### Abstract

Climate change has the potential to increase surface ozone (O<sub>3</sub>) concentrations, known as the ‘ozone–climate penalty’, through changes to atmospheric chemistry, transport and dry deposition. In the tropics, the response of surface O<sub>3</sub> to changing climate is relatively understudied, but has important consequences for air pollution, human and ecosystem health. In this study, we evaluate the change in surface O<sub>3</sub> due to climate change over South America and Africa using 3 state-of-the-art Earth system models that follow the Shared Socioeconomic Pathway 3 7.0 emissions scenario from CMIP6. To quantify the changes driven by climate change alone, we evaluate the difference between end of the century predictions for simulations which include climate change and simulations with the same emissions scenario but with a fixed present-day climate. We find that by 2100, models predict an ozone–climate penalty in areas where O<sub>3</sub> is already predicted to be high due to the impacts of precursor emissions, namely urban and biomass burning areas, although on average models predict a decrease in surface O<sub>3</sub> due to climate change. We identify a small but robust positive trend in annual mean surface O<sub>3</sub> over polluted areas. Additionally, during biomass burning seasons, seasonal mean O<sub>3</sub> concentrations increase by 15 ppb (model range 12 to 18 ppb) in areas with substantial biomass burning such as the arc of deforestation in the Amazon. The ozone–climate penalty in polluted areas is shown to be driven by an increased rate of O<sub>3</sub> chemical production, which is strongly influenced by NO<sub>x</sub> concentrations and is therefore specific to the emissions pathway chosen. Multiple linear regression finds the change in NO<sub>x</sub> concentration to be

a strong predictor of the change in O<sub>3</sub> production whereas increased isoprene emission rate is positively correlated with increased O<sub>3</sub> destruction, suggesting NO<sub>x</sub>-limited conditions over the majority of tropical Africa and South America. However, models disagree on the role of climate change in remote, low-NO<sub>x</sub> regions, partly because of significant differences in NO<sub>x</sub> concentrations produced by each model. We also find that the magnitude and location of the ozone–climate penalty in the Congo basin has greater inter-model variation than in the Amazon, so further model development and validation is needed to constrain the response in central Africa. We conclude that if the climate were to change according to the emissions scenario used here, models predict that forested areas in biomass burning locations and urban populations will be at increasing risk of high O<sub>3</sub> exposure.

## 1. Introduction

Climate change threatens to bring new pressures to the tropical forests, grasslands and agricultural lands of Africa and South America. As a result of shifts in emissions, atmospheric chemistry, and meteorology, as well as changes in vegetation behaviour such as transpiration rate, surface O<sub>3</sub> concentrations are likely to change (e.g. Turnock et al., 2019; Griffiths et al., 2021; Zanis et al., 2022), which may impair or benefit human and vegetation health (Agathokleous et al., 2019; Emberson, 2020) depending on the direction of change. O<sub>3</sub> is a highly oxidising compound, formed in the atmosphere through reaction of volatile organic compounds (VOC) with hydroxyl radicals (OH), and, during the night-time, nitrate radicals (NO<sub>3</sub>) in the presence of nitrogen oxides (NO<sub>x</sub>). However, it can also be removed from the atmosphere through reactions with many of the same chemical species (NO<sub>x</sub>, VOC, OH) depending on their relative concentrations. In addition to chemical pathways, O<sub>3</sub> can be removed from the lower atmosphere by dry deposition, which includes stomatal uptake by plants (Silva & Heald, 2018). Stomatal uptake of O<sub>3</sub> and subsequent ozone–plant damage, can lead to reduced carbon drawdown from the atmosphere (Sitch et al., 2007; Yue & Unger, 2018; Franz & Zaehle, 2020), and changes to biosphere–climate interactions (Sadiq et al., 2017). Sitch et al. (2007) showed that the tropics may be especially sensitive to high O<sub>3</sub> concentrations and therefore susceptible to large productivity losses if surface O<sub>3</sub> were to increase. Additionally, O<sub>3</sub> is a near-term climate forcer with impacts on the radiative balance leading to a positive radiative forcing of climate through increases in anthropogenic precursors (Oswald et al., 2015; Coates et al., 2016; Romer et al., 2018). As the tropical forests are vital as sinks for atmospheric CO<sub>2</sub>, and tropical ecosystems play a vital role in regional and global climate (Lewis, 2006; Bonan, 2008), an understanding of the impact of climate change on surface O<sub>3</sub> concentrations in the tropics is critical.

Whilst there have been no studies specifically assessing changes in surface O<sub>3</sub> due to climate change in the tropics, global studies have suggested that changes in temperature-dependent chemistry, natural emissions of precursors, transport and land surface properties may lead to an ‘ozone–climate penalty over some continental areas (Jacob & Winner, 2009; Doherty et al., 2013; Zanis et al., 2022). The ‘ozone–climate penalty’ is defined as an increase in surface O<sub>3</sub> concentrations due to climate

change alone. It is influenced by many complex chemical and biological processes, which are not all well-understood or represented in current climate models, although there has been substantial recent research to reduce uncertainty in temperature-sensitive chemistry, meteorology and land–atmosphere feedbacks (Oswald et al., 2015; Coates et al., 2016; Sadiq et al., 2017; Romer et al., 2018; Archibald et al., 2020b). There has been relatively little research focusing on O<sub>3</sub> in tropical environments. Unlike the more commonly studied extra-tropical Northern hemisphere, the tropics have relatively low (natural) NO<sub>x</sub> emissions and high biogenic VOC emissions, high actinic flux and strong atmospheric convection (Bond et al., 2002; Pugh et al., 2010; Paulot et al., 2012). This paper focuses on South America and Africa. We exclude equatorial Asia because the atmospheric chemistry in this region is more uncertain due to difficulties in detecting and accounting for peat fire emissions (Prosperi et al., 2020). Equatorial Asia has a greater marine influence and most model grid boxes contain ocean as well as land, so it may also follow a different chemical regime.

Many areas in Africa and South America are considered remote (defined in this paper by low emissions of NO<sub>x</sub>), although increasing anthropogenic activity such as urbanisation and biomass burning causes moderate NO<sub>x</sub> emissions in some regions (e.g. Kuhn et al., 2010; Pacifico et al., 2015; Shi et al., 2020). The sensitivity of O<sub>3</sub> production to NO<sub>x</sub> depends on the relative concentrations of NO<sub>x</sub> and VOCs. Biogenic isoprene is the major O<sub>3</sub>-forming non-methane VOC and must be oxidised in the atmosphere before it can form O<sub>3</sub> (Liu et al., 2016). NO<sub>x</sub> is produced from both natural and anthropogenic sources including lightning, transport and biomass burning. In severely NO<sub>x</sub>-limited regions, increasing isoprene acts to reduce O<sub>3</sub> concentrations through oxidation and formation of isoprene nitrates (Pacifico et al., 2012). In this NO<sub>x</sub>-limited case, increasing NO<sub>x</sub> will lead to greater O<sub>3</sub> formation. Conversely, in highly polluted areas with sufficient NO<sub>x</sub> present, increasing NO<sub>x</sub> concentrations may inhibit O<sub>3</sub> formation by direct reaction and removal of O<sub>3</sub> with NO<sub>x</sub>.

Earlier studies have found that South America and Africa are NO<sub>x</sub>-limited (Ziemke et al., 2009; Bela et al., 2015), and that increases in NO<sub>x</sub> concentration associated with climate change will be a key driver of O<sub>3</sub> increases over South America and Africa. Doherty et al. (2013) attribute the NO<sub>x</sub> increase predominantly to enhanced decomposition of the NO<sub>x</sub> reservoir species, peroxyacetyl nitrate (PAN). A fraction of emitted NO<sub>x</sub> is locked up as PAN, which decomposes back into NO<sub>x</sub> in warmer temperatures, sometimes after having travelled long distances from the NO<sub>x</sub> source. As PAN is unstable at high temperatures, climate change will result in a smaller fraction of NO<sub>x</sub> being stored as PAN in NO<sub>x</sub> source regions and may also decrease the amount of NO<sub>x</sub> that is transported into remote regions (Schultz et al., 1999; Finney et al., 2018). Lightning NO<sub>x</sub> is known to contribute to O<sub>3</sub> formation, however studies project both increases and decreases in future lightning frequency (Clark et al., 2017; Finney et al., 2018) leading to low confidence in how O<sub>3</sub> will be affected by climate-driven changes in lightning (Fu & Tian, 2019; Murray, 2016).

The role of isoprene in the ozone–climate penalty is debated as there is uncertainty about how isoprene emissions will change in the future in response to temperature, CO<sub>2</sub> and land-use change (Fu & Liao, 2016; Fu & Tian, 2019) and how to best

represent isoprene chemistry in climate models (Weber et al., 2021). Biogenic isoprene emissions increase strongly with temperature and vegetation stress (e.g. Guenther et al., 1993; Niinemets et al., 1999; Unger et al., 2013; Morfopoulos et al., 2021), but very high temperatures or moisture stress may cause ‘die-back’ of vegetated areas, which would decrease isoprene emissions overall (Sanderson et al., 2003; Cox et al., 2004; Malhi et al., 2009). On the other hand, elevated CO<sub>2</sub> concentrations directly inhibit isoprene emission but can indirectly increase emission if this CO<sub>2</sub> fertilisation effect results in increased plant productivity (Pacifico et al., 2011; Squire et al., 2014; Hantson et al., 2017).

Besides chemical processes, dry deposition of O<sub>3</sub> to vegetation is a major O<sub>3</sub> sink, accounting for 20% of O<sub>3</sub> removal (Wedow et al., 2021). Most O<sub>3</sub> deposition occurs via plant stomata, which respond to changes in the climate. (Silva & Heald, 2018; Clifton et al., 2020). Increased CO<sub>2</sub>, temperature and vapour pressure deficit (VPD) will decrease stomatal conductance and therefore decrease O<sub>3</sub> deposition rate. This could lead to increased concentrations of O<sub>3</sub> in the atmosphere, although it would have a protective effect for plants (Emberson et al., 2013; Lin et al., 2020).

Studies agree that over the ocean, average surface O<sub>3</sub> concentrations will decrease under the influence of climate change due to increased formation of OH (Zeng et al., 2008; Doherty et al., 2013; Zanis et al., 2022). OH increases because the warmer air can hold more water vapour, leading to increased destruction of O<sub>3</sub>. There may also be O<sub>3</sub> reductions in remote regions over land due to this process although natural emissions can change the atmospheric chemistry over the continents. Other factors contributing to the O<sub>3</sub> concentration over the continents are numerous and complex, including changes to oxidising capacity, stratospheric transport and land-use (Archibald et al., 2010; Squire et al., 2015).

This paper quantifies the effect of climate change on surface O<sub>3</sub> concentrations in the future, with aims to understand its uncertainty and the relative contributions of the underlying processes. We focus on areas with robust O<sub>3</sub> changes in O<sub>3</sub> to identify areas in South America and Africa at greatest risk by 2100. Section 1 has introduced the key chemical species involved in O<sub>3</sub> chemistry and the most important changes that may result from climate change. In Section 2, we provide the model details, data used for evaluation, and description of analysis of model output. Section 3 evaluates model predictions of surface O<sub>3</sub> in the present-day, evaluates model predictions for surface O<sub>3</sub> changes in 2100 and examines the importance of chemical and deposition changes in controlling the ozone–climate penalty in models. Finally, Section 4 discusses the key trends predicted by the models, limitations of the study and crucial uncertainties in the models.

130

## 2. Methods

We analyse surface O<sub>3</sub> for simulations that follow a medium-high emissions pathway created for CMIP6 (Pascoe et al., 2019). The simulations were carried out as part of an ensemble of Earth system model experiments designed to quantify the climate

and air quality impacts of aerosols and trace gases in climate models (Collins et al., 2017) named Aerosol-Chemistry Model  
135 Intercomparison Project (AerChemMIP). For this study three Earth system models were used: UKESM1-0-LL (abbr.  
UKESM1), GISS-E2-1-G (abbr. GISS), MRI-ESM2-0 (abbr. MRI). These were selected because of their detailed tropospheric  
chemistry schemes and availability of output for O<sub>3</sub> and O<sub>3</sub> precursor concentrations on the Earth System Grid Federation  
(ESGF).

140 The simulations follow the Shared Socioeconomic Pathway 3 7.0 (SSP3-7.0) emissions scenario, a scenario assuming low  
international cooperation to protect the environment. This includes high emissions of non-methane near-term climate forc  
and substantial land-use change (O'Neill et al., 2016; Gidden et al., 2019). The prescribed emissions include anthropogenic  
and biomass burning emissions of NO, CO<sub>2</sub> and CO (Rao et al. 2017; Riahi et al., 2017) and the future pathway for CH<sub>4</sub> is  
calculated as an atmospheric concentration (Meinshausen et al., 2019). Emissions due to growing populations and poor  
145 international cooperation results in significant temperature increases by 2100 (Turnock et al., 2019) and societies that are  
highly vulnerable to climate change. This emissions pathway was chosen in order to understand changes in end-of-century O<sub>3</sub>  
concentration if there is no international cooperation to reduce precursor emissions.

## 2.1 Model descriptions

Here we provide a brief description of the Earth system models and their tropospheric chemistry schemes that are relevant to  
150 this study.

### UKESM1-0-LL (abbr. UKESM1)

UKESM1-0-LL is a combination of HadGEM3 (Williams et al., 2018) with additional land and atmospheric chemistry  
components (Sellar et al., 2019). The UK Chemistry and Aerosol scheme (UKCA) contains stratospheric and tropospheric  
155 chemistry (Archibald et al., 2020a) combined with the GLOMAP-mode aerosol microphysics scheme (Mulcahy et al., 2018,  
Mulcahy et al., 2020).

Interactive emissions include isoprene, monoterpenes, lightning NO<sub>x</sub> and soil NO<sub>x</sub>. Isoprene and monoterpene emissions  
respond to light and temperature and the isoprene scheme also includes CO<sub>2</sub> inhibition (Archibald et al., 2020a; Mulcahy et  
160 al., 2018) following the emission model of Pacifico et al. (2011). Lightning NO<sub>x</sub> is calculated using the parameterisation of  
Price and Rind (1992). SOA is calculated as a fixed yield of 26% from gas-phase oxidation reactions involving monoterpene  
sources.

The terrestrial biogeochemistry is provided by JULES (Wiltshire et al., 2019; Wiltshire et al., 2021). Stomatal conductance in  
165 JULES is similar to the Ball-Berry-Leuning model (Leuning, 1995) and responds to the ratio of internal to external CO<sub>2</sub>  
concentrations and leaf humidity deficit (Jacobs, 1994).

The model has a horizontal resolution of 1.25° latitude by 1.875° longitude with 85 vertical levels in a hybrid height coordinate.

#### 170 **MRI-ESM2-0 (abbr. MRI)**

MRI-ESM2-0 (Yukimoto et al., 2019; Kawai et al., 2019; Oshima et al., 2020) contains an atmospheric and land-surface model  
(MRI-AGCM3.5), an ocean and sea-ice model (MRI.COMv4), an aerosol model (MASINGAR mk-2r4c) and an atmospheric  
chemistry model (MRI-CCM2.1). The chemistry model includes tropospheric, stratospheric and mesospheric chemistry with  
175 90 chemical species and 259 chemical reactions (Deushi & Shibata, 2011).

Lightning NO<sub>x</sub> is interactive (Price & Rind, 1992) but natural emissions from land and ocean are prescribed as monthly  
climatologies, including isoprene and soil NO<sub>x</sub> (Deushi & Shibata, 2011). 15% of natural terpene emissions at the surface  
form SOA and SOA have identical properties to POA.

180

Each component employs different horizontal resolutions but the outputs used in this paper are from the chemistry component  
which uses a horizontal resolution of 2.8125° latitude by 2.8125° longitude with 80 vertical levels in a hybrid sigma pressure  
coordinate.

#### 185 **GISS-E2-1-G (abbr. GISS)**

GISS-E2-1-G contains a coupled troposphere and stratosphere chemistry scheme using the G-PUCCINI chemistry mechanism  
(Shindell et al., 2013; Kelley et al., 2020) combined with the One-Moment Aerosol (OMA) scheme for aerosols (Bauer et al.,  
2020).

190

Lightning NO<sub>x</sub> is interactive as described by Kelley et al. (2020). Natural emissions include soil NO<sub>x</sub> and isoprene, which  
respond to light and temperature (Shindell et al., 2006) following the algorithm defined by Guenther et al., (1995).  
Monoterpenes are prescribed. SOA is calculated using the CBM4 chemical mechanism to describe the gas phase tropospheric

chemistry together with all main aerosol components including SOA formation and nitrate, and is calculated using four tracers  
195 in the model. Isoprene (VOCs) contribute to the formation of SOA (Tsigaridis et al., 2018).

GISS has a horizontal resolution of 2.00° latitude by 2.25° longitude with 40 vertical levels output on hybrid sigma pressure coordinate.

## 200 2.2 Data analysis methods

### Model evaluation

In situ observations from 65 sites across South America and tropical Africa, covering key biomes and land-use types, are used for grid level model evaluation. Monthly mean O<sub>3</sub> concentrations from individual sites have been aggregated into 7 regions by grouping together sites within latitude and longitude bounds (see Table S1). To compare to models, the coordinates of the in  
205 situ measurement sites are matched to the nearest model grid cell coordinates. To create an average seasonal cycle for each region, sites with the same nearest grid cell are averaged together to create a grid cell seasonal cycle. Then, grid cell seasonal cycles in the same region are averaged together. Monthly mean data from 1990 up to the 2021 were used, although most sites only provide a few years of data. Data were excluded if there was an unequal distribution of data points over the monthly mean diel cycle.

210

For the model seasonal cycle, the monthly mean O<sub>3</sub> concentration in all grid cells containing observation sites was calculated using CMIP6 historical simulations for the period 1990–2014. The standard deviation in monthly mean O<sub>3</sub> concentrations between the grid cells used was calculated for each region (i.e. it represents variation in O<sub>3</sub> geographically between the sites rather than inter-annual variation).

215

For model evaluation against Tropospheric Emission Spectrometer (TES) data from the Aura satellite, which retrieves O<sub>3</sub> in ppb over 67 pressure levels, we use O<sub>3</sub> concentrations at the lowest level available from TES (825 hPa). Monthly mean gridded outputs are used for the period 2004–2011, the period for which complete monthly mean data is available. As with the model output, satellite grid cell coordinates closest to the in situ site coordinates were selected. The monthly mean and standard  
220 deviation for each region was calculated, only using data from grid cells containing in situ sites.

### CMIP6 model output

We isolate the effect of climate change on surface O<sub>3</sub> concentrations using the difference between two simulations which consider the same trajectory of anthropogenic emissions changes but differ in climate. The simulations are fully-coupled, global model runs driven with prescribed sea surface temperatures (SSTs) over the period 2015–2100. We use a simulation

225 driven with changing SSTs from the coupled simulation ssp370 so that the climate changes in accordance with the emissions  
changes, this simulation is named ssp370SST. We use a second simulation with prescribed SSTs are sea ice concentrations  
taken from a present-day climatology (2005–2014) in historical simulations, named ssp370pdSST. Importantly, although  
emissions are identical in both simulations, ssp370pdSST does not include the resulting climate change. To isolate the effect  
of climate change on tropospheric O<sub>3</sub>, we subtract ssp370pdSST (present-day constant climate + future emissions) from  
230 ssp370SST (future climate + future emissions) following Zanis et al. (2022). Biomass burning and land-use change are  
considered anthropogenic and are prescribed for both models but natural emissions are allowed to change depending on the  
model set-up. In this way, the background atmospheric composition is based on the future emissions scenario used, since the  
response of atmospheric chemistry to climate change may depend on the background concentrations of precursors. In  
UKESM1, CO<sub>2</sub> is also fixed to present-day concentrations in ssp370pdSST to avoid inhibiting isoprene emission by CO<sub>2</sub>.

235

Model output is taken as monthly means during the period 2090–2100 between 40°S and 40°N from experiments ssp370SST  
and ssp370pdSST. All variables used are outlined in Table S2. The change due to climate change refers to subtracting  
ssp370pdSST from ssp370SST, where positive values are considered an O<sub>3</sub>–climate penalty. When evaluating the change due  
to climate change regionally, this study distinguishes between ‘high-NO<sub>x</sub>’ and ‘remote’ areas (Fig. 1). High-NO<sub>x</sub> areas are  
240 defined as areas where the annual mean NO<sub>x</sub> emissions are above the 95<sup>th</sup> percentile for the entire tropics (40°S–40°N).

O<sub>3</sub> concentrations are taken from the lowest model level (~ 20 m above canopy). Where multi-model means are shown, data  
has been re-gridded to the 2.8125° by 2.8125° grid used by MRI. We evaluate the ozone–climate penalty as a yearly average  
and seasonally. To identify seasonal patterns we aggregate the data by burning season. The Western African burning season is  
245 defined as Dec–Feb, the Southern African burning season is June and July and the Southern Amazon burning season is Aug–  
Oct.

To attribute the ozone–climate penalty to precursor variables, we also use NO<sub>x</sub>, isoprene emission rate, OH and surface  
temperature variables. When presenting these variables, the ocean has been masked so that only land surface changes are  
250 presented. ‘Surface concentrations’ shown in this study refer to chemical mixing ratios in the lowest model grid cells and  
‘background concentrations’ refer to chemical mixing ratios in the absence of climate change (using data from ssp370pdSST).

To evaluate the O<sub>3</sub> budget, we also use O<sub>3</sub> chemical production, O<sub>3</sub> chemical loss and dry deposition variables. To compare  
these three variables on the same scale, we convert the units to Tg year<sup>-1</sup> and sum production and loss over the lowest 1 km,  
255 the approximate boundary layer height. We choose 1 km to establish an approximate region that can contribute to surface O<sub>3</sub>  
concentrations.

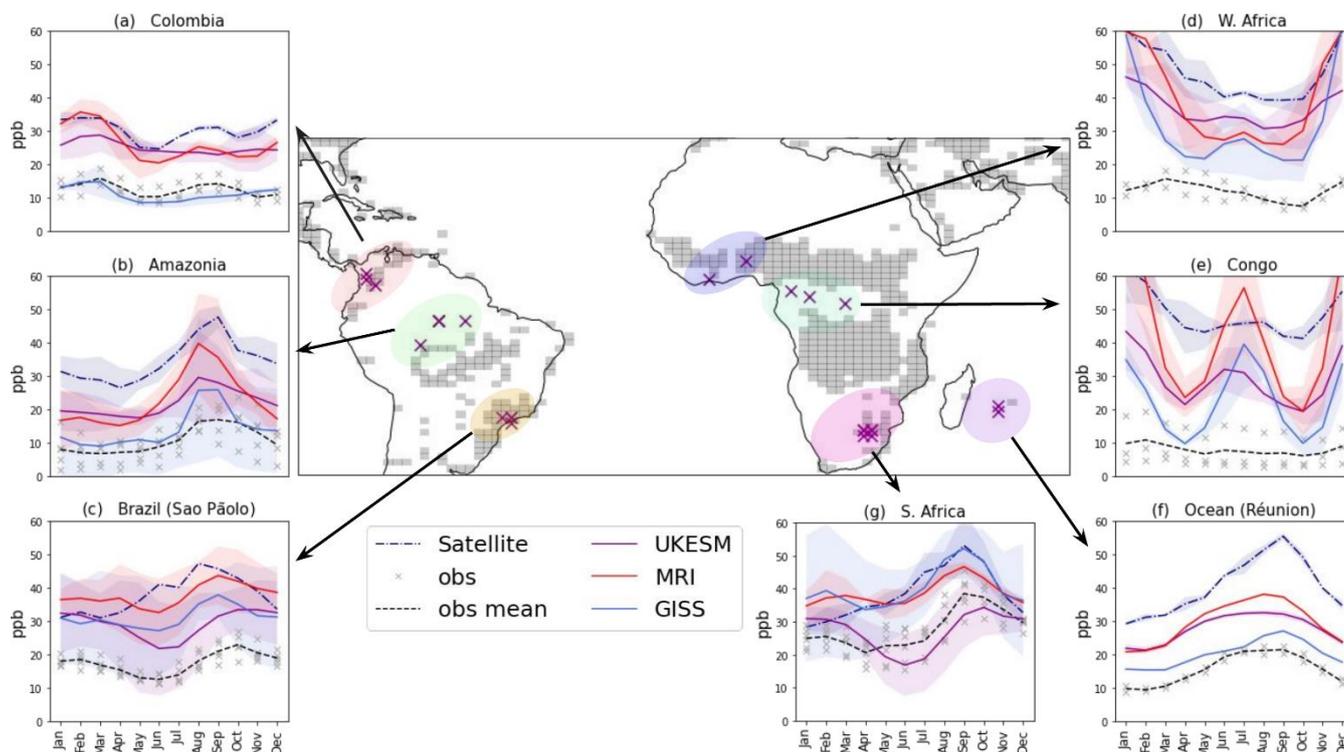

In Sect. 3.4, we present a sensitivity study relating changes in NO<sub>x</sub> concentration and isoprene emissions (see isoprene representation in this paper S2) to changes in O<sub>3</sub> chemical production. We use monthly mean data in South America and Africa within 40°S and 40°N to calculate a monthly climatology for 2090–2100, masking the ocean. To identify the limiting O<sub>3</sub> precursor in the tropics, the percentage change in O<sub>3</sub> production rate (n>500) is modelled with an ordinary least squares linear regression using the percentage change in NO<sub>x</sub> and isoprene as predictor variables (see the relationship between NO<sub>x</sub> and O<sub>3</sub> production S4). To interpret the ability of the model we rely on the central limit theorem to assume that the normalised sum of the residuals can be approximated by a normal distribution. Unique months and grid cells are treated as separate data points. To present the results graphically, we highlight values using star markers if they are above a threshold of the 95<sup>th</sup> percentile for NO<sub>x</sub> concentrations using the monthly climatology for each model individually, with aims to identify biomass burning areas and cities. The atmospheric chemistry in these areas may be different due to the elevated NO<sub>x</sub> concentrations. Therefore, some grid cells will be above the 95<sup>th</sup> percentile for specific months only (biomass burning seasons).

### 3. Results

#### 3.1. Evaluation of model skill for present-day surface O<sub>3</sub> concentrations

Results show the climate models are able to capture the observed seasonal cycle in most regions except for West Africa and DR Congo (Fig. 1). However, the models overpredict monthly mean surface O<sub>3</sub> concentrations by up to 50 ppb, with the largest bias present in remote forest locations such as the Congo area (Fig. 1e). GISS overall has the smallest positive bias out of all the models, and MRI has the largest. UKESM1 shows the smallest seasonal variation in O<sub>3</sub> concentration, which is often closer to the observed seasonal pattern.

**Figure 1:** panels a–g compare monthly mean O<sub>3</sub> (black dashed line) from site measurements averaged over 7 regions to model predictions for the period 2015–2020 and satellite products from the TES satellite at 825 hPa (navy dash-dot line). Model means are shown for UKESM1 (purple solid line), GISS (blue solid line) and MRI (red solid line) and 2 standard deviations from the mean are shaded. Grey crosses indicate monthly mean O<sub>3</sub> measurements from individual sites and years.

The central panel marks the locations where O<sub>3</sub> measurement sites are located (purple crosses) and how the sites have been grouped (coloured shading). Observations 1a–1c and 1f–1g use data from the Tropospheric O<sub>3</sub> Assessment Report (TOAR I, Schröder, 2021; Schultz et al., 2017), 1d and 1e from INDAAF (<http://www.indAAF.obs-mip.fr>) and 1e from CONGOFLUX in Yangambi, DR Congo. Grey grid cells cover areas where NO<sub>x</sub> emissions are above the 95th percentile for the tropics in 2100 (prescribed by (Rao et al., 2017; Riahi et al., 2017), indicative of biomass burning areas and cities. Un-shaded areas are referred to as ‘remote’ throughout.

Grey shading on Fig. 1 highlights the areas in South America and Africa with the highest NO<sub>x</sub> emissions. The shaded areas represent areas with high biomass burning emissions and urban areas and are referred to as ‘high-NO<sub>x</sub>’ areas in this paper. In the Southern Amazon (Fig. 1b), the biomass burning months are August and September and both models and observations predict the highest O<sub>3</sub> concentrations in this season. However, the observed monthly mean O<sub>3</sub> concentrations fall within 9 to 20 ppb whereas models predict values up to 40 ppb, with GISS displaying the smallest positive bias. In Africa (Figs 1d–1f), the biomass burning months are December–February (North / West Africa) moving to June–July (Southern Africa). Whilst models predict concentrations of up to 80 ppb in the Congo during these months due to transport of precursors from biomass burning, observations show substantially lower surface O<sub>3</sub> concentrations of less than 20 ppb at the remote locations sampled, although the highest O<sub>3</sub> concentrations occur during December–February (Adon et al., 2010; 2013; Ossouhou et al., 2019). In

fact, seasonal variation is low at the Congo sites whereas models predict strong seasonal patterns (Fig. 1e). In months without substantial burning, GISS captures the low O<sub>3</sub> values well and UKESM1 and MRI overestimate by 10 to 15 ppb.

300 The enhanced O<sub>3</sub> concentrations predicted by models in burning seasons over the Congo and West Africa are also captured in satellite retrievals at 825 hPa. Satellite O<sub>3</sub> concentrations in the DR Congo are 10 ppb higher in Dec–Feb compared to months without burning (Fig. 1e). At 825 hPa, these satellite capture O<sub>3</sub> concentrations above the altitude of in situ observation sites and the lowest model level. Model predictions for O<sub>3</sub> at 825 hPa are ~10 ppb higher than the lowest model level and therefore compare well to satellite retrievals (Fig. S1), especially in Amazonia (Fig. S1b) and West Africa (Fig. S1d).

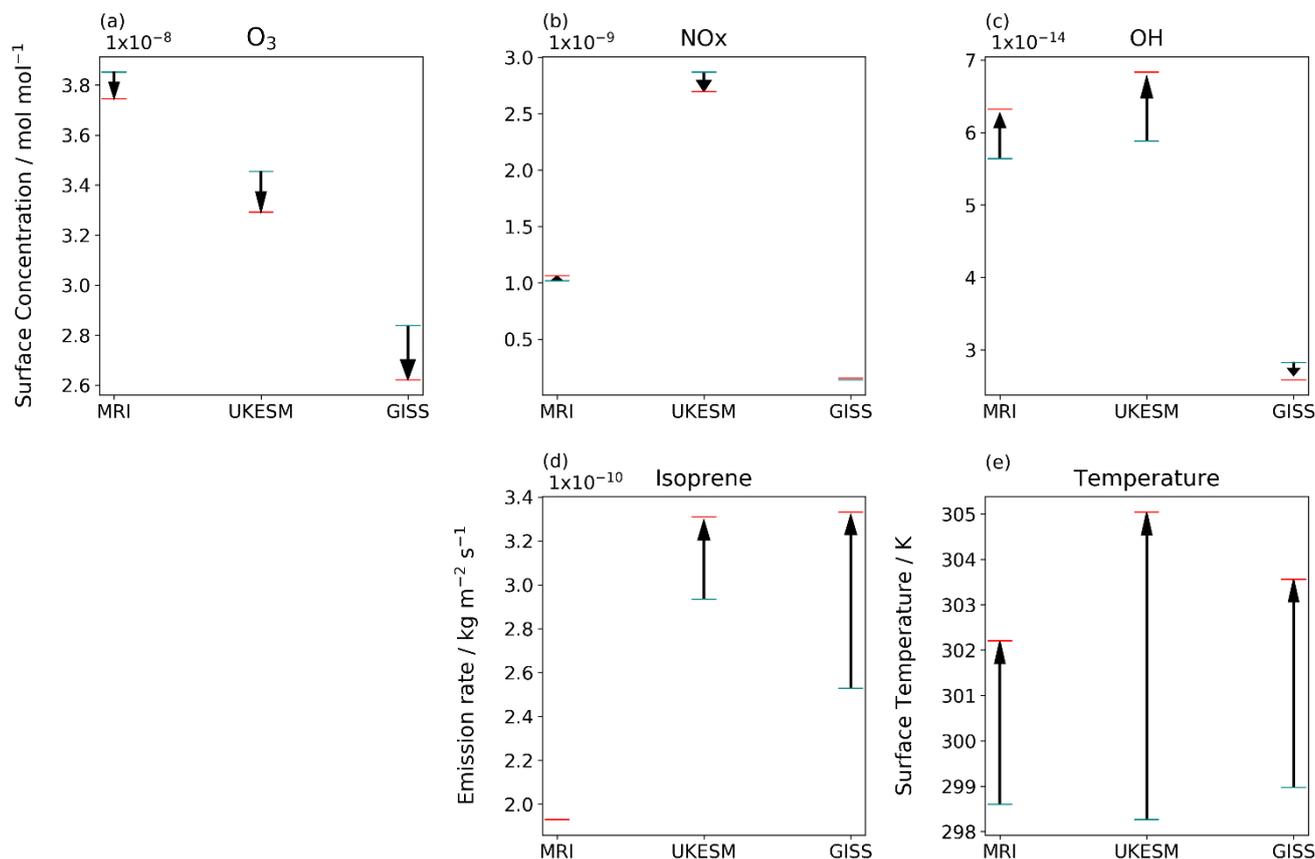

305

Similar to biases over the remote continents, measurements from Réunion Island (Fig. 1f), which capture oceanic air masses, are overestimated by 5 ppb in GISS and by 12 ppb in UKESM1 and MRI, although the seasonal cycle is reproduced. On the other hand, over the urban sites in South Africa, Johannesburg, UKESM1 replicates the observed mean with moderate accuracy, whereas GISS and MRI overestimate by 15 ppb (Fig. 1g).

### 310 **3.2. Average changes to atmospheric composition over Africa and South America at the end of 2100**

The overall change in O<sub>3</sub> concentration due to climate change over the African and South American land surface is shown in Fig. 2a for each model compared to the simulation with a fixed present-day climate. All models predict that on average O<sub>3</sub> concentrations will decrease due to climate change over the tropical land surface in this study. The magnitude of the predicted O<sub>3</sub> change for each model will depend on background concentrations of O<sub>3</sub> chemical precursors, their change due to climate change and individual model mechanistic details. There is significant diversity in background atmospheric composition between models (Fig. 2, blue marker) and the direction of change in surface NO<sub>x</sub> and OH concentration due to climate change varies (Figs 2b, 2c, arrows).

320 Different temperature sensitivities of the models (differing by up to 2.7 K) and different biogenic VOC schemes will contribute to the inter-model variation (Fig. S2). UKESM1 has the greatest temperature sensitivity with a 6.5 K increase in temperature over the tropical land surface due to climate change (Fig. 2e). The temperature change due to climate change varies seasonally and regionally, which may affect concentration of ozone precursors locally (discussed further in Sect. 3.4), with dry seasons temperatures predicted to rise by 1–1.5 K more than wet season temperatures (Fig. S3).

325 **Figure 2: The change in surface concentration of (a) O<sub>3</sub> (b) NO<sub>x</sub>, (c) OH, and the change in (d) isoprene emission rate and (e) surface temperature and from experiment ssp370pdSST with no climate change (blue line) to experiment ssp370SST with climate change (red line) for the three climate models in this study. Variables have been averaged over the African and South American continents between 12° N–30° S for the period 2090–2100. The change due to climate change is significant at the 5% level for all variables and models except isoprene in MRI (which is prescribed so does not change).**

330

NO<sub>x</sub> emissions, including biomass burning emissions, are prescribed based on the SSP3-7.0 scenario but lightning NO<sub>x</sub> differs between the models based on the chosen parameterisation of individual models. Compared to the present-day, NO<sub>x</sub> emissions in biomass burning areas decrease in Africa to follow projected trends, but do not change in South America. NO<sub>x</sub> emissions increase in cities and Nigeria especially has major growth in urban areas. Additionally, lightning NO<sub>x</sub> emissions can change due to climate change. In all models, lightning NO<sub>x</sub> emissions increase due to climate change and the locations of the increases vary in latitude to follow the wet season (not shown).

335

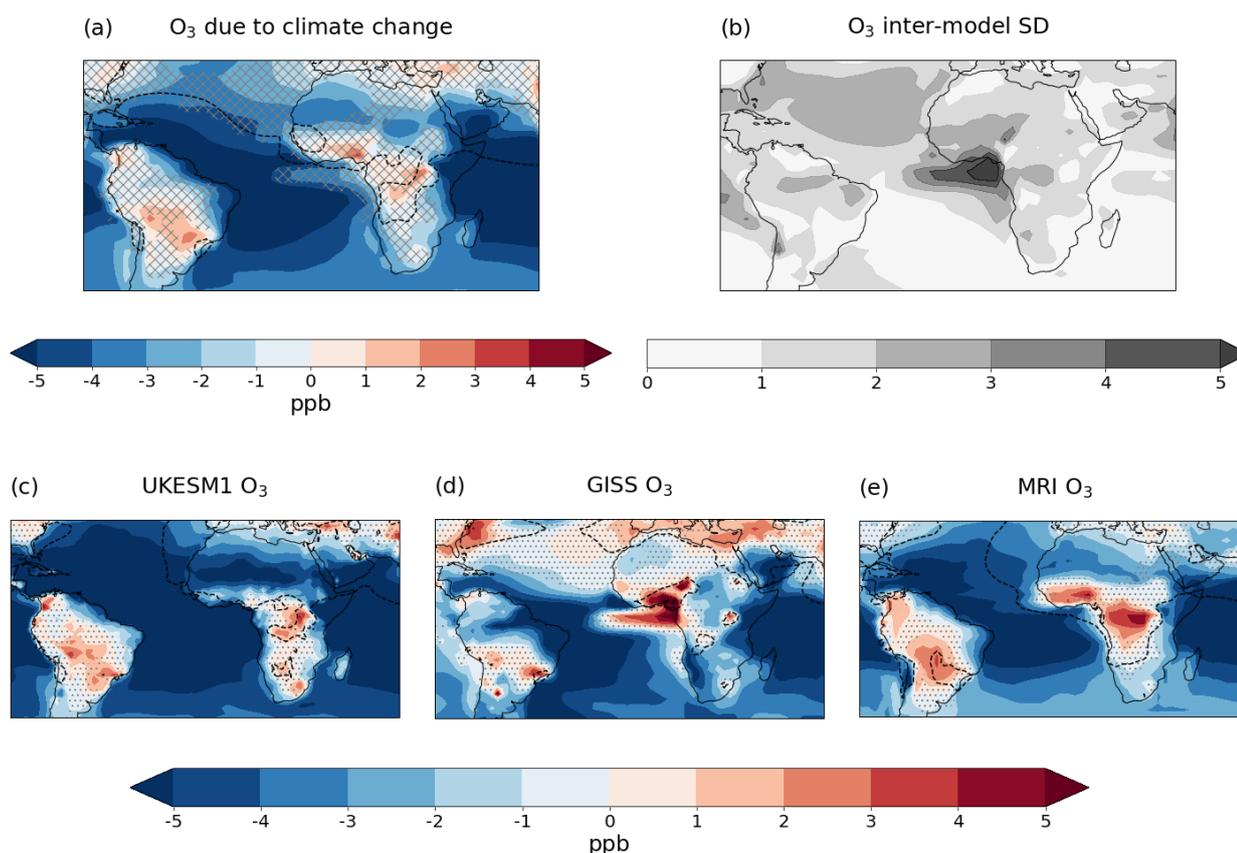

The increase in isoprene emission rate due to climate change depends on the isoprene emission scheme used, or in MRI, isoprene emissions are prescribed as a climatology. The greatest increase in isoprene emissions rate occurs in the GISS model,

340 which increases from  $2.5 \times 10^{-10} \text{ kg m}^{-2} \text{ s}^{-1}$  to  $3.3 \times 10^{-10} \text{ kg m}^{-2} \text{ s}^{-1}$  when climate change is considered, whereas UKESM1, which accounts for  $\text{CO}_2$  inhibition, increases more modestly from  $2.9 \text{ kg m}^{-2} \text{ s}^{-1}$  to  $3.3 \times 10^{-10} \text{ kg m}^{-2} \text{ s}^{-1}$ . Isoprene emissions are presented throughout rather than isoprene concentrations (see Isoprene representation in this paper S2).

### 3.3 Changes in surface O<sub>3</sub> concentration due to climate change over remote regions compared to high-NO<sub>x</sub> areas

345 This study focuses on the change in surface O<sub>3</sub> concentration over land in 2100, although we note there are significant decreases in O<sub>3</sub> concentration over the oceans and non-vegetated areas such as Saharan Africa (Fig. 3). Over land, the multi-model mean shows increases of up to 4 ppb over urban areas and the biomass burning areas of South America and Africa (Fig. 3a) whereas ocean-influenced locations such as Northeast Brazil are expected to benefit by a 4 to 5 ppb decrease in surface O<sub>3</sub>. However, the direction of change in surface O<sub>3</sub> concentration over central Africa and the remote Amazon (North West) is not robust between models (Fig. 3c, 3d, 3e).

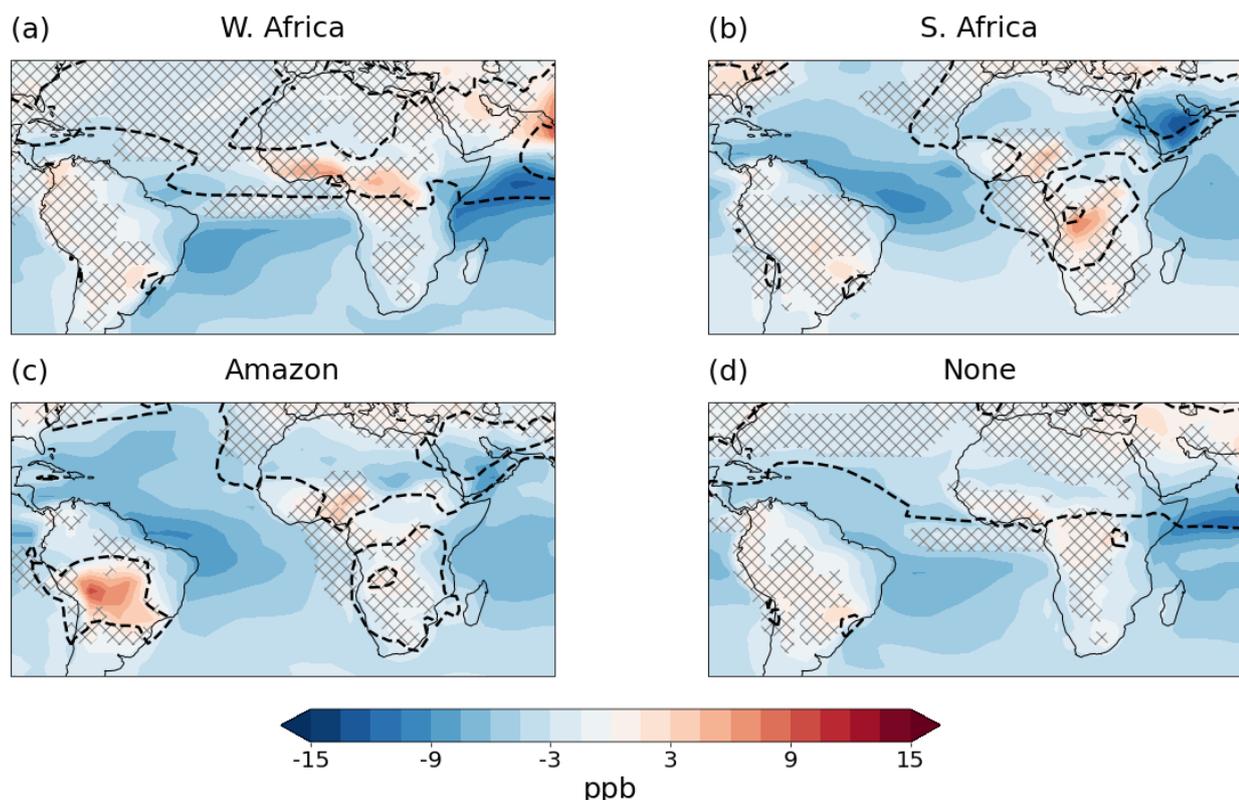

350

355 **Figure 3: The average change in surface O<sub>3</sub> concentration due to climate change for the period 2090–2100 for (a) the multimodel mean, (c) UKESM1 only, (d) GISS only, (e) MRI only. (b) shows the inter-model standard deviation in the same units. Grey hatching in (a) covers areas where the inter-model standard deviation is greater than 20% of the multimodel mean value. Grey dots in panels (c)–(e) cover areas that are not significant at the 5% level from a student's t-test. Black dotted lines outline areas where background O<sub>3</sub> is higher than 40 ppb.**

UKESM1 and MRI predict increases in surface O<sub>3</sub> concentration of up to 5 ppb in the Amazon and central Africa, with decreases over coastal regions due to climate change (Figs 3c, 3e). In the remote Amazon, MRI predicts an increase and UKESM1 a decrease in O<sub>3</sub> concentration, but neither change is significant. On the other hand, GISS predicts significant O<sub>3</sub> decreases across remote regions of up to 4 ppb (Fig. 3d), including central Africa which experiences O<sub>3</sub> increases in the other simulations (Figs 3c, 3e).

Changes in surface O<sub>3</sub> concentration due to climate change in 2100 are shown in Fig. 4, grouped by regional biomass burning season, with dotted contours where background O<sub>3</sub> is 40 ppb (a number assumed associated with thresholds for plant O<sub>3</sub> damage) and 70 ppb. High background O<sub>3</sub> is associated with biomass burning and pollution in and around cities due to their higher NO<sub>x</sub> emissions. These high O<sub>3</sub> areas also show the greatest increase in O<sub>3</sub> due to climate change (Fig. 4).

**Figure 4: The multimodel mean change in surface O<sub>3</sub> concentration for the period 2090–2100 for (a) the Western African burning season (Dec–Feb), (b) the Southern African burning season (June, July), (c) the Southern Amazon burning season (Aug–Oct), and (d) the remaining months with limited burning (March–May, Nov). Grey hatching covers areas where models disagree on the sign of the change due to climate change. Black dotted lines outline areas where background O<sub>3</sub> is higher than 40 ppb and 70 ppb.**

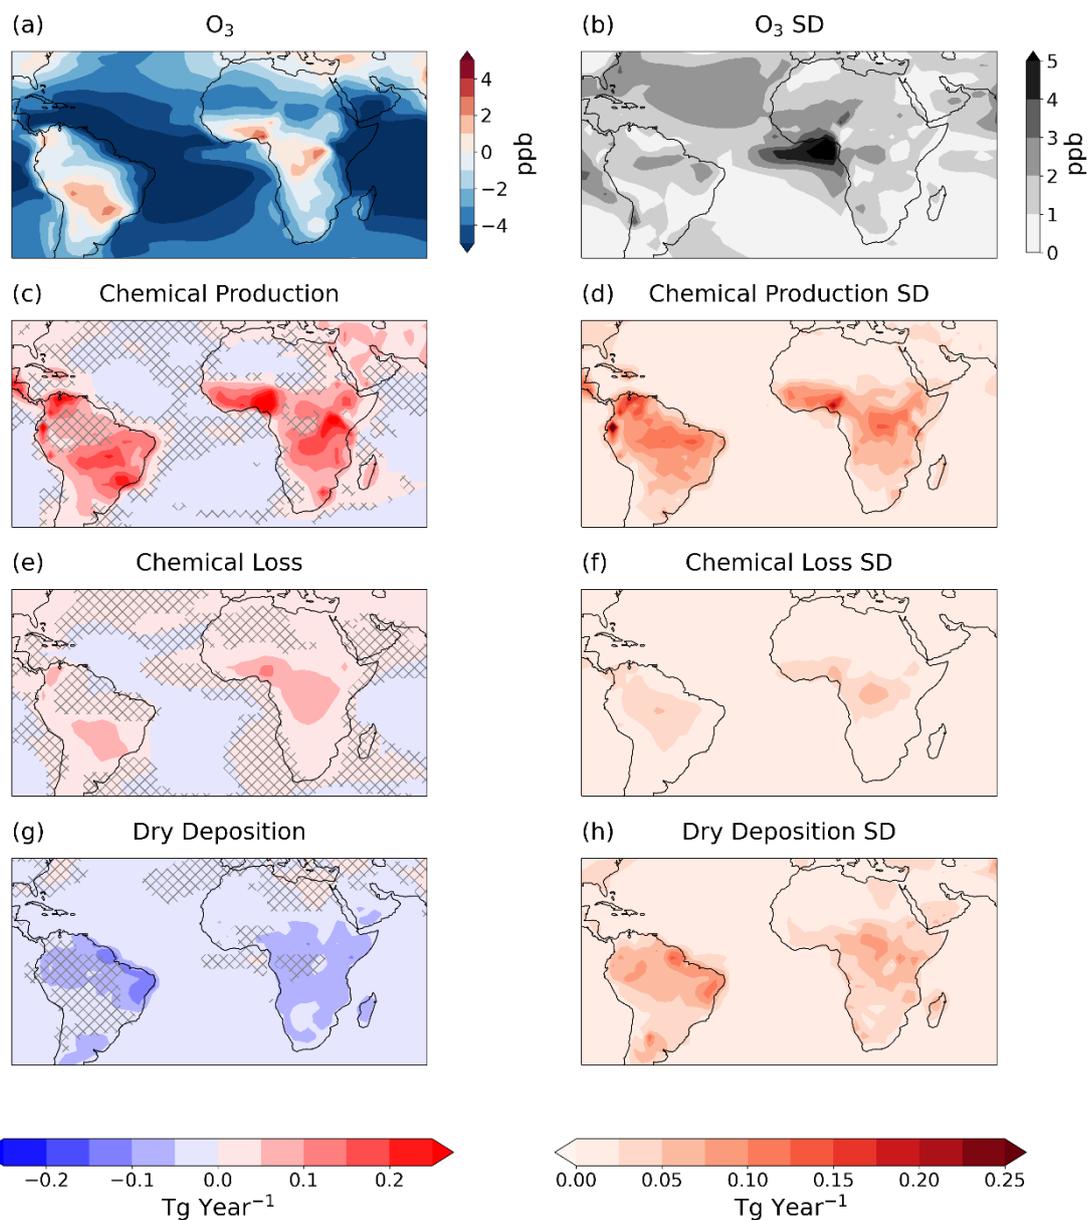

During December–February, the biomass burning area in Western Africa coincides with O<sub>3</sub> increases of 9 ppb (5 ppb for UKESM1, 7 ppb for MRI and 15 ppb for GISS, Fig. 4a) and similar penalties are seen for Southern African biomass burning periods during June–August (Fig. 4b). During the Amazon biomass burning season, there are even larger increases of up to 12 ppb in the Southern Amazon (Fig. 4d). In months without biomass burning, these areas have minor increases of 2 ppb for UKESM1 and MRI and a decrease of 3 ppb for GISS (Fig. 4c).

GISS is the only model to show significant decreases in monthly mean surface O<sub>3</sub> concentration over land, which consistently occur in areas and seasons with low background O<sub>3</sub> (not shown). This includes biomass burning areas but in seasons without burning (Fig. 4d), which are followed by large increases in the biomass burning season. The result is that seasonal changes in surface O<sub>3</sub> concentration due to climate change in GISS are much more extreme than UKESM1 and MRI and models do not agree on the direction of change in remote areas, although the yearly average increase is similar between models (Fig. 3). This results in uncertainty in the response to climate change from regions and seasons with low background O<sub>3</sub>, but likely increases in areas and seasons with high background O<sub>3</sub> from anthropogenic NO<sub>x</sub> emissions (Fig. 4, black dashed lines).

Emissions from cities create consistent increases in O<sub>3</sub> concentration in all months, leading to an increase of up to 5 ppb in the yearly average. In particular, megacities in Nigeria (Lagos), Brazil (São Paulo, Rio de Janeiro) and Colombia (Bogotá, Medellín) can be identified by a 3 ppb increase in all seasons, which is robust over Southeast Brazil (Fig. 4).

### 3.4 Changes in chemical production and deposition of O<sub>3</sub> due to climate change

Attribution of changes in surface O<sub>3</sub> to changes in chemical production, chemical loss and dry deposition at the surface are shown in Fig. 5. The increase in O<sub>3</sub> production due to climate change is the largest out of these terms (Fig. 5c) and increases the most (over 0.25 Tg year<sup>-1</sup>) in high-NO<sub>x</sub> areas where surface O<sub>3</sub> increases (Fig. 5a). Therefore, the increase in the rate of O<sub>3</sub> production is likely to be the main cause of the ozone–climate penalty in high-NO<sub>x</sub> areas (high-NO<sub>x</sub> defined as in Fig. 1). Removal of O<sub>3</sub> by deposition and chemical destruction has a smaller effect on O<sub>3</sub> concentration since, to a degree, the two terms cancel each other out; in high-NO<sub>x</sub> areas, chemical loss increases by up to 0.1 Tg year<sup>-1</sup> and dry deposition decreases by up to 0.05 Tg year<sup>-1</sup>. In remote regions, there is considerable variation between models as indicated by the higher standard deviation in these areas (Figs 5, column 2). GISS predicts decreases in O<sub>3</sub> production over remote regions of up to 0.1 Tg year<sup>-1</sup> and increases of up to 0.25 Tg year<sup>-1</sup> over high-NO<sub>x</sub> regions, whereas MRI and UKESM1 predict increases in O<sub>3</sub> production across all regions except Saharan Africa. MRI predicts the largest increases in O<sub>3</sub> chemical production in remote areas of 0.25 Tg year<sup>-1</sup> (not shown).

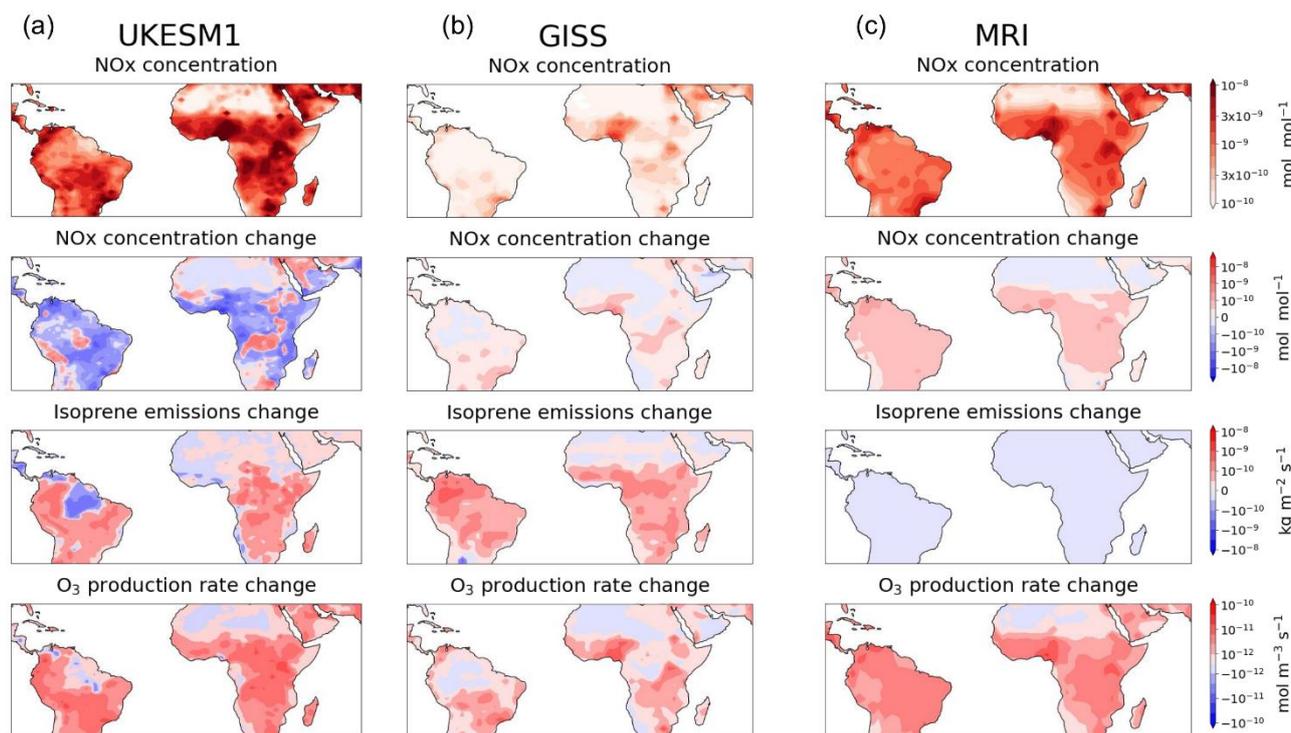

405 **Figure 5. The multi-model mean change in (a) surface  $O_3$  concentration, (c) chemical production of  $O_3$ , (e) chemical destruction of  $O_3$  and (g) dry deposition of  $O_3$  due to climate change. Panels (c), (e) and (g) show the change in  $O_3$  in  $Tg\ year^{-1}$  and chemical terms have been summed over a 1 km height. The inter-model standard deviations are shown in panels (b), (d), (f), (h).**

410 Chemical loss and deposition changes become important in remote areas because these areas have the smallest increases in  
 chemical production, but can have the largest changes in loss rate (Fig. S6) and deposition rate. The rate of O<sub>3</sub> loss is correlated  
 with the change in isoprene concentration, which is typical of a low-NO<sub>x</sub> region due to reactions between isoprene and O<sub>3</sub>  
 directly (Fig. S7). This leads to increases in the loss rate in most vegetated areas (Fig. S6). Conversely, the deposition rate  
 decreases, presumably because the increased temperatures and lower relative humidity cause stomatal closure.

415 In high-NO<sub>x</sub> areas, the increase in O<sub>3</sub> production is greater than the increase in loss leading to net chemical production of O<sub>3</sub>.  
 Evaluation of the sensitivity of O<sub>3</sub> chemical production rate to changes in isoprene emissions and NO<sub>x</sub> concentration due to  
 climate change for each model is shown in Fig. 6. NO<sub>x</sub> decreases in most areas in UKESM1 including high-NO<sub>x</sub> areas,  
 whereas GISS and MRI predict increases in NO<sub>x</sub> (Fig. 6, row 2). The magnitude of the background NO<sub>x</sub> concentration in  
 UKESM1 and the change due to climate change is also much larger than the other models. GISS predicts increases of  $2 \times 10^{-11}$   
 420 to  $6 \times 10^{-11}$  mol mol<sup>-1</sup> in high-NO<sub>x</sub> areas (Fig. 6b), and MRI predicts more uniform increases of  $4 \times 10^{-11}$  mol mol<sup>-1</sup> although  
 urban areas increase by  $8 \times 10^{-11}$  mol mol<sup>-1</sup> in some cases (Fig. 6c). Despite differences in the magnitude and direction of the  
 NO<sub>x</sub> change, the change in O<sub>3</sub> chemical production rate has similar spatial patterns in all models (Fig. 6, row 4). Exceptions  
 occur in central Africa where GISS predicts a decrease in production rate, and UKESM1 is the only model which does not  
 predict a large increase in O<sub>3</sub> production in Nigeria. These areas of Africa also exhibit differences in surface O<sub>3</sub> concentration  
 425 between models, discussed in Sect. 3.3.

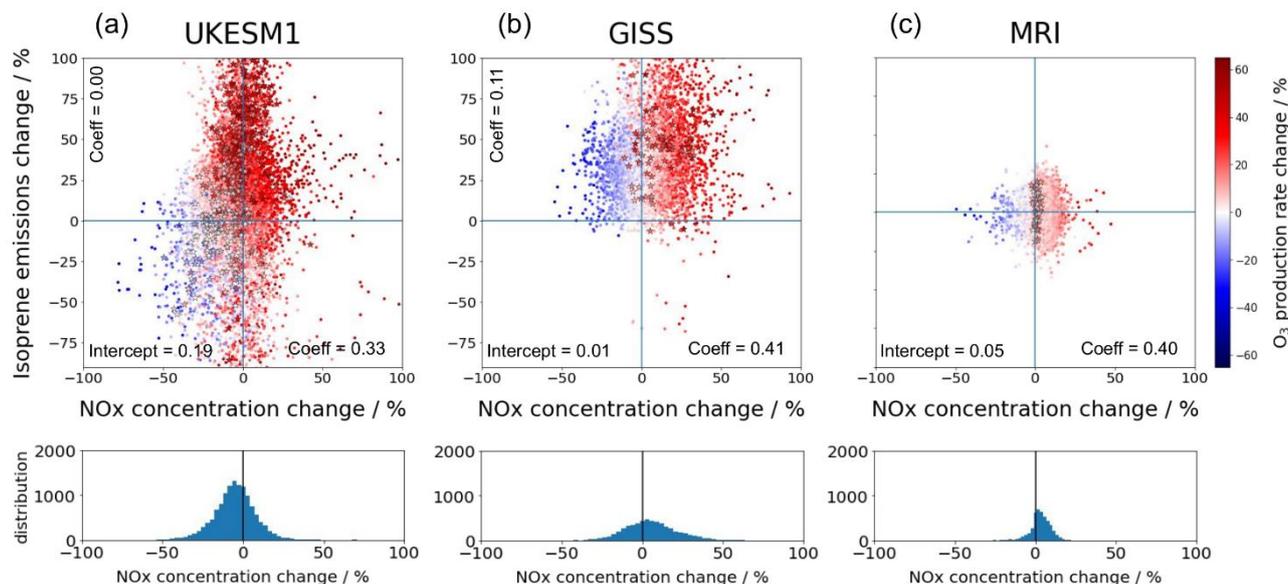

**Figure 6: (row 1) Surface NO<sub>x</sub> concentrations in the absence of climate change and the average change due to climate change in (row 2) NO<sub>x</sub> concentration, (row 3) isoprene emission rate and (row 4) O<sub>3</sub> production rate for the period 2090–2100 for (a) UKESM1, (b) GISS and (c) MRI.**

430

On average, isoprene emission rate increases in both GISS and UKESM1, as expected in a warmer climate (MRI does not have interactive isoprene emission) (Fig. 6, row 3). UKESM1 predicts a substantial decrease in isoprene emission rate in the Northern Amazon and fractionally in West Africa (Fig. 6a). Decreases in isoprene emission and stomatal conductance have previously been simulated in the same area due to CO<sub>2</sub> inhibition (Pacifico et al., 2012; Chadwick et al., 2017; Turnock et al., 435 2020).

435

The O<sub>3</sub> production rate for GISS appears highly correlated with the change in NO<sub>x</sub> concentration in Fig. 6b, whereas NO<sub>x</sub> concentration decreases in many areas where O<sub>3</sub> production increases for UKESM1. Areas in which both NO<sub>x</sub> and isoprene decrease exhibit decreases in rate of O<sub>3</sub> production, such as the Northern Amazon and Nigeria (Fig. 6a). To determine the 440 strength of the relationship between O<sub>3</sub> production rate and changes in precursors NO<sub>x</sub> and isoprene, coefficients from a multiple linear regression are presented in Fig. 7. The monthly mean change in isoprene emission rate, NO<sub>x</sub> concentration and chemical production of O<sub>3</sub> for each grid cell are shown graphically with locations and months of high-NO<sub>x</sub> (above the 95th percentile) marked with stars. All three climate models produce coefficients between 0.33 and 0.41 for the relationship between 445 changes in NO<sub>x</sub> concentration and O<sub>3</sub> production rate (Fig. 7). However, the change in isoprene emissions using GISS and UKESM1 is a weaker predictor of O<sub>3</sub> production, even though increases in isoprene emission of over 100 % are predicted. All predictors are considered significant due to the large sample size, with  $r^2$  values of 0.384, 0.732 0.590 for UKESM1, GISS and MRI respectively (S4). The lower  $r^2$  value for UKESM1 indicates that the changes in NO<sub>x</sub> concentration and isoprene emissions explain less than half of the change in O<sub>3</sub> production rate. Additional analysis shows that the O<sub>3</sub> production rate in UKESM1 is also related to the background NO<sub>x</sub> concentration (S4).

450

**Figure 7: Scatter plots of the monthly mean percentage change in surface NO<sub>x</sub> concentration, isoprene emission rate and O<sub>3</sub> production rate for each grid cell and each month for (a) UKESM1, (b) GISS and (c) MRI. Data for MRI has been randomly normally distributed along the y-axis. Grid cells and months where the background NO<sub>x</sub> concentration is greater than the 95th percentile for the region shown in Fig. 3.1 are marked with stars. The labelled intercept and coefficients refer to the results of a multiple linear regression  $\Delta O_3 \text{ prod (\%)} \sim \Delta NO_x \text{ (\%)} + \Delta \text{Isoprene (\%)}$  using the data plotted. The second row contains the number of data points with each NO<sub>x</sub> concentration change. The data is divided into 50 bins.**

455

GISS simulates increases and decreases in NO<sub>x</sub> concentration of 50 %, compared to the smaller changes predicted by MRI, which fall mostly in the range 0–20 % (Fig. 7c). GISS therefore predicts decreases in production over remote regions (Fig. 6b) and seasons, whereas MRI predicts consistent increases (Fig. 6c). Additionally, high-NO<sub>x</sub> areas simulated by GISS experience an increase in O<sub>3</sub> production regardless of the NO<sub>x</sub> concentration change (Fig. 7b, stars). In high-NO<sub>x</sub> areas simulated by UKESM1, the percentage change in NO<sub>x</sub> concentration is small so there is not enough information to identify individual isoprene and NO<sub>x</sub> sensitivities, although areas with increased isoprene emission also show increases in O<sub>3</sub> production rate (Fig. 7a, stars).

465

#### 4. Discussion

When compared to in situ observations, the three climate models used in this study overestimate present-day surface O<sub>3</sub> in tropical regions by 14 ppb on average, including 11 ppb over the oceans. This is close to the global bias of 16 ppb calculated by Turnock et al. (2020) which included data from six climate models, including the three in this study. Therefore, the sources

470 of error may not be unique to the tropics. The major sources of variation between model and observations are related to differences in the area sampled and the heights of the stations relative to the lowest model grid cell (Pacifico et al., 2015).

In the tropics, we expect in-canopy deposition and chemical processes to be the most important contributor to the positive bias because these processes create a steep O<sub>3</sub> gradient at the surface, whereas models aim to predict O<sub>3</sub> concentrations at 20+ m  
475 from the canopy top where these deposition processes are not included (Stroud et al., 2005; Gordon et al., 2014). Additionally, the volume of the model grid box is many times larger than the area sampled by measurement sites, and also larger than the area of precursor emission sources such as fires. Therefore, the model inputs and predictions represent the average over a region that is not directly comparable with in situ measurements (Sinha et al., 2004). As a further validation, we also provide data from the TES satellite at 825 hPa, which likely records higher O<sub>3</sub> concentrations than the in situ sites since it measures at  
480 an altitude away from the canopy sink. Although this is much higher in altitude than the lowest grid box of any of the models, it should capture the above-canopy seasonal cycle at a resolution closer to the model grid resolution.

We find that the modelled surface O<sub>3</sub> bias compared to in situ observations is largest in biomass burning areas, although in South America the models capture the seasonal cycle well (Fig. 1). In situ sites, especially in the DR Congo (Fig. 1e), do not  
485 detect the large increases in O<sub>3</sub> predicted by models during biomass burning months although observed O<sub>3</sub> concentrations are also highest during biomass burning season (Adon et al., 2013). It is likely that effective removal within the canopy that is not included in models dampens the observed seasonal cycle. In this region, the trends captured by satellites are closer to the model predictions, which increases confidence that models are correctly identifying O<sub>3</sub> enhancements above the canopy due to fires. However, future studies assessing the risks to human and ecosystem health should be aware of this limitation in current models.

490  
The remainder of the study focuses on the change in surface O<sub>3</sub> due to climate change. Although model biases increase uncertainty in the change due to climate change, we quantify the difference between two simulations, which should remove systematic biases, and we note that the models capture seasonal and regional trends that are explained by either in situ measurements or satellite measurements (Fig. 1). This gives confidence in the trends in future O<sub>3</sub> change presented in this  
495 study, but we highlight O<sub>3</sub> from biomass burning as an area for further study. The models have different chemistry schemes, land processes and temperature sensitivities which contribute to model variation (Stevenson et al., 2006; Wu et al., 2007; Archibald et al., 2020b). For this reason, we do not attempt to completely diagnose reasons for inter-model variation and instead the aim of this study is to identify robust predictions and areas of uncertainty for the change in O<sub>3</sub> due to climate change.

500  
We find that while overall O<sub>3</sub> concentrations over the tropical land areas are reduced under the climate scenario examined here, climate change could lead to an ozone–climate penalty in areas which already have a high background O<sub>3</sub> concentration (above 40 ppb). Models predict that climate change will lead to seasonal mean increases in surface O<sub>3</sub> concentration of up to

12 ppb in tropical areas with high-NO<sub>x</sub> emissions (Fig. 4). The increase in surface O<sub>3</sub> in high-NO<sub>x</sub> areas is robust, with seasonal  
505 mean increases of up to 15 ppb for UKESM1, 18 ppb for GISS and 12 ppb for MRI. These areas are defined by emission  
magnitudes above the 95th percentile for the tropics, and often have anthropogenic contributions such as biomass burning or  
urban emissions. O<sub>3</sub> pollution in forested areas has the potential to reduce forest productivity, decreasing the amount of carbon  
removed from the atmosphere and impairing forest resilience (e.g. Sitch et al., 2007; Grulke et al., 2020).

510 The ozone–climate penalty in high-NO<sub>x</sub> regions is likely to be driven by an increase in chemical production, which is largest  
in areas of high-NO<sub>x</sub> (Figs 5, 6). This is in agreement with results from Doherty et al. (2013) and Archibald et al. (2020b) who  
showed that the rate of change of O<sub>3</sub> with temperature increases with NO<sub>x</sub> concentration. Firstly, the reaction happens faster  
at higher temperatures and scaling up O<sub>3</sub> production in an area where O<sub>3</sub> production is already high will often lead to greater  
O<sub>3</sub> increases than an area with a low O<sub>3</sub> precursor concentrations. Secondly the NO<sub>x</sub> concentration can increase due to  
515 increased PAN decomposition at higher temperatures (Doherty et al., 2013), changes in lightning frequency, or changes to  
atmospheric chemistry. The modelled O<sub>3</sub> increases during burning seasons (dry seasons) are likely compounded by the fact  
that these seasons often show the greatest temperature increase due to climate change (Fig. S3). However, we find that lightning  
NO<sub>x</sub> emissions increase in wet seasons suggesting lightning NO<sub>x</sub> is not a key driver of O<sub>3</sub> trends. Some temperature-sensitive  
sources of NO<sub>x</sub> were not included in the simulations such as soil NO<sub>x</sub> emissions and changes in wildfire frequency. Wildfire  
520 feedbacks such as O<sub>3</sub> damage to vegetation were also not considered (Pacifico et al., 2015) so future studies could consider  
the effect of these sources and feedbacks.

The change in O<sub>3</sub> production due to climate change has a high standard deviation in remote regions (Fig. 5d) due to variation  
between models in the effect of climate change on NO<sub>x</sub> concentrations. GISS predicts a decrease in NO<sub>x</sub> of  $2 \times 10^{-11}$  mol mol<sup>-1</sup>  
525 <sup>1</sup> in remote areas (up to 50 %), which could be related to decreased transport of PAN from source regions and greater loss  
through reaction with OH and isoprene. Meanwhile, MRI predicts an increase of  $2 \times 10^{-11}$  to  $6 \times 10^{-11}$  mol mol<sup>-1</sup> in remote regions.  
As NO<sub>x</sub> concentration has been shown to be a key driver of changes in O<sub>3</sub> production due to climate change, further work to  
constrain future NO<sub>x</sub> concentrations is needed to reduce uncertainty in predictions for O<sub>3</sub> concentrations.

530 Using a multiple linear regression, we find that changes in NO<sub>x</sub> concentration have a stronger relationship with changes in O<sub>3</sub>  
production rate than changes in isoprene emissions in GISS and UKESM1 (coefficients of 0.3 – 0.4 compared to ~0.1)  
confirming that Africa and South America are NO<sub>x</sub>-limited on average (Fig. 7). UKESM1 has previously been identified as  
being among the least responsive to changes in precursor concentrations out of the CMIP6 models (Turnock et al., 2020), and  
we find that linear regression using changes in NO<sub>x</sub> concentration and isoprene emission explains less than 50 % of the change  
535 in O<sub>3</sub> production rate. Including background NO<sub>x</sub> concentration in the linear regression improves the  $r^2$  value and suggests  
that, although NO<sub>x</sub> concentrations in UKESM1 decrease in many areas due to climate change, the rate of O<sub>3</sub> production  
increases in proportion to the background NO<sub>x</sub> concentration (Fig. S4). Furthermore, UKESM1 predicts the highest

concentration of background NO<sub>x</sub>, so high-NO<sub>x</sub> areas may experience a different chemical regime in which VOCs are also important (e.g. Liu et al., 2013), decreasing linearity in the data.

540

In remote areas, models tend to predict a decrease in surface O<sub>3</sub> over regions strongly affected by ocean air such as North Brazil. This is due to robust decreases in O<sub>3</sub> over the oceans. However, models disagree on the direction of change over inland remote areas (Fig. 4). The increase in chemical production rate is small in these areas compared to high-NO<sub>x</sub> areas, but the increase in chemical loss is similar in magnitude and these terms act in opposite directions (Fig. 5). The recent study by Zanis et al. (2022) employs 2 additional climate models and also finds climate benefits and uncertainties in surface O<sub>3</sub> concentrations in the same remote regions. We excluded these models from our own study as data for the sensitivity study (NO<sub>x</sub> concentration and isoprene emission rate) were not available at the time of writing.

545

The increase in chemical loss is correlated with isoprene concentration, so although it is not limited to low NO<sub>x</sub> regions it only becomes relevant in magnitude where chemical production is low (Fig. S6). Therefore, the different isoprene schemes used by each model contributes to uncertainty in the loss rate over the continents. In particular, MRI used climatological isoprene resulting in no significant change in the loss rate (Fig. S7) and UKESM1 includes CO<sub>2</sub> inhibition, which decreases the isoprene emission rate and loss rate in Northern Amazonia (Fig. S6). Overall, this means that GISS has a higher loss rate, which may partly account for the larger decreases in O<sub>3</sub> in remote regions using this model (Fig. 8).

555

The global study by Zanis et al. (2022) highlights the different isoprene emission schemes as a reason for model variation however our analysis (Fig. 7) highlights NO<sub>x</sub> as the most important precursor. The fact that the models contain positive correlations between the change in NO<sub>x</sub> and O<sub>3</sub> production, and between the change in isoprene and O<sub>3</sub> loss, indicates the tropics exhibit NO<sub>x</sub>-limited behaviour, although isoprene may be important in high-NO<sub>x</sub> areas. For example, UKESM1 show increases in O<sub>3</sub> production rate as isoprene increases in high-NO<sub>x</sub> areas (Fig. 7, stars). We also find that isoprene is relevant for the change in loss rate and for indirect effects on O<sub>3</sub> through changes in related atmospheric chemistry (see Isoprene representation in this paper S2).

560

We finally note that Nigeria experiences substantial increases in O<sub>3</sub> production according to GISS and MRI, whilst a slight decrease is predicted using UKESM1. This is an important geographical area for future research since poor air quality could affect large numbers of people living in West African cities. In this area, the choice of emissions scenario is also important for determining the O<sub>3</sub> response to climate change because NO<sub>x</sub> emissions in Nigeria increase rapidly in the SSP3-7.0 scenario compared to the present-day due to predicted urbanisation. Therefore, future studies should explore alternative emissions pathways to better inform policy.

565

## 570 5. Conclusion

Using a multimodel mean of data from three Earth system models, we identify that by 2100, there will be an ozone–climate penalty in areas where  $O_3$  due to emissions is already high, such as major cities and biomass burning areas (Fig. 4). This is not due to increased fire emissions, but due to the increasing temperature and associated Earth system changes. It shows that the ozone–climate penalty is greatest in areas already experiencing high  $O_3$ , putting forests in these areas at greater risk of  $O_3$  damage and urban populations at increasing threat of health problems. This study adds to findings from the World Health Organisation World Air Quality Report (2021) that air pollution is an increasing issue across the tropics, and that there is a need for greater monitoring of air pollution across Africa and South America.

The Earth system models display  $NO_x$ -limited behaviour, including that higher  $NO_x$  concentrations lead to increased  $O_3$  chemical production and therefore increased surface  $O_3$  concentration (Figs 5–7). As the background concentrations of  $NO_x$  are largely anthropogenic, this suggests that without reduction in emissions, forested areas in urban and fire-prone locations are more at risk from increases in surface  $O_3$  due to climate change than remote forests. As  $O_3$  damage can reduce plant productivity, this has implications for the success of secondary forests and other human-modified forests which are mostly located in agricultural areas, deforestation frontiers and forest edges (Heinrich et al., 2021), and may reduce their carbon sequestration potential (Sitch et al., 2007).

In remote regions, differences in the direction of  $O_3$  concentration change between models creates uncertainty as to whether remote locations are at greater risk of  $O_3$  damage in a warmer climate, although ocean influenced areas display robust climate benefits (Fig. 4). Further work is needed to constrain the climate response of isoprene emissions and the temperature sensitivity of  $NO_x$  and  $O_3$  chemistry.

### Data availability statement

All CMIP6 model data used in the present study can be obtained from <https://esgf-node.llnl.gov/search/cmip6/>.

All TOAR I data used in the study can be obtained from <https://join.fz-juelich.de/services/rest/surfacedata/>.

All INDAAF data used in this study can be obtained from <http://www.indaaf.obs-mip.fr>

### 595 Author contributions

FB wrote the paper and led the data analysis with contributions from all authors. SS and GAF contributed to the interpretation of the data. MB contributed to the statistical analysis. IDS, HV, PB, MB and CGL contributed in situ data for model evaluation. SEB and KT contributed in the GISS-E2-1-G simulations; MD and NO contributed in the MRI-ESM2-0 simulations; JK and FMO contributed in the UKESM1-0-LL simulations.

JK was financially supported by NERC through NCAS (Grant no. R8/H12/83/003), and the Met Office CSSP-China programme funded POZsUM project. FMO'C and GAF were supported by the Met Office Hadley Centre Climate Programme funded by BEIS and the EU Horizon 2020 Research Programme CRESCENDO project (Grant no. 641816). Resources supporting the GISS simulations were provided by the NASA High-End Computing (HEC) Program through the NASA Center for Climate Simulation (NCCS) at the Goddard Space Flight Center. GISS authors, SEB and KT acknowledge funding from the NASA Modeling and Analysis program. IV was funded by the Fonds Wetenschappelijk Onderzoek Flanders (FWO; grant no. G018319N). The INDAAF project is funded by the INSU/CNRS/IRD and is part of the ACTRIS-FR Research Infrastructure. The authors are grateful to the field and chemistry analytical technicians who operate the African sites and help to provide reliable data.
