Reduced surface fine dust under droughts over the southeastern United States during summertime: observations and CMIP6 model simulations

Wei Li[1] and Yuxuan Wang[1]

Abstract. Drought is an extreme hydroclimate event that has been shown to cause the increase of surface fine dust near source regions, while the drought-dust relationship in regions predominantly influenced by long-range transported dust such as the southeastern US (SEUS) has received less attention. Using long-term surface fine dust observations, weekly US Drought Monitor (USDM), and monthly Standardized Precipitation-Evapotranspiration Index (SPEI), this study unmasks spatial disparity in drought-dust relationships where the SEUS stands out as being abnormous in that it shows a decrease in surface dust concentrations during drought in contrast to the expected increase in dust found in other contiguous US (CONUS) regions. Surface fine dust was found to decrease by ~0.5 $\mu g/m^3$ with a unit decrease of SPEI in the SEUS, as opposed to an increase of ~0.15 $\mu g/m^3$ in the west. The anomalies of elemental ratios, satellite aerosol optical depth (AOD), and dust extinction coefficients suggest that both the emissions and trans-Atlantic transport of African dust are weakened when the SEUS is under droughts. Through the teleconnection patterns of negative North Atlantic Oscillation (NAO), a lower than normal and more northeastward displacement of the Bermuda High (BH) was present during SEUS droughts which resulted in less dust being transported into the SEUS. At the same time, enhanced precipitation in Sahel associated with the northward shift of the Intertropical Convergence Zone (ITCZ) leads to lower dust emissions therein. Of the four selected models participating in the sixth phase of the Coupled Model Intercomparison Project (CMIP6), GISS-E2-1-G was found to perform the best in capturing the drought-dust sensitivity in the SEUS. This study reveals the mechanism of how regional-scale droughts influence aerosol abundance through changing long-range transport of dust.

1 Introduction

Mineral dust plays an important role in the climate system by modifying the Earth's energy budget through direct aerosol-radiation forcing and indirect aerosol-cloud interactions (Tegen et al., 1996; Sassen, 2002; Carslaw et al., 2010). Fine mode mineral dust with an aerodynamic diameter of less than 2.5 µm can be transported over long distances and has a wide-ranging socioeconomic effect such as degeneration of air quality, disruption of public transport by poor visibility, and reduction of soil productivity (Middleton, 2017). Dust events can also be linked with a higher risk of valley fever and other respiratory and cardiovascular diseases (Karanasiou et al., 2012; Tong et al., 2017), and more non-accidental mortality (Crooks et al., 2016). Lifted by strong winds from arid and bare land, dust particles in the atmosphere are significantly modulated by hydroclimate variables, such as precipitation, temperature, relative humidity, and soil moisture (Achakulwisut et al., 2017; Brey et al., 2020; Pu and Ginoux, 2018). Thus, drought, as a recurring hydroclimate extreme, can impose large changes on the abundance of dust particles in the atmosphere. As the contiguous United States (CONUS) is prone to droughts and projected to be warmer and dryer in the future (Cook et al., 2015), it is essential to quantify the drought-dust relations and evaluate the ability of climate models to capture such relations to better understand the climate-dust feedbacks.

Most of the previous studies of drought-dust sensitivity in the US focused on the southwest (Aarons et al., 2019; Achakulwisut et al., 2018, 2019; Arcusa et al., 2020; Borlina and Rennó, 2017; Kim et al., 2021) where the major dust emission sources are located (e.g. the Chihuahuan, Mojave, and Sonoran Deserts). For example, Achakulwisut et al. (2018) quantified an increase of fine dust by 0.22–0.43 $\mu g/m^3$ with a unit decrease of two-month Standardized Precipitation-Evapotranspiration Index (SPEI) over the US southwest across the seasons. Both observations (Aarons et al., 2019) and simulations (Kim et al., 2021) have shown that the dust enhancement under droughts can be attributed to the simultaneous increase of local dust emissions and long-range transport of dust from Asia. The observed drought-dust relationship can be used as a process-level metric to evaluate dust simulation in coupled chemistry-climate models and Earth system models. For example, a recent evaluation of dust emissions in 19 models participating in the sixth phase of the Coupled Model Intercomparison Project (CMIP6) found that interannual variations of dust emissions simulated by these models are strongly correlated with drought over major dust source regions (Aryal and Evans, 2021).

While the abovementioned studies improved our understanding of dust-drought relationships in dust source areas, regions predominantly influenced by long-range transported dust such as the southeastern US (SEUS) have received less attention. The dusty Saharan air from western Africa can reach the US southeast during boreal summer through long-range transport across the tropical Atlantic Ocean and Caribbean Basin (e.g., Perry et al., 1997; Prospero et al., 2010). Fine dust is estimated to contribute to 20-30% of the total particulate matter smaller than 2.5 µm (PM2.5) aerodynamic diameter at the surface in the southeast during summertime (Hand et al., 2017). Extreme "Godzilla" dust events have occurred in recent years, leading to considerably worse air quality in the southeast region (Yu et al., 2021). Our previous study (Wang et al. (2017) estimated that growing-season (March-October) droughts during 1990-2014 caused an average fine dust increase of 27% in the west and 16% in the Great Plains, with a much lower effect on fine

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

dust in the southeastern and northeastern US. That study used a coarse time scale (i.e., averaging of the eight-month growing season) which may not fully capture the episodic nature of dust emissions or dust transport.

Here we improve upon previous studies by using drought and dust datasets of better spatial coverage and finer temporal scales (Section 2). In Section 3.1, we first examine how the spatial distributions of surface fine dust change with weekly and monthly drought indices over the CONUS. The finer-scale analysis unmasks spatial disparity in drought-dust relationships where the SEUS stands out as being abnormous in that it shows a decrease in surface dust concentrations during drought in contrast to the expected increase in dust found in other CONUS regions. We then focus on the southeast, an area largely overlooked by prior studies of dust response to drought, and investigate in Section 3.2 how drought conditions in the SEUS affect the trans-Atlantic transport of African dust.

Among the surface fine dust measurement datasets examined in this study, the Barbados site located in the eastmost of the Caribbean Windward Islands is the only long-term site on the main outflow pathway of African dust to the SEUS, which is suitable to evaluate dust-drought relationships simulated by coupled climate-chemistry models. The surface dust mass concentration has been continuously measured at the Barbados site since August 1965. This rare and unique dataset was widely used to improve our understanding of the variations of African dust transport and model evaluations (Chiapello et al., 2005; Prospero and Nees, 1986; Zuidema et al., 2019). Given the correct sensitivity of dust emissions to drought in CMIP6 models (Aryal & Evans, 2021), in Section 3.3 we use the dust-drought relationship at the Barbados site to evaluate the performance of four CMIP6 models in capturing the drought-dust sensitivity in the SEUS.

2 Data and Methods

The datasets and related variables used in this study were summarized in Table S1-2 with details given below.

2.1 Drought indicator

The US Drought Monitor (USDM) index was selected as the primary drought indicator because it incorporates not only objective indicators but also inputs from regional and local experts around the country (Svoboda et al., 2002). USDM maps have been released every week from 2000 to the present on its website (https://droughtmonitor.unl.edu/). There are five dryness categories in the map, labeled Abnormally Dry (D0), Moderate (D1), Severe (D2), Extreme (D3), and Exceptional (D4) Drought. We converted these maps into 0.5° × 0.5° gridded data and combined D2-D4 levels as "severe drought" due to limited data availability caused by their low spatial coverage if treated individually (Li et al., 2022). Non-drought (wet and normal) conditions, denoted as N0, are defined when a grid is not under any of the five dryness categories. There are 262 weeks in total during our study period of 2000 to 2019 summers (June, July, August; JJA). To compensate for the categorical nature of the USDM data, one-month gridded SPEI data from the global SPEI database (http://sac.csic.es/spei/) with a spatial resolution of 0.5° × 0.5° and temporal range of 1973-2018 was also used to conduct statistical analysis (e.g., correlation and regression). The criteria of SPEI < -1.3 and

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

SPEI > -0.5 were applied to denote severe drought and non-drought conditions, respectively, as suggested by Wang et al. (2017).

2.2 Surface dust and satellite products

To expand the spatial coverage, we created a gridded daily fine dust dataset (1° × 1°) that aggregates site-based observations from both US Environmental Protection Agency Chemical Speciation Network (EPA-CSN) and the Interagency Monitoring of Protected Visual Environments (IMPROVE) networks using the modified inverse distance weighting method as done by Schnell et al., (2014). These two datasets have been widely used by previous studies to investigate surface fine dust variations (Achakulwisut et al., 2017; Hand et al., 2017; Kim et al., 2021). The gridded dust data was further remapped through bilinear interpolation to match the spatial resolution of the USDM and SPEI data. We used the latest version of total surface dust data at the Barbados site (Figure 4b) created and published by Zuidema et al. (2019). The Barbados JJA monthly data was averaged from at least 20 daily samples in each month between 1973 and 2014.

To examine the westward transport of African dust, Level3 daily aerosol optical depth AOD (550nm) retrieved from Moderate Resolution Imaging Spectroradiometer (MODIS) aboard Aqua (MYD07_D3 v6.1) and Terra (MOD08_D3 v6.1) with a resolution of 1° × 1° from 2003 to 2019 are combined (Payra et al., 2021; Pu and Jin, 2021). Level3 monthly cloud-free dust extinction coefficients at 532nm between 2006 and 2019 from Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) satellite were also used to analyze the vertical profiles of trans-Atlantic dust plumes. The CALIPSO data was obtained from https://asdc.larc.nasa.gov/project/CALIPSO with a 2° × 5° horizontal grid and a vertical resolution of 60 m up to 12km from the ground.

2.3 Meteorological data

To analyze the emission and transport of African dust, several meteorological variables were applied. Daily precipitation was taken from the Global Precipitation Climatology Project version 1.3 (GPCP V1.3). The data is a satellite-based global product from 1996 with a 1° x 1° spatial resolution. Other variables, including zonal (U) and meridional (V) winds, and geopotential height at different pressure levels were from the European Centre for Medium Range Weather Forecast (ECMWF) reanalysis version5 (ERA5) dataset. Weekly data was averaged from hourly data with a resolution of 0.25° x 0.25°. Monthly North Atlantic Oscillation (NAO) data was obtained from the Climate Research Unit (CRU) calculated as the difference of normalized sea-level pressure between Azores and Iceland (Jones et al., 1997).

2.4 CMIP6 models

Four models from the CMIP6 Aerosol Chemistry Model Intercomparison Project (AerChemMIP) were selected: CNRM-ESM2-1, GFDL-ESM4, GISS-E2-1-G, and MRI-ESM2-0. They are the only models found with surface dust outputs from historical simulations with prescribed sea surface temperature. All the model outputs cover the period of 1850 to 2014. Dust emissions are interactively calculated based on factors such as surface wind speed, soil type, and

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

aridity. Dust particles are resolved to different size bins ranging from 0.01 to 32 μm in diameter. More information and references (Dunne et al., 2020; Kelley et al., 2020; Séférian et al., 2019; Yukimoto et al., 2019) for each model are listed in Table S2.

3 Results

3.1 Reduced dust in the southeast under droughts

Figure 1a shows the mean summertime (JJA 2000 – 2019) surface fine dust concentrations under non-drought conditions (N0) and their changes under severe droughts (D2-D4) relative to non-drought. Higher concentrations (~2 μg/m^3) can be found in the southwest and southeast regions under non-drought conditions, reflecting the average spatial distributions of summertime dust. Under severe droughts, most of the grids/sites display an enhanced dust level, with the highest enhancement (~1.5 μg/m^3) occurring near the source regions in the southwest (e.g., Arizona and New Mexico). This indicates higher local dust emissions under droughts, which can be attributable to regional precipitation, bareness, wind speed, and soil moisture anomalies (Achakulwisut et al., 2017; Kim et al., 2021; Pu and Ginoux, 2018). By contrast, reduced fine dust is shown in the southeastern grids/sites under severe drought, especially for the ones near the coast. Density plots in Figure 1b illustrate that the overall gridded dust distributions under severe droughts across the CONUS move towards the high end compared with non-drought conditions, with an increase of the mode and mean value by ~0.12 μg/m^3 and ~0.20 μg/m^3, respectively. Conversely, dust distributions over the southeast (25◦-33◦N, 100◦-75◦W; black box in Figure 1a) move to the low end with a respective decrease of the mode and mean value by ~0.41 μg/m^3 and ~0.23 μg/m^3. To test whether the spatial interpolation process could potentially cause bias due to the low site numbers over the southeast region, Figure 1b also plots the density distribution using on-site IMPROVE data. Similar distributions can be seen between the gridded and on-site data, except that the latter shows a "fatter" (more variable) distribution. This indicates that the interpolation did not significantly affect the results.

Preprint. Discussion started: 28 February 2022

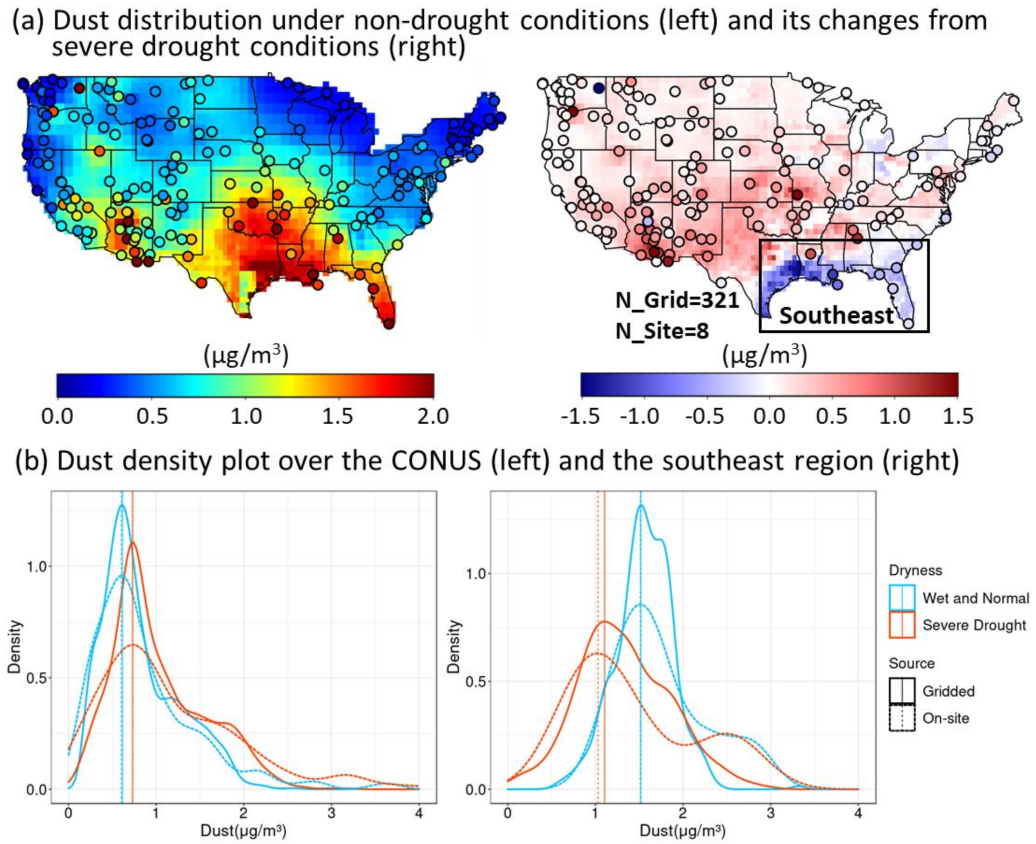

Figure 1. (a) Maps of the mean gridded and in-situ (dots) fine dust under USDM-based non-drought (wet and normal) conditions (left) from 2000 to 2019 and its changes from severe drought conditions (right). The number of grids (sites) within the southeast region is denoted by N_Grid (N_Site). (b) Comparisons of density distributions of gridded (solid lines) and in-situ (dash lines) fine dust concentrations under drought (red lines) and non-drought (blue lines) conditions over the CONUS (left) and southeast region (right), respectively. Vertical dash and solid lines indicate the modes.

We also reproduced the above analysis using SPEI-based monthly drought criteria and similar results were found (Figure S1). The consistency indicates the drought-dust relationship can be captured on both a weekly and monthly scale. To further quantify the drought-dust relationship, we conducted a linear regression between SPEI and dust concentrations, taking advantage of the non-categorical nature of SPEI. The slopes of the regression at each grid were shown in Figure 2a. Almost all the grids in the western CONUS have significant negative slopes at a 95% confidence level. As negative SPEI values indicate drought, these negative slopes reveal an increasing level of dust with dryer conditions. The highest value about -0.6 μg/m^3 per SPEI unit occurs in Arizona, which is also indicative of higher dust emissions consistent with the composite analysis in Figure 1. However, not all the grids in the southeast exhibit significant positive slopes as expected from Figure 1. This may imply a non-linear relationship that cannot be identified via composite analysis. To better explain this, we compared how the regional mean dust concentrations vary with SPEI bins between the southeast (same as Figure 1) and west (100∘W westwards) in Figure 2b. A clear nonlinear

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

pattern is revealed for the southeast with dust decreasing with the absolute value of SPEI in both wet (SPEI > 0.5) and dry (SPEI < -0.5) portions. By contrast, the west exhibits a linear relationship throughout the SPEI range. Decreasing dust conditions with increasing wetness (SPEI > 0) is expected as dust in the atmosphere can be largely washed out by precipitation under wet conditions. However, including SPEI bins larger than zero would result in a near-zero slope from the linear regression in the southeast. To avoid this, we conducted the linear regression using only the lowest four SPEI bins under dry conditions (SPEI < 0.5). The resulting regression slope is 0.49 μg/m^3 per unit of SPEI for the southeast and -0.15 μg/m^3 per unit of SPEI for the west, respectively. As SPEI is more negative with increasing dryness, the positive slope in the southeast means a decrease of dust with increasing dryness which is consistent with the result from Figure 1 based on USDM. Hereafter we focused on the southeast region and investigated why surface fine dust in this region shows an opposite response to droughts compared with other CONUS regions.

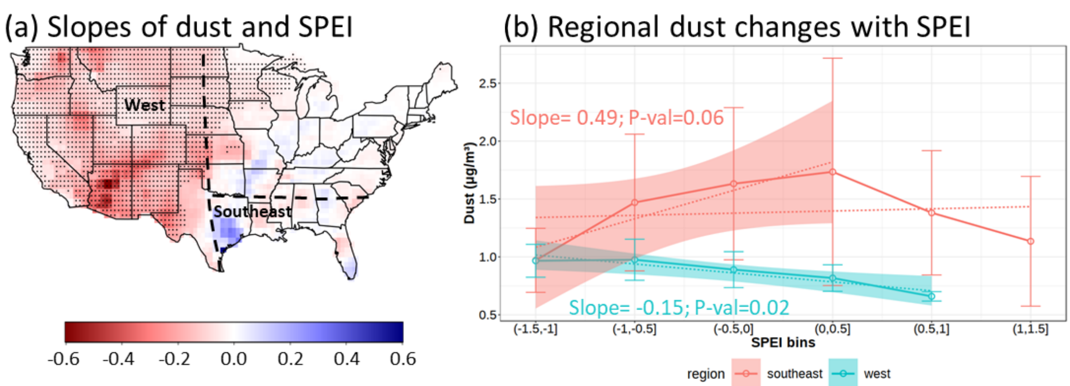

Figure 2. (a) Maps of the linear regression slopes between fine dust concentrations and SPEI. Black dots denote the grids with regression significance at a 95% confidence level. Dash lines mark the boundaries of the west and southeast regions. (b) Reginal average dust varies with SPEI bins over the west and southeast with error bars indicating one standard deviation. Dash lines display linear regression results with shadings showing the 95% confidence level. The numbers indicate the slopes and P-values (P-val) of the regression using all the SPEI bins in the west and only the first four bins in the southeast.

Dust elemental ratios contain important information signifying the dust particle origins (e.g., local or transport). African dust, relative to Asian and local dust, normally has higher Fe:Ca (> 1.50) and Al:Ca (> 2.60) ratios, and lower K:Fe (< 1.10) and Si:Al (< 2.90) ratios (Aldhaif et al., 2020; Gonzalez et al., 2021; VanCuren and Cahill, 2002). Based on these reported thresholds, we analyzed dust elemental observations at eight sites within the southeast region (Figure 1a) and compared how the elemental ratios changed under severe drought based on the USDM drought indicator. The results are displayed in Figure 3, with more statistical descriptions listed in Table S3. Under non-drought conditions (wet and normal), the ratios are generally within the typical ranges mentioned above, indicating the dominance of African dust over Asian dust and locally-emitted dust as reported by other studies (Aldhaif et al., 2020; VanCuren and Cahill, 2002). Under severe drought, Fe:Ca and Al:Ca become lower; K:Fe and Si:Al become higher, and all these changes are in the direction of reducing the characteristic elemental ratios of African dust. Most of the Fe:Ca, Al:Ca, and K:Fe ratios under severe drought have their medians falling below the reported thresholds of African dust. This

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

indicates a significantly reduced dust source from Africa. As dust deposition is unlikely to increase under drought conditions, the lower African dust signature in surface dust under severe drought is most likely attributable to the reduced import of African dust to the SEUS, which is discussed below.

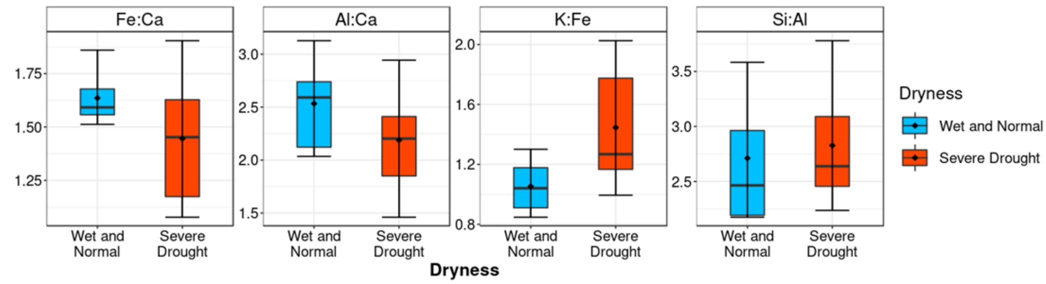

Figure 3. Boxplots of four dust elemental ratios under non-drought (wet and normal) and severe drought conditions. Observations are from eight IMPROVE sites in the southeast region shown in Figure 1a. The upper and lower whiskers of the boxplots represent the ninth and first quantile, respectively. Black dots indicate the mean values. Detailed values of this figure can be found in Table S3.

3.2 Weakened trans-Atlantic dust transport under droughts

In this section, we examined how the trans-Atlantic transport of African dust changes with droughts in the southeast region. To do so, we first selected regional-scale drought events to better depict the aridness across the southeast, and then associated these events with the long-range transport of African dust and compared them with regional-scale non-drought events. Regional severe drought (non-drought) events were identified when more than 30% (70%) of the southeastern grids are under D2-D4 (N0) on a weekly scale (USDM-based), or when the regional-mean SPEI is within (out of) the lowest 20% percentile during the study period (dependent on data records) on a monthly scale (SPEI-based). The time series in Figure 4a shows that the regional drought events mainly occurred in 2000, 2006, 2007, and 2011 JJA.

Maps of MODIS AOD under non-drought conditions and its changes during severe droughts are shown in Figure 4b. Horizontally, the major transport pathway of the dusty African air is within 10◦-20◦N, 100◦-0◦W (red box), indicated by the high AOD values greater than 0.15. The dust flow, emitted from northern Africa (e.g., Sahara Desert and Sahel), travels through the tropical Atlantic, Caribbean Sea, Gulf of Mexico and reaches the SEUS. Under droughts, almost all the AOD values along the pathway show negative differences, which indicates both the African dust transport and emissions (mainly from the Sahel) are depressed when the SEUS is under droughts. To better present the transport pathway, we also examined the vertical profiles of the dust extinction coefficient from CALIPSO along the pathway (Figure 4c). Since the CALIPSO data is monthly, we used the SPEI-based drought events definition here. The dust particles can be injected up to ~4km altitude from the source region through strong desert surface heating (Alamirew et al., 2018; Flamant et al., 2007), low-level wind convergence (Bou Karam et al., 2008), synoptic-scale disturbance (Knippertz and Todd, 2010) and other processes (Francis et al., 2020), and then descend to lower levels as they travel westwards. Such vertical structures have been discerned by previous studies (Prospero and Mayol-Bracero, 2013;

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

Ridley et al., 2012). Similar to Figure 4b, a decreased dust extinction coefficient was found along the vertical transport pathway, which verifies the conclusion that both the transport and emissions of African dust are weakened when the SEUS is under droughts.

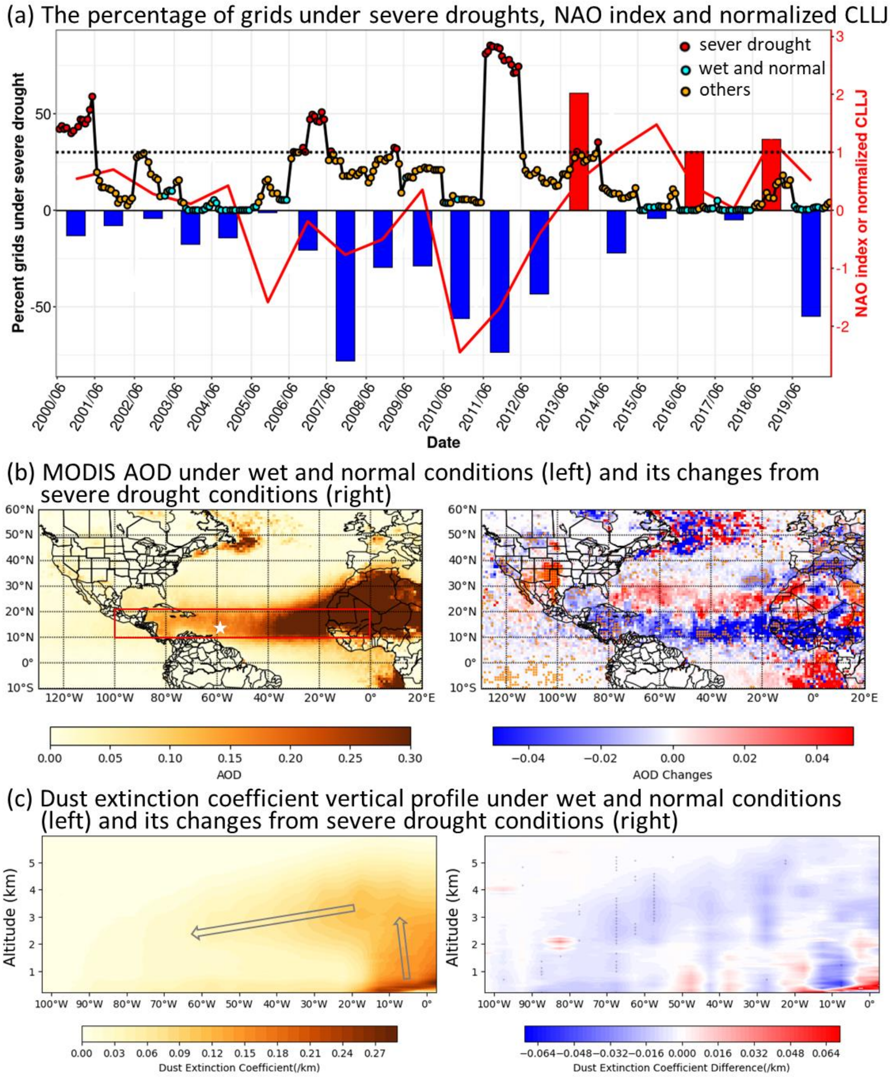

Figure 4. (a) Time series of weekly regional dryness levels indicated by the percentage of grids under severe drought (D2-D4) in the southeast area (filled dots; left axis), the JJA-mean North Atlantic Oscillation (NAO) index (bars; right axis) and normalized Carrabin low-level jet (CLLJ; red line; right axis). The black dash line indicates the position of 30%. (b) Maps of AOD under non-drought (wet and normal) conditions (left column) and its changes from severe droughts (right column) based on the weekly time series in a. The white asterisk denotes the location of the Barbados site (13°6'N, 59°37'W). (c) The same as b except for showing the vertical profiles of dust extinction coefficient over the major transport pathway (red box in b) based on monthly SPEI between 2006 and 2018. Black or orange dots in b and c (right column) indicate the significant difference at a 95% confidence level relative to non-drought conditions.

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

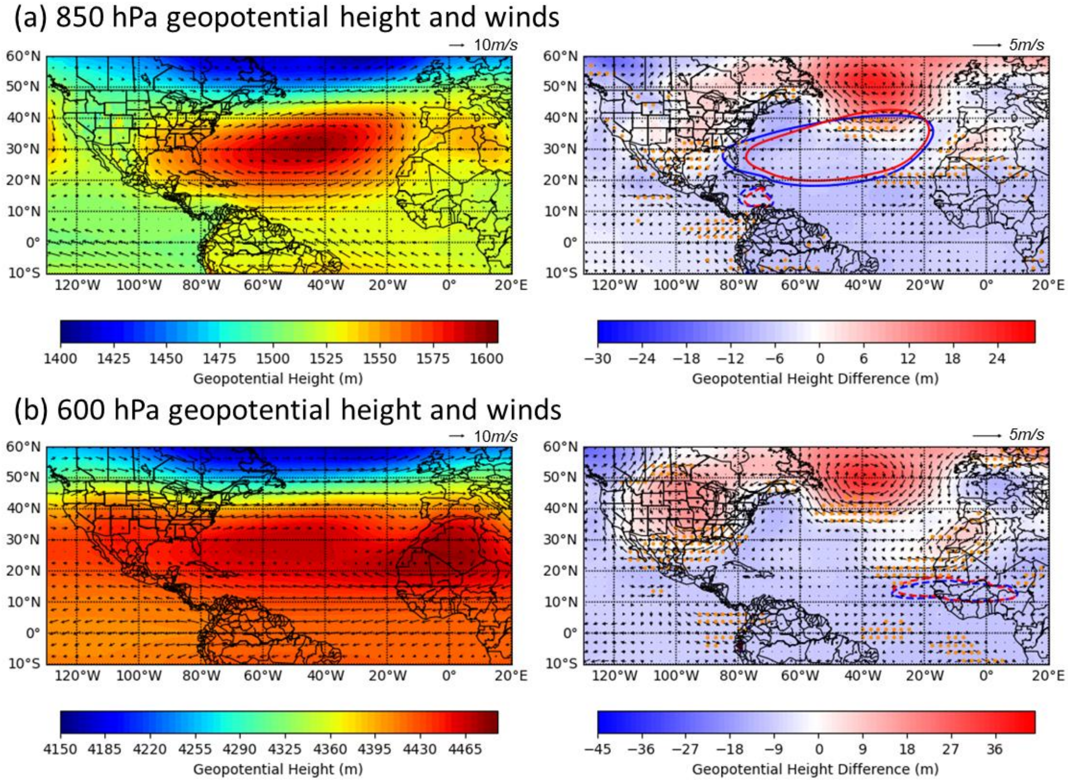

Figure 5. Maps of geopotential height (shadings) and wind vectors (arrows) at 850 hPa (a) and 600 hPa (b) under USDM-based non-drought (wet and normal) conditions (left column) and their changes during severe drought periods (right column). Solid lines in a indicate the edge of Bermuda High under non-drought (blue) and severe droughts (red). Dash lines show the edge of Caribbean low-level jet (a) and African easterly jet (b) under non-drought (blue) and severe droughts (red). Orange dots (right column) indicate the grids with significant differences of zonal winds at a 95% confidence level.

The teleconnections between the SEUS droughts and the transport and emissions of African dust are displayed in Figure 5. At low levels near the central North Atlantic, a semipermanent high-pressure system called North Atlantic Subtropical High (NASH) or Bermuda High (BH) favors the dust transport with its southwestward extensions towards the Caribbean and Gulf of Mexico steering dust into CONUS (Doherty et al., 2008; Kelly and Mapes, 2011). This can be clearly seen from the anticyclonic wind circulations in Figure 5a. Using the 1560m contour (solid lines in Figure 5a) as the edge of the BH following Li et al. (2011), a retreat of the BH towards the northeast can be recognized under droughts, causing northerly wind anomalies over the Caribbean and Gulf of Mexico. As the normal winds are southerly, the northerly wind anomalies reveal a weakened dust transport into the SEUS. Accompanied by the southwestward extension of BH, the Caribbean low-level jet (CLLJ), defined as the mean zonal wind speed at 925 hPa over 11°–17°N, 70°–80°W, is also used to assess the westward transport of dust over the Caribbean Sea (Wang, 2007). The edge of CLLJ is denoted by the 12 m/s zonal wind speed contour (dash lines in Figure 5a). The shrinkage of CLLJ under droughts further verifies the weakened dust transport at low levels.

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

The geopotential height pattern associated with these circulation and jet changes is a higher than normal subpolar low and lower than normal BH, which is consistent with the negative phase of North Atlantic Oscillation (NAO) (Barnston and Livezey, 1987). A negative phase of NAO has been proven to be teleconnected with dry weather over the SEUS and northern Europe, and wet weather over southern Europe and the Mediterranean due to fewer and weaker storms caused by the reduced pressure gradient between the subtropical high and low (Hurrell, 1995; Visbeck et al., 2001). The time series in Figure 4a show severe drought events (e.g., 2011) are associated with strong negative NAO and abnormally low CLLJ. Similarly, we found both NAO and CLLJ are positively correlated with SPEI over the SEUS (Figure 6a, c) with their corresponding mean magnitude reduced by 0.80 and 1.27 m/s compared with non-drought conditions (Figure 6b, d). This further confirms the weakened low-level dust transport into the southeast region.

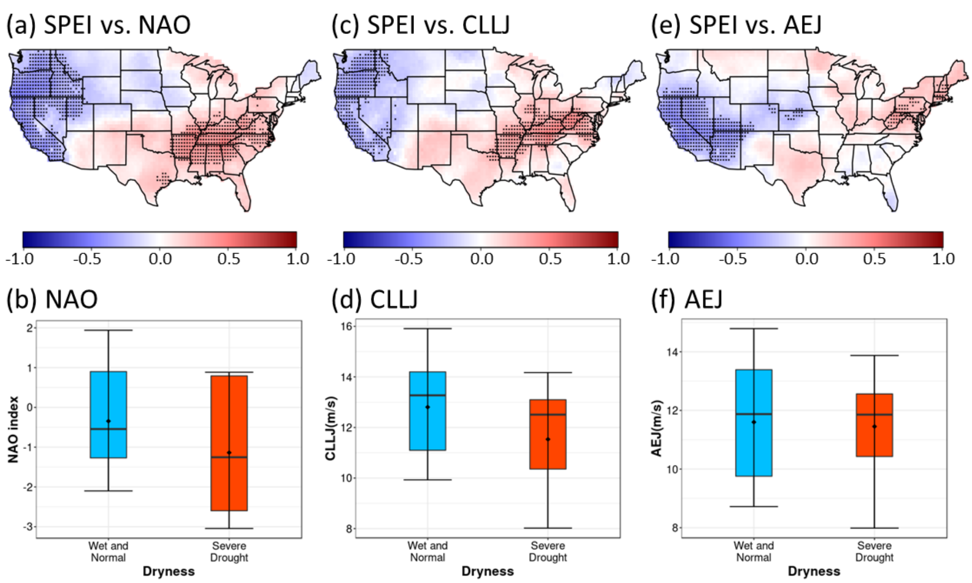

Figure 6. Map of the correlation coefficient between SPEI and NAO (a), CLLJ (c), and AEJ (e) with black dots denoting the significant correlation at 95% confidence level. And the boxplots of NAO (b), CLLJ (d), and AEJ (f) distributions under non-drought (wet and normal) and severe drought conditions.

The westward dust propagation at high levels (e.g., at ~3 km altitude) mainly occurs near the source region after being injected from the surface (Figure 4c). The African easterly jet (AEJ), defined as the average zonal wind speed at 600 hPa over the area of 10°–15°N, 30°W–10°E (Cook, 1999), has been widely linked with the transport of the African dust towards tropical Atlantic (e.g., Jones et al., 2003; Pu & Jin, 2021). Another strengthened high pressure over North Africa (Saharan Anticyclone) at 600 hPa (also seen at 850 hPa) leads to stronger winds to the northern rim of AEJ (Figure 5b). However, the core jet area seems to be less affected as shown by the comparable magnitude of AEJ between non-drought and drought conditions in Figure 6f. The edge of AEJ, denoted by the 11 m/s zonal wind contour (dash lines in Figure 5b), only slightly moves northwards and does not show noticeable expansion or shrinkage. There are no significant correlations between SPEI and AEJ over the SEUS either (Figure 6c), which indicates weak

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

teleconnection exists between droughts in the SEUS and the dust transport strength at a high level. The abnormally high Saharan Anticyclone at both 850 hPa and 600 hPa (Figure 5a-b) is likely to intensify both emissions and transport of dust from the Sahara Desert as seen from the positive differences in Figure 4b.

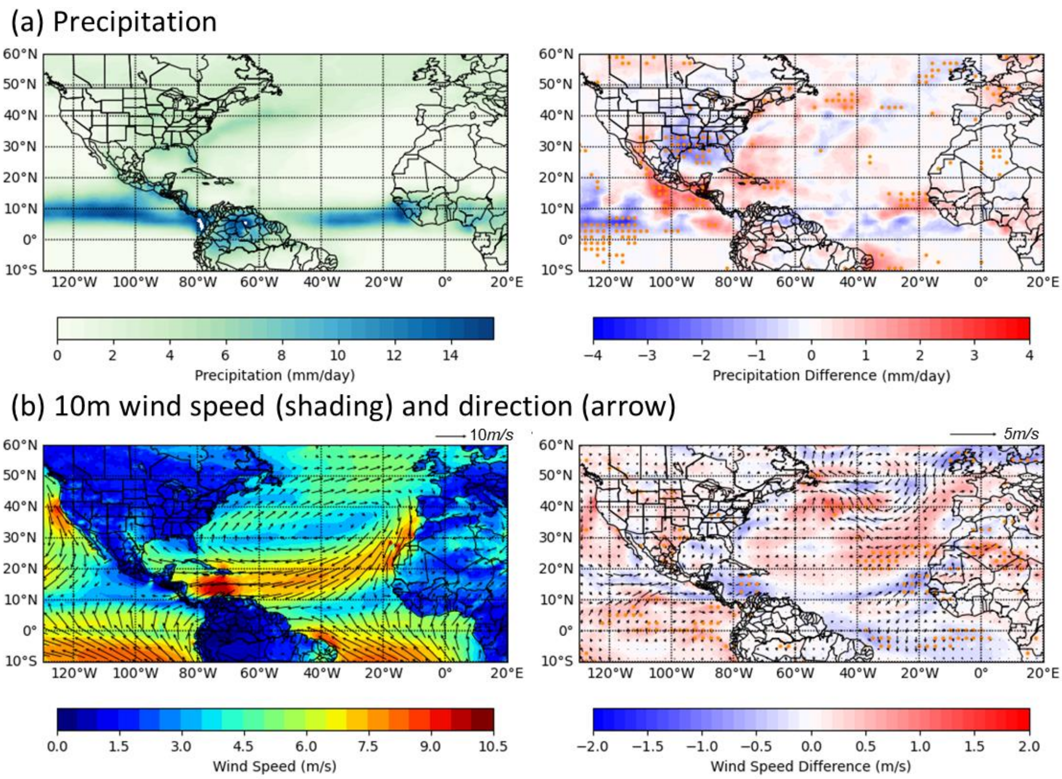

Figure 7. Maps of precipitation (a) and 10m wind speed (shadings in b) and directions (arrows in b) under USDM-based non-drought (wet and normal) conditions (left column) and their changes during severe drought periods (right column). Orange dots (right column) indicate the grids with significant differences of precipitation (a) and wind speed (b) at a 95% confidence level.

Precipitation is one of the dominant factors influencing African dust emissions (Moulin and Chiapello, 2004). A maximum precipitation zonal belt near 5°–10°N can be seen under non-drought conditions in Figure 7a, which represents the location of the Intertropical Convergence Zone (ITCZ). We found enhanced precipitation in southern West Africa (10°–20°N, 30°–0°W) and the Caribbean Sea, which will reduce dust emissions from the major source region of Sahel (e.g., southern Mauritania and Mali) and intensify the wet scavenging of dust to the Caribbean Sea. A significant anticorrelation between summertime Sahel precipitation and NAO has been reported by previous studies on a multidecadal scale (Folland et al., 2009; Linderholm et al., 2009) caused by the northward displacement of ITCZ shifting the "rain belt" into the Sahel region in response to a warmer North Atlantic (Sheen et al., 2017; Yuan et al., 2018). By locating the maximum rainfall within 0°–20°N, 30°–0°W following Liu et al., (2020), we found an average

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

of ~0.6° norward movement of ITCZ during the SEUS droughts. This can also be seen from the southwesterly 10m wind anomalies over the same region, which are contradicting to the northeasterly winds under non-drought conditions (Figure 7b). Surface wind speed is another important factor associated with dust emissions in this region (Evan et al., 2016). However, Figure 7b does not show clear negative anomalies over the Sahel region under droughts, which implies that surface wind speed is not a significant factor causing the weakened dust emissions in the Sahel.

In summary, the reduction of surface fine dust in the SEUS under severe drought results from the weakened African dust transport and emissions from the Sahel through the teleconnection patterns of negative NAO. The weaker and less southwestward extension of BH reduces the wind speed over the Caribbean and Gulf of Mexico, making it less favorable for African dust to enter the SEUS at low levels. Intensified precipitation over Sahel related to the northward shift of ITCZ is the main factor causing lower Sahelian dust emissions during the SEUS droughts, and this factor dominates over surface wind speed changes.

3.3 CMIP6 model evaluation

In this section, we evaluated the surface dust concentrations from four CMIP6 models regarding their capability of capturing the drought-dust relationships in the SEUS in comparison with the monthly observations (1973-2014; JJA) at the Barbados site. Dust values were extracted at a grid point nearest to the observation site. Out of the 120-month study period, 24 severe drought months were identified based on the same SPEI-based regional-drought criteria as described in the last section.

Figure 8a displays the scatter plots between model simulations and observations with more statistics listed in Table 1. CNRM-ESM2-1 considerably underestimates the dust concentrations by more than 20 μg/m^3 (80%) regardless of the drought conditions. This is possibly due to its relatively high dry deposition (Zhao et al., 2021). GFDL-ESM4 simulations have a relatively lower underestimation of ~7 μg/m^3 (26%) but do not reproduce the variability as indicated by the negative correlation coefficient (R) and slope. Under droughts, the underestimation is reduced by ~50% with R and slope values turning to positive, which indicates this model has better performance under droughts. An overall overestimation by 4.92 μg/m^3 (17.93%) was found in the simulations of GISS-E2-1-G. A near-zero value of R and slope also show that the GISS-E2-1-G model can barely capture the dust variability. If only the drought months are considered, GISS-E2-1-G has a better model performance in predicting the dust variability with R increasing to 0.38. MRI-ESM2-0 generally shows a minimum bias with an underestimation of ~4.76 (17.38%), yet a poor capability of reproducing the dust variability. Using drought months alone does not improve the performance, implying its dust simulations are not sensitive to drought conditions.

https://doi.org/10.5194/egusphere-2022-18
Preprint. Discussion started: 28 February 2022

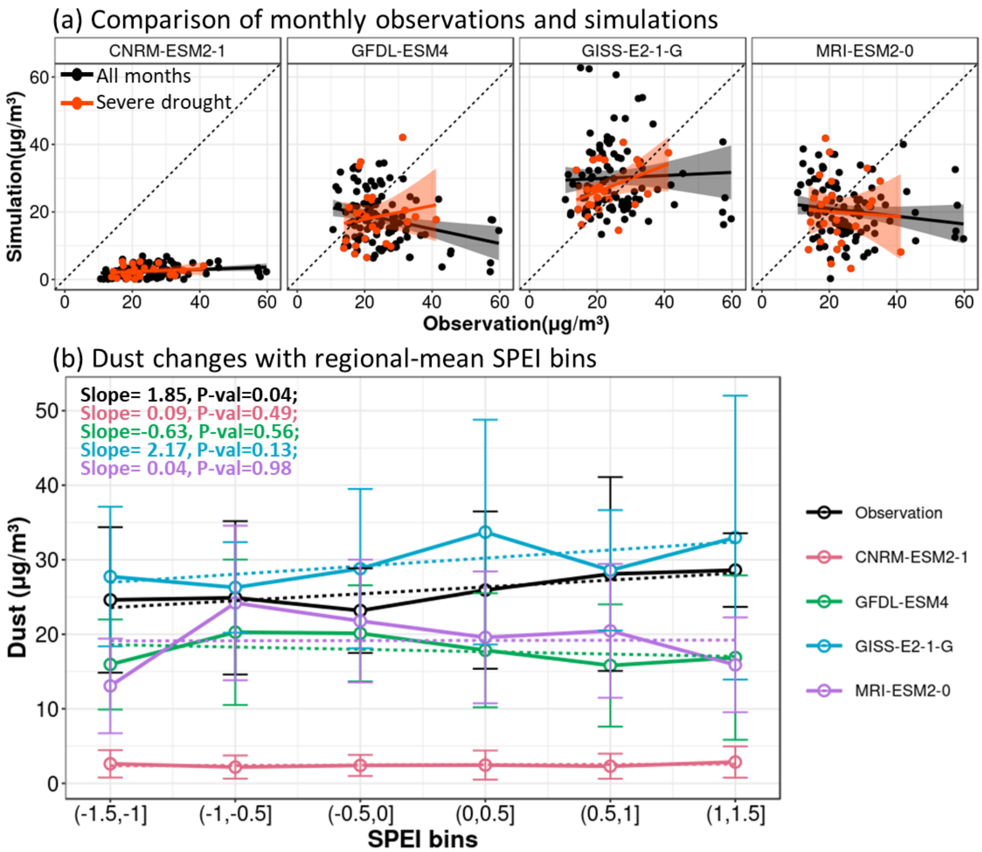

Figure 8. (a) Scatter plots between dust observations and four CMPI6 models. Black (red) dots and lines represent dust in all (severe drought) months and their linear regression fits, respectively. The shadings indicate a 95% confidence level of the linear regressions. (b) Observed and simulated dust means (dots) and standard deviations (error bars) vary with the SEUS regional-mean SPEI. Dash lines represent the linear regressions of the average dust concentrations with their slopes (Slope) and P-values (P-val) listed at the top-left corner.

The sensitivity of surface dust in response to the SEUS regional drought was also evaluated in the same way as Figure 2b. The results are displayed in Figure 8b. Similar to the fine dust responses to drought in the southeast, Barbados total dust also shows a decreasing tendency with lower SPEI. On average, dust at the Barbados site reduces by 1.85 µg/m^3 with a unite decrease of SPEI over the southeast region. This consolidates the conclusion that the weakened across-Atlantic transport of African dust is the reason causing the reduced fine dust in the SEUS as the Barbados site sits in the major transport pathway. GISS-E2-1-G simulations have a comparable sensitivity of 2.17 µg/m^3 (P-value= 0.13) despite its general overestimation, which makes it outperform the other three models which all have a much lower and less statistically significant sensitivity in response to SPEI changes.

337 **Table 1. Evaluation metrics of four CMIP6 models in comparison with observations at the Barbados site. Metrics include**
338 **correlation coefficient (R), mean bias (MB), normalized mean bias (NMB), root mean square error (RMSE), and slope.**

Simulations	Drought Conditions	Observed Mean (μg/m^3)	Simulated Mean (μg/m^3)	R	MB (μg/m^3)	NMB (%)	RMSE (μg/m^3)	Slope
CNRM-ESM2-1	All months	25.51	2.38	0.20	-22.75	-82.98	24.75	0.03
	Severe Drought	23.53	2.33	0.17	-20.52	-80.49	21.62	0.04
GFDL-ESM4	All months	25.51	18.20	-0.26	-7.11	-25.93	15.94	-0.21
	Severe Drought	23.53	18.81	0.15	-4.49	-17.64	11.19	0.20
GISS-E2-1-G	All months	25.51	30.09	0.03	4.92	17.93	16.12	0.04
	Severe Drought	23.53	27.20	0.38	4.16	16.32	8.78	0.38
MRI-ESM2-0	All months	25.51	20.35	-0.12	-4.76	-17.38	14.91	-0.11
	Severe Drought	23.53	20.58	-0.05	-3.02	-11.84	12.90	-0.07

In conclusion, GISS-E2-1-G generally shows an overestimation of surface dust, while the other three models exhibit an underestimation with the highest underestimation found in the CNRM-ESM2-1 simulations. None of the four models are capable of capturing the dust variability using all the months, with GFDL-ESM4 and GISS-E2-1-G performing better if using the drought months only. GISS-E2-1-G can reproduce the dust-SPEI sensitivity much better than the other three models. It is noted that systematic bias should arise when comparing single-site observations with grid-mean predictions, which could presumably cause the between-model diversity as they have different spatial resolutions (Table S2). However, the dust-sensitivity evaluation should be less affected as its calculation depends more on relative changes, instead of absolute values.

4 Conclusions

We found an opposite response of surface fine dust to severe droughts between the western and southeastern CONUS, with an increase of ~0.15 μg/m^3 and a decrease of ~0.5 μg/m^3 per unit decrease of SPEI, respectively. Similar results were reached by the USDM-based drought conditions, with an average decrease of 0.23 μg/m^3 over the SEUS relative to non-drought conditions. The dust and drought relationship over the west/southwest region has been investigated before due to its vicinity to the major dust source regions, and the increase of dust with drought is expected. As the southeast region is strongly influenced by long-range transport of African dust in the summer, we investigated how drought conditions in the SEUS affect the trans-Atlantic transport of African dust.

The elemental ratios are indicative of the dominance of African dust in the southeast region. The tendency of these ratios moving out of the normal range under severe droughts implies a reduced African dust input. The anomalies of satellite AOD and dust extinction coefficients suggest that both the transport and emissions of African dust are weaker during the southeast drought periods than normal. The composite analysis reveals that the weaker across-Atlantic dust transport is through the teleconnection patterns of the negative NAO. During the drought periods, a lower than normal and more northeastward displacement of the Bermuda High results in less dust being brought into the SEUS at low levels from the Caribbean and Gulf of Mexico by its southwestward extensions. This can also be seen from a weaker and more shrinking CLLJ. Enhanced precipitation in Sahel associated with the northward shift of ITCZ leads to lower dust emissions therein.

At last, we evaluated four CMIP6 models with surface dust outputs. CNRM-ESM2-1 generally performs the worst with an up to 80% underestimation of the dust concentrations. While GFDL-ESM4 and MRI-ESM2-0 underpredict the dust level by 17% and 26%, respectively, GISS-E2-1-G shows an overestimation by 18%. All four models fail to reproduce the dust variability using data from all the months, with GFDL-ESM4 and GISS-E2-1-G models significantly improving their performance if only the drought months are used. Besides, GISS-E2-1-G outperforms other models in capturing the dust-SPEI sensitivity.

This study reveals how the local- or regional-scale drought conditions in the SEUS can be linked with the long-range transport and emission changes of African dust through teleconnections. Thus, in order to better predict how the local dust air quality will change in response to an increasing drought frequency in a warming climate (Cook et al., 2015), climate and Earth system models not only need to represent various physical processes associated with the entire dust cycle, but also should capture the abnormal atmospheric processes (e.g., circulation and precipitation) related to droughts. Evaluation of these models should use observations of dust-drought relationships not only in dust source regions but also in dust transported regions.

Acknowledgments

This research was supported by the NOAA's Atmospheric Chemistry, Carbon Cycle, and Climate (AC4) Program (NA19OAR4310177). The authors acknowledge NASA for providing the MODIS AOD and CALIPSO data, EPA and IMPROVE in making the dust observations. We thank individuals and groups for creating the USDM maps and the SPEI dataset. The authors also thank the modelling groups participating in the CMIP6 AerChemMIP project for making the surface dust outputs available.

Data Availability

The data used for this study can be downloaded through the links provided in Table S1 and Section 2.

Competing interests

The authors declare that they have no conflict of interest.
