018; Shiau & Hassan, 2021). Important structural input parameters from our recommended workflow are layer boundaries, facies types, faults, fractures, and sinkhole geometries. In addition, density and electrical resistivity values, and elastic parameters can be used as physical constraints, in order to depict, e.g., the mechanical

strength of the modelled layers/formations. The derived geophysical and structural constraints could also be extended by adding a time component in the form of repeated surveys that enable the detection of time-varying parameters (e.g. mass loss rates and fracture propagation; e.g. Herwanger et al. (2013); Kobe et al. (2019)), which would enhance risk scenario simulations.

545 Furthermore, the presented workflow could also be applied to investigate other geohazards with similar controlling factors, such as landslides (Malehmir et al., 2016), which are affected by subsurface structures and facies distribution, ground stability of the layers/formations, hydrological conditions, e.g., fluid pathways, and mass redistribution.

Data availability. The seismic, ERT and TEM data are the property of LIAG. The data are available from the first author upon request. Please contact Sonja H. Wadas for details. The gravimetry data is the property of the Thuringian State Institute for Environment, Mining and

550 Conservation.

Author contributions. The seismic data was conducted by SW, HB and UP, and LIAG's seismic field crew. Data processing of the S_H -wave seismic data was carried out by SW and data processing of the P-wave seismic data was carried out by HB. The seismic facies was analyzed by SW. The ERT and TEM data was surveyed by RR, TG and MG, and inversion of the ERT data was carried out by TG and processing of the TEM data was performed by RR. The modelling of the gravimetry data was carried out by PS. All authors contributed to the interpretations.

555 SW created all figures except for figure 8 which were created by RR and TG. SW prepared and discussed the results with all co-authors. SW wrote the manuscript and all co-authors inspired and improved the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We thank our colleagues Jan Bayerle, Dieter Epping, Eckhardt Großmann, Siegfried Grüneberg, Robert Meyer, Frank Oppermann, Wolfgang Südekum and Sven Wedig for their excellent work during the field surveys. Furthermore we thank Lutz Katzschmann, Sven Schmidt and Ina Pustal from the Thuringian State Institute for Environment, Mining and Conservation for supporting this work and providing the gravity data. Further thanks go to Ronny Stolz and Andreas Chwala from IPHT Jena and Supracon AG Jena for conducting the TEM survey, which was funded by the Federal Ministry of Education and Research (BMBF), as part of INFLUINS under BMBF grant 031S2091A. We thank Matthias Queitsch and Nina Kukowski from University of Jena for their advice on TEM data processing and interpretation as well as Pritam Yogeshwar and Sascha Janser from University of Cologne for providing the inversion code EMUPLUS.
