## Abstract.

A new method is presented for estimating urban hydroxyl radical (OH) concentrations using the downwind decay of the ratio of nitrogen dioxide over carbon monoxide column mixing ratios ( $XNO_2 / XCO$ ) retrieved from the Tropospheric Monitoring Instrument (TROPOMI). The method makes use of plumes simulated by the Weather Research and Forecast model (WRF-CHEM) using passive tracer transport, instead of the encoded chemistry, in combination with auxiliary input variables such as Copernicus Atmospheric Monitoring Service (CAMS) OH, Emission Database for Global Atmospheric Research v4.3.2 (EDGAR) NO<sub>x</sub> and CO emissions, and National Center for Environmental Protection (NCEP) based meteorological data. NO<sub>2</sub> and CO mixing ratios from the CAMS reanalysis are used as initial and lateral boundary conditions. WRF overestimates NO<sub>2</sub> plumes close to the center of the city by 15 % to 30 % in summer and 40 % to 50 % in winter compared to TROPOMI observations over Riyadh. WRF simulated CO plumes differ by 10 % with TROPOMI in both seasons. The differences between WRF and TROPOMI are used to optimize the OH concentration, NO<sub>x</sub>, CO emissions and their backgrounds using an iterative least square method. To estimate OH, WRF is optimized using a) TROPOMI  $XNO_2/XCO$ , b) TROPOMI derived  $XNO_2$  only.

25 For summer, both the NO<sub>2</sub>/CO ratio optimization and the  $XNO_2$  optimization increase the OH prior from CAMS by  $32 \pm 5.3$  % and  $28.3 \pm 3.9$  % respectively. EDGAR NO<sub>x</sub> and CO emissions over Riyadh are increased by  $42.1 \pm 8.4$  % and  $101 \pm 21$  %, respectively, in summer. In winter, the optimization method doubles the CO emissions also, while increasing OH by  $\sim 52 \pm 14$  % and reducing NO<sub>x</sub> emission by  $15.5 \pm 4.1$  %. TROPOMI derived OH concentrations and pre-existing Exponentially Modified Gaussian function fit (EMG) method differ by 10 % in summer and winter, confirming that urban OH concentrations

30 can be reliably estimated using the TROPOMI-observed NO<sub>2</sub>/CO ratio. WRF optimization method can be applied to single  
TROPOMI overpass, allowing to analysis day to day variability in OH, NO<sub>x</sub> and CO emission.

## 1. Introduction

The rapidly growing urbanization has led to an increase in the number of big cities globally. More than 55 % of the global  
population resides in cities and this fraction is projected to increase to 68 % in 2050 (United Nations, 2018). The associated  
35 rise in consumption of energy and materials leads to severe air pollution that is estimated to have caused premature death of 4  
to 9 million people globally in 2015 (Sicard et al., 2021; Pascal et al., 2013; Burnett et al., 2018). Air pollution control measures  
and the application of cleaner technology have reduced the NO<sub>2</sub> concentrations in developed cities such as Los Angeles and  
Paris by 1.5 % to 3.0 % yr<sup>-1</sup> between 1996 to 2017 (Georgoulas et al., 2019). The CO emission is reduced by 28.8 % to 60.7  
% in these cities in the period 2000 to 2008 (Dekker et al., 2017). In developing cities such as Tehran and Baghdad, however,  
40 NO<sub>2</sub> concentrations have increased by 8.6 % yr<sup>-1</sup> and 16.9 % yr<sup>-1</sup> between 1996 to 2017 (Georgoulas et al., 2019). The CO  
emission increased by 15 % in New Delhi in the period 2000 to 2008 (Dekker et al., 2017). As a consequence, air pollution  
monitoring and mitigation in developing cities is becoming an increasingly important priority.

Nowadays, urban air pollution can be studied using a combination of ground-based measurement networks and satellite  
observations (Sannigrahi et al., 2021; Ialongo et al., 2020). Satellite observations have helped to investigate urban air pollution,  
45 particularly in cities without a ground-based monitoring network (Beirle et al., 2019; Borsdorff et al., 2019). In past decades,  
improvements in the quality and spatial resolution of satellite measurements have allowed the detection of trends in air  
pollutants and the quantification of urban emissions (Lorente et al., 2019; Verstraeten et al., 2018; Wennberg et al., 2018).  
Several studies have focused on NO<sub>x</sub>, using NO<sub>2</sub> observations from the SCanning Imaging Absorption spectroMeter for  
Atmospheric CartographY (SCIAMACHY), the Ozone Monitoring Instrument (OMI) and TROPOMI (Ding et al., 2017;  
50 Lorente et al., 2019). At the resolution and sensitivity of TROPOMI, urban NO<sub>2</sub> enhancements can be detected readily, even  
in single satellite overpass. OMI derived NO<sub>2</sub> data have been used to quantify NO<sub>x</sub> emissions, as well as the urban lifetime of  
NO<sub>2</sub>, as demonstrated by Beirle et al. (2011) using the Exponentially Modified Gaussian function fit (EMG) method.

In the EMG method, the satellite observed exponential decay of NO<sub>2</sub> downwind of the city centre is used to quantify the first  
order loss of NO<sub>2</sub>, which is used to quantify the hydroxyl radical (OH) neglecting other NO<sub>x</sub> removal pathways. Liu et al.  
55 (2016) modified the EMG method for application to complex emission patterns. The quantification of CO emissions from  
cities is more complicated compared with NO<sub>2</sub> because of its longer lifetime, and the related importance of CO sources from  
the surroundings of cities. Nevertheless, a few studies have demonstrated the feasibility of quantifying relative changes in  
urban CO emission, using Measurement of Pollution in the Troposphere (MOPPIT), Infrared Atmospheric Sounding  
Interferometer (IASI), Atmospheric Infrared Sounder (AIRS), and TROPOMI observations (Borsdorff et al., 2019; Dekker et  
60 al., 2017; Pommier et al., 2013).

In recent years, methods have been developed that combine satellite measurements of different trace gases, for example the combined use of NO<sub>2</sub> and CO, to obtain specific information about pollutant sources (Lama et al., 2020, Hakkarainen et al., 2015; Miyazaki et al., 2017; Reuter et al., 2019; S. Silva & Arellano, 2017 ). The emission factors of CO and NO<sub>x</sub> from fuel combustion are uncertain and vary strongly with the combustion efficiency (Flagan and Seinfeld, 1988). The satellite observed  $\Delta\text{NO}_2/\Delta\text{CO}$  ratio is particularly sensitive to this fuel burning efficiency, as demonstrated by Lama et al., (2020) and can be used to evaluate emission inventories. However, another important uncertainty arises from the removal of NO<sub>2</sub> by OH. OH is an important oxidant in the atmosphere, which determines the lifetime of trace gases such as CO, NO<sub>x</sub>, sulphur dioxide (SO<sub>2</sub>) and volatile organic compound (VOCs) (Monks et al., 2009) . OH plays the important role in atmospheric chemistry on scales ranging from urban air pollution to the global residence times of greenhouse gases. The direct measurement of OH is possible using spectroscopic methods, but the spatial representativeness of the data is limited due to its short lifetime (de Gouw et al., 2019). OH estimates from global Chemical Transport Models (CTM's) has an uncertainty of > 50 % (Huijnen et al., 2019). Urban measurement campaigns point to large discrepancies between modelled and observed OH abundances, for example in Lu et al., (Lu et al., 2013) who found a factor 2.6 difference in a campaign in the suburbs of Beijing.

The aim of this study is therefore to estimate the average OH concentration in the urban plume of large cities (hereafter referred to as urban OH) from the downwind decay of the TROPOMI observed NO<sub>2</sub>/CO ratio. The proposed method makes use of the WRF model (Grell et al., 2005) to simulate the meteorological fields and atmospheric transport. The TROPOMI instrument (Veefkind et al., 2012), launched on 13 October 2017 on board the Sentinel-5 Precursor satellite, is particularly well suited for this task, as it measures both compounds with high sensitivity and spatial resolution. Our method uses CO, because it has a longer lifetime than NO<sub>2</sub> (weeks-months compared to a few hours). Therefore, CO can be considered as an inert tracer at the time-scale of urban plumes. The difference in the rate of decay between NO<sub>2</sub> and CO provides therefore information about the photochemical oxidation of NO<sub>2</sub>, because atmospheric dispersion is expected to have a very similar impact on both tracers and therefore cancels out in their ratio. The use of the NO<sub>2</sub>/CO ratio for estimating urban scale OH is further compared to the Exponentially Modified Gaussian function fit (EMG) method, using only satellite retrieved NO<sub>2</sub> (Beirle et al., 2011).

The city of Riyadh (24.63° N, 46.71° E ) is chosen as a test case. Riyadh is an isolated city and a strong source of CO and NO<sub>2</sub> pollution (Beirle et al., 2019; Lama et al., 2020). The frequent clear sky conditions over Riyadh yield a large number of valid TROPOMI CO and NO<sub>2</sub> data. The signal to noise in TROPOMI is high enough to detect the enhancement of CO and NO<sub>2</sub> over Riyadh in a single overpass (Lama et al., 2020). Model results from the Copernicus Atmospheric Monitoring Service (CAMS) for Riyadh show a distinct seasonality in OH (see Fig S1), which we attempt to evaluate using TROPOMI data for summer and winter.

This paper is organized as follows: Section 2 describes the TROPOMI NO<sub>2</sub> and CO data, the WRF model setup that was used, and the optimization method that is used for estimating OH. Optimization results and comparisons between TROPOMI and WRF are presented in section 3, followed by a summary and conclusion of the main finding in section 4. Additional figures and information about the optimization method are provided in the Supplement.

## 2. Data and Method

### 95 2.1 TROPOMI NO<sub>2</sub> tropospheric column

We used the offline TROPOMI level 2 tropospheric column NO<sub>2</sub> [mole m<sup>-2</sup>] data from retrieval versions 1.2.x for 2018 and 1.3.x for 2019 available at <https://s5phub.copernicus.eu>; <http://www.tropomi.eu> (last access: 21 September, 2020). NO<sub>2</sub> data of versions 1.2.x and 1.3.x have minor processing differences such as removal of negative cloud fraction, better flagging and uncertainty estimation. However, they use the same retrieval algorithm applied to level-1b version 1.0.0 spectra (Babic et al., 2019) recorded by the TROPOMI UV-Vis module in the 405-465nm spectral range. The TROPOMI NO<sub>2</sub> DOAS software, developed at KNMI, is used for the processing of NO<sub>2</sub> slant column densities (van Geffen et al., 2019). The improved NO<sub>2</sub> DOMINO algorithm of Boersma et al. (2018) has been used to translate slant columns into tropospheric column densities. In this algorithm, stratospheric contributions are subtracted from the slant column densities and the residual tropospheric slant column density is converted to tropospheric vertical column density using the air mass factor (AMF). The AMF depends on the surface albedo, terrain height, cloud height, cloud fraction and a priori NO<sub>2</sub> profiles from TM5-MP at 1° × 1° (Eskes et al., 2018; Lorente et al., 2017). The comparison of MAX-DOAS ground based measurements in European cities shows that TROPOMI underestimates of NO<sub>2</sub> columns by 7 % to 29.7 % (Lambert et al., 2019). To reduce the differences between satellite and model, we re-calculated the AMF by replacing the tropospheric AMF based on TM5 simulated vertical NO<sub>2</sub> columns, with the WRF-chem equivalent (Lamsal et al., 2010; Boersma et al., 2016; Visser et al., 2019; Huijnen et al., 2010), using the equation provided in the Appendix A. After the AMF recalculation, the NO<sub>2</sub> vertical profiles are consistent between satellite and model. Furthermore, the use of WRF-Chem has the advantage that it resolves NO<sub>2</sub> gradients between urban and downwind regions better than the coarser resolution TM5-MP model (Russell et al., 2011; McLinden et al., 2014; Kuhlmann et al., 2015). During summer, the AMF recalculation increases TROPOMI NO<sub>2</sub> by 5 % to 10 % and in winter by 25 % to 30 % in the urban plume over Riyadh, whereas background areas are less affected (see Fig S2). The S5P-PAL reprocessed NO<sub>2</sub> data available at <https://data-portal.s5p-pal.com/products/no2.html> differs by 7.5 % to 10 % in summer (June to October, 2018) and 13.5 % to 16 % in winter (November, 2018 to March, 2019) compared to the AMF recalculated TROPOMI NO<sub>2</sub> data used in this study. These differences have been used to quantify the systematic uncertainty of the NO<sub>2</sub> data and its contribution to the uncertainty in the NO<sub>x</sub> emission and lifetime derived using our method (see Table S1, S2 and S3).

### 2.2 TROPOMI CO

120 For CO, the offline level 2 CO data product version 1.2.2 has been used, available at <https://s5phub.copernicus.eu> (last access: 20 September, 2020). The SICOR algorithm is applied to TROPOMI 2.3 μm spectra to retrieve CO total column density [molec cm<sup>-2</sup>] (Landgraf et al., 2016). The retrieval method is based on a profile scaling approach, in which TROPOMI-observed spectra are fitted by scaling a reference vertical profile of CO using the Tikhonov regularization technique (Borsdorff et al., 2014). The reference CO profile is obtained from the TM5 transport model (Krol et al., 2005). The averaging kernel (A)

125 quantifies the sensitivity of the retrieved total CO column to variations in the true vertical profile ( $\rho_{true}$ ), as follows (Borsdorff et al., 2018a):

$$C_{retrieval} = A \cdot \rho_{true} + \epsilon_{CO} \quad (1)$$

where,  $C_{retrieval}$  is the retrieved column average CO mixing ratio,  $\epsilon_{CO}$  is the retrieval error, statistically represented by the retrieval uncertainty that is provided for each CO retrieval.

130 The comparison of TROPOMI derived XCO to the 28 different TCCON ground based station suggest that difference between TCCON and TROPOMI is in the range of  $9.1 \pm 3.3 \%$  (Shah et al., 2020). Such difference is used to estimate the uncertainty in the NO<sub>x</sub> emission and life time (see Table S1, S2, S3 and Text S6).

### 2.3 Satellite Data Selection and Filtering Criteria

As NO<sub>2</sub> and CO are retrieved from different channels of TROPOMI using different retrieval algorithms, the filtering criteria and spatial resolutions of CO and NO<sub>2</sub> are different. The data filtering makes use of the quality assurance value (qa) and is provided with the CO and NO<sub>2</sub> retrievals, ranging from 0 (no data) to 1 (high quality data). We selected NO<sub>2</sub> retrievals with  $qa \geq 0.75$  (clear sky condition) and CO retrievals with  $qa \geq 0.7$  (clear sky or low level cloud) as in Lama et al., (2020). The SICOR algorithm was originally developed for SCIAMACHY to account for the presence of low elevation clouds, increasing the number of valid measurements (Borsdorff et al., 2018a). In addition, the CO stripe filtering technique is applied as described by Borsdorff et al. (2018). Using dry air column density derived from the surface pressure data in CO and NO<sub>2</sub> TROPOMI files, the total CO column and tropospheric NO<sub>2</sub> column densities are converted to dry column mixing ratios XCO (ppb) and XNO<sub>2</sub> (ppb). The spatial resolution of the NO<sub>2</sub> data is finer compared to the CO data ( $3.5 \times 7 \text{ km}^2$  versus  $5.5 \times 7 \text{ km}^2$ ). After the CO and NO<sub>2</sub> retrievals pass the filtering criteria, their co-location is approximated by assigning the centre coordinates of an NO<sub>2</sub> retrieval to the CO footprint in which it is located (Lama et al., 2020).

### 145 2.4 Weather Research Forecast model (WRF)

We have used WRF- chemistry model (<http://www.wrf-model.org/>), version 3.9.1.1 to simulate NO<sub>2</sub> and CO mixing ratios over Riyadh. WRF is a non-hydrostatic model designed by the National Center for Environmental Protection (NCEP) for both atmospheric research and operational forecasting applications. For this study, we have setup three nested domains in the model at resolutions of 27 km, 9 km and 3 km, centred at 24.63°N, 46.71°E. The first and second domain cover Saudi Arabia and provide the boundary conditions for the nested third domain (see Fig. S3). The analysis in this paper uses the  $500 \times 500 \text{ km}^2$  sub region around Riyadh in the third domain, containing 161 by 161 grid cells. All domains are extended vertically from the Earth's surface to 50 hPa, using 31 vertical layers, with 17 layers in the lowermost 1500 m. WRF simulations are performed using a time step of 90 seconds for the period June 2018 to March 2019, using a spin-up time of 10 days.

We have used the Unified Noah land surface model for surface physics (Ek et al., 2003; Tewari et al., 2004), an updated version of the Yonsei University (YSU) boundary layer scheme (Hu et al., 2013) for the boundary layer processes, and the

Rapid Radiative Transfer Method (RRTM) for short-wave and long-wave radiation (Mlawer et al., 1997). Cloud physics is solved with the new Tiedtke cumulus parameterization scheme (Zhang and Wang, 2017). The WRF Single Moment 6-class scheme is used for microphysics (Hong and Lim, 2006). The WRF coupling with chemistry (WRF-chem) allows the simulation of tracer transport and the chemical transformation of trace gases and aerosols. Here, we used the passive tracer transport function instead of the encoded chemistry in WRF to speed up the model simulation and reduce the computational cost. In addition, the passive tracer option helps in separating the influences of wind, OH and the rate constant of the  $\text{NO}_2 + \text{OH}$  reaction ( $K_{\text{NO}_2 + \text{OH}}$ ) on the  $\text{NO}_2/\text{CO}$  ratio in the downwind city plume. Compared to previously used methods (Beirle et al., 2011b; Valin et al., 2013) which did not use a transport model at all, we consider this an important improvement. The function of different tracers, their acronym and explanation of different WRF simulations is provided in Table 1.

The meteorological initial and boundary conditions are based on NCEP data at  $1^\circ \times 1^\circ$  spatial and 6-hr temporal resolution available at <https://rda.ucar.edu/datasets/ds083.2/>. Nitrogen Oxides ( $\text{NO}_x = \text{NO}_2 + \text{NO}$ ) and CO anthropogenic emissions have been taken from the Emission Database for Global Atmospheric Research v4.3.2 (EDGAR) 2012 at  $0.1^\circ \times 0.1^\circ$  spatial resolution (Crippa et al., 2016). The EDGAR 2012 data have been re-gridded to the resolution of the WRF domains and hourly, weekly and monthly emission variations are taken into account using the temporal emission factors provided by van der Gon et al. (2011). The chemical boundary conditions for CO and  $\text{NO}_x$  are based on the CAMS chemical reanalysis product at  $0.75^\circ \times 0.75^\circ$  spatial, and 3-hourly temporal resolution (Inness et al., 2019), retrieved from <https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset/cams-global-reanalysis-eac4?tab=form>, last access: 1<sup>st</sup> November, 2020). XCO and  $\text{XNO}_2$  boundary condition based on CAMS is assumed to be representative as background value within the domain. Since we do not explicitly compute the sources and sinks of background  $\text{NO}_2$  inside the domain, we decide to transport the boundary conditions as background passive tracers.

**Table 1. Summary of WRF simulations and the definition of tracers and acronym used.**

WRF Simulation / Tracer	WRF input / Tracer definition
<b>Prior</b>	WRF run using NCEP meteorological data, EDGAR CO and $\text{NO}_x$ emissions, CAMS OH, and CAMS CO and $\text{NO}_x$ as initial and lateral boundary conditions.
<b><math>\text{WRF}_{\text{OH} \times 1.1}</math></b>	Prior run with CAMS OH increased by 10 %
<b>Optimized run<sub>1st iter</sub></b>	Optimized state (background, emission, OH) after iteration 1
<b>Optimized run<sub>2nd iter</sub></b>	Optimized state (background, emission, OH) after iteration 2
<b>CO</b>	
<b><math>\text{XCO}_{\text{emis}}</math></b>	The contribution of urban CO emissions to XCO

<b>WRF Ratio<sub>opt</sub></b>	Ratio of XNO <sub>2 WRF,opt</sub> and XCO <sub>WRF,opt</sub>

The atmospheric transport in WRF causes the influence of NO<sub>x</sub> and CO emissions from Riyadh on their column average mixing ratios to be linear. Instead of a simplified photochemistry solver, we make use of a WRF-chem module for passive tracer transport for transporting NO<sub>x</sub>. This WRF module has been modified to account for the first order loss of NO<sub>x</sub> in reaction of NO<sub>2</sub> with OH, using NO<sub>x</sub>/NO<sub>2</sub> ratios from CAMS to translate NO<sub>x</sub> into NO<sub>2</sub> and CAMS OH fields to compute the chemical transformation of NO<sub>2</sub> to HNO<sub>3</sub> (see Text S1 for detail ).

In addition, we account for the chemical transformation of NO<sub>x</sub> to HNO<sub>3</sub> in the reaction of NO<sub>2</sub> with OH. This is a simplified treatment of the lifetime of NO<sub>x</sub> as other photochemical pathways play a role, such as:

- The oxidation of NO<sub>2</sub> in reaction with organic radicals (RO<sub>2</sub>) to form the alkyl and multifunctional nitrates (RONO<sub>2</sub>) (Romer Present et al., 2019)
- NO<sub>x</sub> loss due to the formation dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>) followed by heterogeneous transformation to HNO<sub>3</sub> (Shah et al., 2020).
- Peroxyacetyl nitrate (PAN) formation in equilibrium between NO<sub>2</sub> and the peroxyacetyl radical (Moxim, 1996).
- The dry deposition of NO<sub>2</sub> on the surface and plant stomata (Delaria et al., 2020).

The loss of NO<sub>2</sub> by OH to HNO<sub>3</sub> accounts for 60 % of the global NO<sub>x</sub> emission (Stavrakou et al., 2013). Macintyre and Evans.,(2010) showed that the N<sub>2</sub>O<sub>5</sub> pathway reduces NO<sub>x</sub> concentrations by 10 % in the tropics (30° N to 30° S) and 40 % at northern latitudes. The NO<sub>x</sub> loss through N<sub>2</sub>O<sub>5</sub> hydrolysis is largest at northern latitudes during winter (50 % to 150 %), unlike the tropics where its seasonality is small. Moreover, the removal of N<sub>2</sub>O<sub>5</sub> is primarily important during night time because of its photolysis during daytime, whereas our analysis focuses on the midday overpass time (13:30) of TROPOMI when OH abundances are highest. For these reasons, we consider it safe to neglect the loss of NO<sub>x</sub> through N<sub>2</sub>O<sub>5</sub> in our analysis for Riyadh. The dry deposition flux is also expected to be low as it is controlled largely by stomatal uptake, which is assumed to be insignificant for the low vegetation cover of Riyadh. The same is expected to be true for PAN formation because of its thermal decomposition at increasing temperatures. We acknowledge that our OH estimates should be regarded as upper limits due to the neglect of other NO<sub>x</sub> transformation pathways. A quantification of the combined effect would require full chemistry simulations, which we consider outside of the scope of this paper.

Note that in this study, OH is only applied to the urban NO<sub>x</sub> emission tracer (XNO<sub>x emis</sub>). The CAMS NO<sub>x</sub> background tracer (XNO<sub>x Bg</sub>) is transported in WRF without OH decay, since it already represents the balance between regional sources and sinks. CAMS hydroxyl radical (OH) data at a resolution of 0.75° x 0.75° spatial and 3 hourly temporal resolution (Inness et al., 2019) retrieved at <https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset/cams-global-reanalysis-eac4?tab=form>, last access: 1<sup>st</sup> July, 2020) is spatially, temporally and vertically interpolated to the WRF grid. The NO<sub>x</sub> lifetime is derived as follows:

$$\frac{dNO_2}{dt} = K_{NO_2 OH} \cdot [OH] \cdot [NO_2] \quad (2)$$

$$fact = \frac{NO_x}{NO_2} \quad (3)$$

$$\tau_{NO_x} = \frac{1}{\frac{K_{NO_2 OH}}{fact} \cdot [OH]} \quad (4)$$

where, K<sub>NO<sub>2</sub> OH</sub> is the International Union of Pure and Applied Chemistry (IUPAC) 2<sup>nd</sup> order rate constant for the reaction of NO<sub>2</sub> with OH. “fact” represents the fractional contribution of NO<sub>2</sub> to NO<sub>x</sub> (NO<sub>x</sub>/NO<sub>2</sub>). This NO<sub>x</sub> to NO<sub>2</sub> conversion factor is derived from the CAMS reanalysis and re-gridded to WRF, to account for its spatial and temporal variation. τ<sub>NO<sub>x</sub></sub> is the lifetime of NO<sub>x</sub>.

**Figure 1.** TROPOMI derived XCO (left) and average wind speed and wind direction from the surface to the top of boundary layer (right) derived from the CAMS global reanalysis eac4 data at the TROPOMI overpass time over Riyadh for August 4<sup>th</sup>, 2018. The white star represents the centre of Riyadh. The black box (B1) with a dimension of 300 x 100 km<sup>2</sup> is rotated in the average wind direction at 50 km radius from the centre of Riyadh at the TROPOMI overpass time resulting in the red box. For the calculation of cross-directional averaged NO<sub>2</sub> and CO, the red box is divided into 29 smaller cells with the width ( $\Delta x$ ) ~11 km. For this TROPOMI derived XCO is gridded at 0.1°x0.1°.

The components of NO<sub>x</sub> (NO and NO<sub>2</sub>) have short lifetimes during daytime because of the photo stationary equilibrium exchanging NO and NO<sub>2</sub> into each other. For this reason, we estimate the lifetime of their sum (NO<sub>x</sub>) which is determined largely by the reaction with OH. In earlier work with satellite NO<sub>2</sub> data, the Jet Propulsion Laboratory (JPL) high pressure limit was used as rate constant to represent the first order loss of NO<sub>2</sub> (Beirle et al., 2011; Lama et al., 2020; Lorente et al., 2019). However, we found this approximation to be too crude, and therefore apply the full IUPAC recommended pressure dependent formula for the 2<sup>nd</sup> order rate constant. Supplement Figure S4 shows the difference between the three rate constants, i.e. JPL high pressure limit, JPL 2<sup>nd</sup> order and IUPAC 2<sup>nd</sup> order, confirming the importance of accounting for the pressure dependence.

WRF output for the third domain is interpolated spatially and temporally to the footprints of TROPOMI. The interpolated WRF- NO<sub>x</sub> tracers are converted to NO<sub>2</sub> using the conversion factor derived from the CAMS reanalysis accounting for its spatial and temporal variation (for the names and functions of tracers see Table 1). The averaging kernel available for each TROPOMI CO and NO<sub>2</sub> observation is applied to the WRF output, after interpolation to the vertical layers of the TROPOMI retrieval. To compare WRF output to TROPOMI, WRF derived XNO<sub>2</sub> (XNO<sub>2</sub><sub>WRF</sub>) is calculated by combining the NO<sub>2</sub> tracer that accounts for the OH effect (XNO<sub>2</sub><sub>(emis,OH)</sub>) and the CAMS NO<sub>2</sub> background (XNO<sub>2</sub><sub>Bg</sub>) (see Fig. S5 and S6). Similarly, the CO emission tracer (XCO<sub>emis</sub>) is added to the CAMS CO background (XCO<sub>Bg</sub>) to calculate WRF simulated XCO (XCO<sub>WRF</sub>) (see Fig. S7 and S8).

## 235 2.5 NO<sub>2</sub>/CO ratio calculation using box rotation

The variation of the NO<sub>2</sub>/CO ratio in the downwind city plume is calculate as a function of distance  $x$  from the city centre in downwind direction. We select days with an average wind speed ( $U$ ) in the range of  $3.0 \text{ ms}^{-1}$  (Beirle et al., 2011)  $< U < 8.5 \text{ ms}^{-1}$  (Valin et al., 2013) within a 50 km radius from the centre of Riyadh (24.63° N, 46.71° E). The horizontal distribution of EDGAR emissions over Riyadh is used within this 50 km radius (Fig S9). Ninety five days in summer and 70 days in winter  
240 meet the wind speed criteria over Riyadh for the ratio calculation. The boundary layer average wind speed and direction is calculated using the CAMS global reanalysis eac4 (retrieved at <https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset/cams-global-reanalysis-eac4?tab=form> , last access : 1<sup>st</sup> August, 2020) at a resolution of  $0.75^\circ \times 0.75^\circ$  spatial and 3 hourly temporal resolution. For this, the CAMS wind vector is spatially and temporally interpolated to the central coordinate of TROPOMI pixels.

245 To compute the NO<sub>2</sub>/CO ratio as function of the downwind distance  $x$ , TROPOMI and WRF data have been re-gridded at  $0.1^\circ \times 0.1^\circ$ . A box (B1) is selected with a width of 100 km, from 100 km in upwind to 200 km in downwind direction of the city centre (see Fig 1a). The dimension of the box is motivated by multiple TROPOMI overpasses over Riyadh showing NO<sub>2</sub> and CO enhancements advected downwind over a ~200 km distance, without other large sources of NO<sub>2</sub> and CO within a 100 km radius of the city centre (see Fig. 1a). Figure 1(b) shows the boundary layer averaged wind speed and wind direction over  
250 Riyadh indicating flow towards the northeast on 4<sup>th</sup> of August, 2018. The box is rotated for every TROPOMI overpass depending upon the daily average wind direction within a 50 km radius from centre of Riyadh as shown in Figure 1(a) and Figure S10. The rotated box B1 is divided into  $N$  rectangular boxes, orthogonal to the wind direction with length ( $\Delta x$ ) ~11 km (see Fig. 1 and Fig. S10). The XNO<sub>2</sub> and XCO grid cells that fall within the  $N$  rectangular boxes are selected to derive zonally averaged XNO<sub>2</sub> and XCO for summer and winter.

255 Unlike the enhancements over the city,  $\Delta XNO_2$  and  $\Delta XCO$  become smaller than retrieval uncertainties at large distance from the city, where the ratio  $\Delta XNO_2/\Delta XCO$  becomes ill-defined. Therefore, we decided to use the ratio of mean XNO<sub>2</sub> and XCO instead of enhancements over the background. To analyse the influence of atmospheric transport and the OH sink on the WRF derived XNO<sub>2</sub>/XCO ratio two different ratios are derived: 1.  $\frac{XNO_2 \text{ emis}}{XCO \text{ emis}}$ , named “Ratio<sub>without OH</sub>”, 2.  $\frac{XNO_2 (\text{emis,OH})}{XCO \text{ emis}}$ , named “Ratio<sub>with OH</sub>”( see Table 1). The CAMS background accounts for the balance between regional source and sink in CTMs so  
260 it is excluded to analyse the influence of atmospheric transport on the ratio. For the comparison between TROPOMI and WRF, the CAMS backgrounds are included in “WRF RATIO” ( $\frac{XNO_2 \text{ WRF}}{XCO \text{ WRF}}$ ) (see Table 1). The comparison of WRF RATIO to TROPOMI ratio, and the contribution of its components, is presented in section 3.2.

## 2.6 OH estimation: satellite data only

In the EMG method, following Beirle et al. (2011), 2D NO<sub>2</sub> column densities maps are assigned to eight equal wind sectors,  
265 spanning 360 ° for summer and winter. 1D column densities per wind sector are computed by averaging in cross wind direction.

This way, average NO<sub>2</sub> column density functions of the downwind distance to the city centre have been constructed for summer and winter (see Fig. S11). Using the EMG method as in Beirle et al., (2011), the e-folding distance x<sub>0</sub> and NO<sub>2</sub> emissions have been estimated. The NO<sub>2</sub> lifetime is derived by dividing x<sub>0</sub> by the average wind speed (5.46 ms<sup>-1</sup> and 5.24 ms<sup>-1</sup> for winter and summer, respectively) and is provided in Table 2. The OH concentration is derived from the inferred NO<sub>2</sub> lifetime using the IUPAC second order rate constant (for details see section Text S2 and S3). Rate constants at the time of TROPOMI overpasses are obtained from WRF by averaging the IUPAC second order rate constant from the surface to top of the planetary boundary layer. The PBL height at the time TROPOMI overpass has been taken from WRF. EMG derived NO<sub>2</sub> emissions are also converted to NO<sub>x</sub> emissions using the CAMS-derived conversion factor. Summer and winter averaged CAMS derived conversion factors for the box of 300 km x 100 km are 1.28 and 1.31, respectively.

## 2.7 OH estimation: WRF optimization

To jointly estimate the NO<sub>x</sub> and CO emissions as well as the OH concentration from the TROPOMI data, a least squares optimization method is used. This method fits the model to the data by minimizing a cost function (J) (see Text S4 for details). The reaction of NO<sub>2</sub> with OH introduces a non-linearity in the OH optimization. To account for this non-linearity, we linearize the problem around the a priori starting point, using small perturbations (10 %) Δ<sub>background</sub>, Δ<sub>emission</sub>, ΔOH. The non-linear model is fitted to the observations, by optimizing scaling factors f<sub>Bg</sub>, f<sub>emis</sub>, f<sub>OH</sub> to the perturbation functions Δ<sub>background</sub>, Δ<sub>emission</sub> and ΔOH, respectively. This process is repeated iteratively, updating the linearization point and re-computing the perturbation functions. The scaling factor f<sub>emis</sub>, f<sub>oh</sub> and f<sub>bg</sub> represent the modification of the prior in percentage change.

We estimate OH by optimizing WRF with TROPOMI in two ways 1) optimizing the simulated NO<sub>2</sub>/CO ratio using TROPOMI-derived ratios, named as “Ratio optimization” and 2) optimizing NO<sub>2</sub> and CO separately using TROPOMI derived XCO and XNO<sub>2</sub> named as “Component wise optimization”. First the ratio optimization is described followed by the component wise optimization. Optimized ratios are derived as follows:

$$F_{\text{TROPOMI}} = F + \frac{\Delta F}{\Delta_{\text{emis}}} * \frac{f_{\text{emis}}}{10} + \frac{\Delta F}{\Delta_{\text{OH}}} * \frac{f_{\text{OH}}}{10} + \frac{\Delta F}{\Delta_{\text{Bg}}} * \frac{f_{\text{Bg}}}{10} \quad (5)$$

$$F = \frac{X\text{NO}_2_{\text{WRF}}}{X\text{CO}_{\text{WRF}}}$$

$$X\text{NO}_2_{\text{WRF}} = X\text{NO}_2_{(\text{emis}, \text{OH})} + X\text{NO}_2_{\text{Bg}} \quad (6)$$

$$X\text{CO}_{\text{WRF}} = X\text{CO}_{\text{emis}} + X\text{CO}_{\text{Bg}} \quad (7)$$

$$\frac{\Delta F}{\Delta_{\text{emis}}} = \frac{X\text{NO}_2_{(\text{emis}, \text{OH})} * 1.05 + X\text{NO}_2_{\text{Bg}}}{X\text{CO}_{\text{emis}} * 0.95 + X\text{CO}_{\text{Bg}}} - F \quad (8)$$

$$\frac{\Delta F}{\Delta OH} = \frac{XNO_2 (emis,OH*1.1) + XNO_2 Bg}{XCO_{emis} + XCO_{Bg}} - F \quad (9)$$

$$\frac{\Delta F}{\Delta Bg} = \frac{XNO_2 (emis,OH) + XNO_2 Bg * 1.05}{XCO_{emis} + XCO_{Bg} * 0.95} - F \quad (10)$$

Here,  $F_{TROPOMI}$  is the TROPOMI derived  $NO_2/CO$  ratio,  $F$  is the WRF Ratio,  $\frac{\Delta F}{\Delta emis}$  is the change in  $F$  due to an increase in the  $NO_2$  emission by 5 % and a decrease in the  $CO$  emission by 5 % ( $1.05/0.95 \approx 10\%$ ),  $\frac{\Delta F}{\Delta OH}$  is the change in  $F$  due to an increase in  $OH$  by 10 % and  $\frac{\Delta F}{\Delta Bg}$  is the change in  $F$  due to an increase in the  $XNO_2$  background by 5 % and a decrease in the  $CO$  background by 5 %.  $XNO_2 (emis,OH)$  is the contribution of city  $NOx$  emissions to  $XNO_2$  accounting for the  $OH$  sink,  $XNO_2 Bg$  is the  $NO_2$  background.  $XCO_{emis}$  is the contribution of the EDGAR city  $CO$  emissions to  $XCO$  and  $XCO_{Bg}$  is the  $CO$  background derived from CAMS.  $XNO_2 WRF$  and  $XCO_{WRF}$  is the WRF derived  $XNO_2$  and  $XCO$  respectively.  $XNO_2 (emis,OH*1.1)$  is the contribution of city  $NOx$  emissions to  $XNO_2$  after increasing CAMS  $OH$  by 10 %. The scaling factors  $f_{emis}$ ,  $f_{OH}$  and  $f_{Bg}$  obtained from the ratio optimization have been divided by 10 because  $\frac{\Delta F}{\Delta emis}$ ,  $\frac{\Delta F}{\Delta OH}$  and  $\frac{\Delta F}{\Delta Bg}$  are defined as the change in  $F$  due to modification of emission,  $OH$  and background by 10 %.

Although the ratio optimization is sensitive to the emission ratio and the  $OH$  sink of  $NO_2$ , it is not sensitive to the absolute emissions of  $CO$  and  $NO_2$ . Therefore, we performed component-wise optimizations for  $XCO$  and  $XNO_2$  to optimize absolute emissions. We also compare the  $OH$  factor obtained from the ratio optimization and component-wise optimization to test the robustness of the method. The optimized  $XNO_2$  is derived using Eq. (11).  $XCO$  is optimized using the same equation but without considering the  $OH$  sink (see Appendix B).

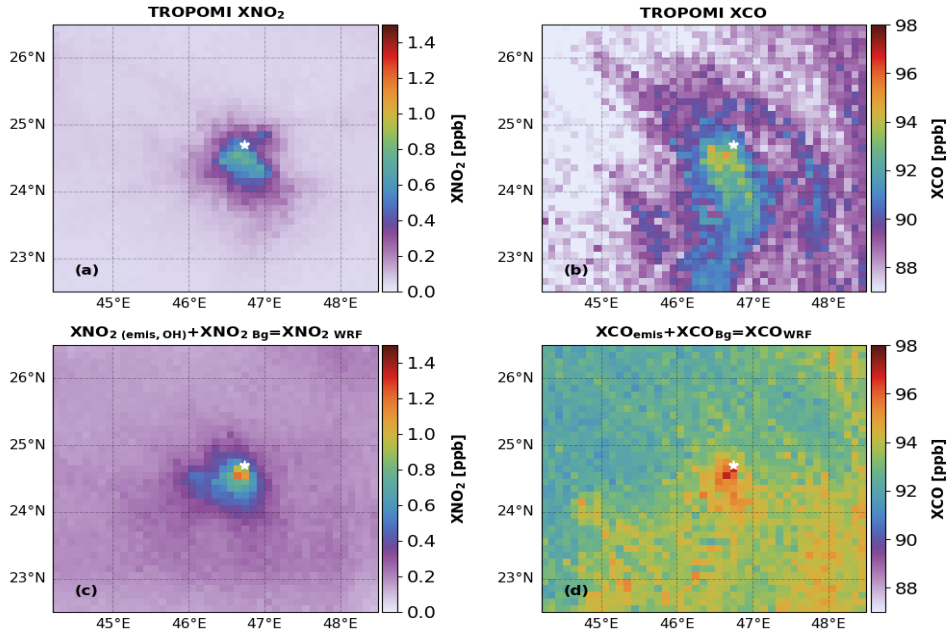

$$XNO_2 TROPOMI = XNO_2 WRF + \Delta XNO_2 emis * \frac{f_{emis}}{10} + \Delta XNO_2 OH * \frac{f_{OH}}{10} + \Delta XNO_2 Bg * \frac{f_{Bg}}{10} \quad (11)$$

$$\Delta XNO_2 emis = XNO_2 (emis,OH) * 1.10 - XNO_2 (emis,OH) \quad (12)$$

$$\Delta XNO_2 OH = XNO_2 (emis,OH*1.1) - XNO_2 (emis,OH) \quad (13)$$

$$\Delta XNO_2 Bg = XNO_2 Bg * 1.10 - XNO_2 Bg \quad (14)$$

Here,  $XNO_2 TROPOMI$  is the TROPOMI derived  $XNO_2$ ,  $XNO_2 WRF$  is the WRF  $XNO_2$ .  $\Delta XNO_2 emis$  is the change in  $XNO_2$  due to an increase in emission by 10 %,  $\Delta XNO_2 OH$  is change in  $XNO_2$  due to an increase in CAMS  $OH$  by 10 % and  $\Delta XNO_2 Bg$  is a change in the background  $XNO_2$  by 10 %. The scaling factors  $f_{emis}$ ,  $f_{OH}$  and  $f_{Bg}$  are divided by a factor 10, because  $\Delta XNO_2 emis$ ,  $\Delta XNO_2 OH$  and  $\Delta XNO_2 Bg$  are defined as 10 % changes in  $NOx$  emission,  $OH$  and background level.

**Figure 2.** Comparison between XNO<sub>2</sub> (left) and XCO (right) from TROPOMI and WRF over Riyadh averaged over June to October, 2018. Top panels show TROPOMI data and bottom panels the corresponding co-located WRF results. XNO<sub>2</sub> WRF is derived by adding XNO<sub>2</sub> (emis,OH) and XNO<sub>2</sub> Bg. XCO WRF is derived by adding XCO<sub>emis</sub> and XCO<sub>Bg</sub>. The white star represents the centre of city. TROPOMI and WRF results are gridded at 0.1°x0.1°.

### 3. Results and Discussion

#### 3.1. XNO<sub>2</sub> and XCO over Riyadh

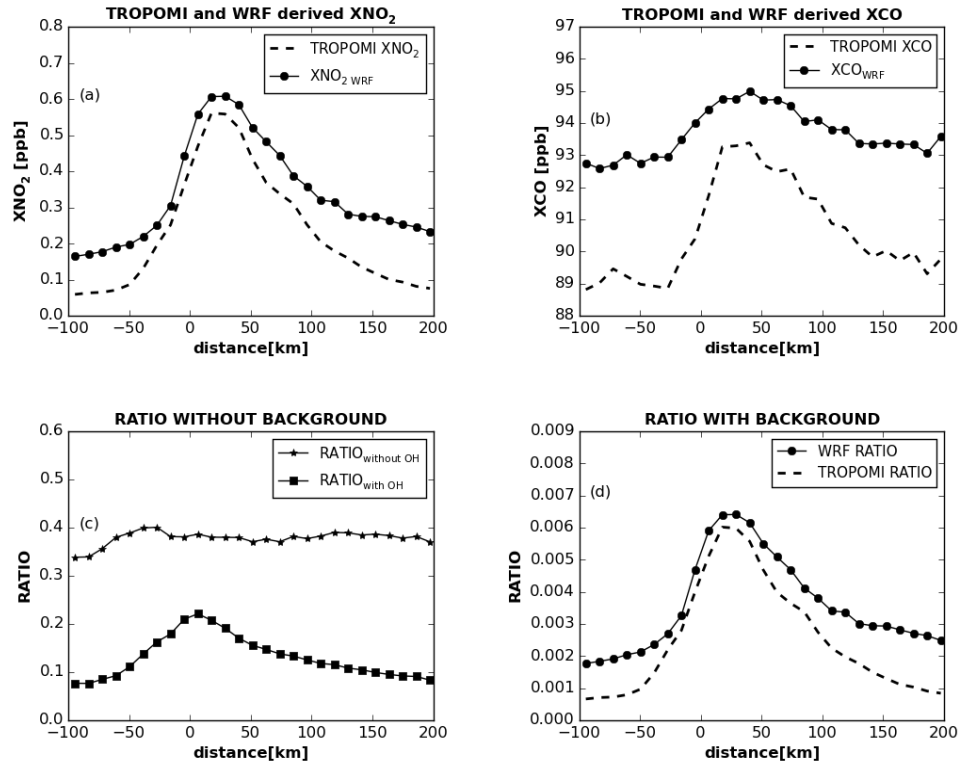

In this subsection, we compare WRF-derived XCO<sub>WRF</sub> and XNO<sub>2</sub> WRF with TROPOMI for summer (see Fig. 2) and winter (see Fig. S6) over Riyadh. TROPOMI and WRF derived XCO and XNO<sub>2</sub> are averaged from June to October 2018 for summer and November 2018 to March 2019 for winter in a domain of 500 x 500 km<sup>2</sup> centered around Riyadh.

The comparison for summer in Figure 2 shows TROPOMI NO<sub>2</sub> after replacing the TM5-based tropospheric AMF with WRF profiles as described in Visser et al. (2019). The enhancement of XNO<sub>2</sub> and XCO over Riyadh due to urban emissions is clearly separated from the background for TROPOMI and WRF, showing that the city of Riyadh is well suited to investigate the use of the NO<sub>2</sub>/CO ratio to quantify OH in urban plumes. Due to the longer life-time of CO, the TROPOMI-observed XCO plume

extends further in the southeast direction compared to  $\text{XNO}_2$ . Figure 2 shows that our WRF simulations are able to reproduce the TROPOMI retrieved  $\text{XNO}_2$  ( $r^2 = 0.96$ ) and  $\text{XCO}$  ( $r^2 = 0.78$ ) plumes, confirming that WRF-derived  $\frac{\text{XNO}_2 \text{ WRF}}{\text{XCO WRF}}$  is suitable for the optimization of CTM-derived OH concentrations using TROPOMI data.  $\text{XNO}_2 \text{ WRF}$  is higher by 25 % compared to TROPOMI in the city centre. In the background,  $\text{XCO WRF}$  shows a similar spatial distribution as TROPOMI  $\text{XCO}$ , but the values are higher by 5 to 10 % (see Fig 2.). Close to the city centre,  $\text{XCO WRF}$  is ~5.7 % higher than TROPOMI  $\text{XCO}$ . In EDGAR 2011, emission sources are located in the centre of Riyadh (see Fig. S9). However, as noted by Beirle et al. (2019) they extend to a larger part of the city in reality. This difference in spatial distribution leads to higher  $\text{XNO}_2 \text{ WRF}$  and  $\text{XCO WRF}$  close to centre of Riyadh compared to TROPOMI.

335 In winter, the wind direction is predominantly from the south easterly sector in WRF and TROPOMI (see Fig S12). The spatial distribution of  $\text{XCO WRF}$  ( $r^2 = 0.73$ ) and  $\text{XNO}_2 \text{ WRF}$  ( $r^2 = 0.88$ ) matches quite well with TROPOMI. Therefore, the difference between summer and winter should offer the opportunity to quantify the seasonality in emissions and OH concentrations over Riyadh. In winter,  $\text{XCO WRF}$  is ~5 to 10 % higher than TROPOMI, while  $\text{XNO}_2 \text{ WRF}$  is higher by 40 % to 50 %. The difference could either point to uncertainties in the  $\text{NO}_2/\text{CO}$  emission ratio, uncertainties in the  $\text{NO}_2$  lifetime, or inaccuracies in the background. By quantifying OH, we can evaluate these explanations (see section 3.3).  $\text{XNO}_2 \text{ WRF}$  is higher by 20 % in winter than in summer. Contrary, TROPOMI  $\text{NO}_2$  is lower by ~30 % in winter (Fig S12.) compared to summer (Fig. 2). Again, to disentangle the role of changing sources and sinks, we need an independent estimate of OH.

340

**Figure 3.** Comparison of WRF and TROPOMI averaged across the wind for each small box a) XNO<sub>2</sub>, b) XCO and c) WRF Ratio (XNO<sub>2</sub>/ XCO) without CAMS background d) WRF Ratio (XNO<sub>2</sub>/ XCO) with background and TROPOMI as a function of distance to the centre of Riyadh for summer ( June, 2018 to October, 2018).

### 3.2. The XNO<sub>2</sub>/XCO ratio and OH

Before comparing TROPOMI and WRF-derived XNO<sub>2</sub>/XCO ratios, we first analyse the influence of atmospheric transport and the OH sink on the WRF derived XNO<sub>2</sub>/XCO ratio. To do this three ratios are used 1. Ratio<sub>without OH</sub> 2. Ratio<sub>with OH</sub> 3. WRF RATIO (see Table 1). As seen in Figure 3, S13 and S14, WRF is able to reproduce the TROPOMI-observed downwind evolution of XNO<sub>2</sub> and XCO in summer and winter. The peak of the XNO<sub>2</sub> and XCO plumes is shifted away from the city centre due to the balance between the accumulation of urban emissions in the atmospheric column and atmospheric transport (Lorente et al., 2019).

As expected, Ratio<sub>without OH</sub> shows an approximately straight line when the background is removed, because transport influences NO<sub>2</sub> and CO in the same way and therefore cancels out in the ratio (see Fig. 3b). The Ratio<sub>with OH</sub> however, shows an approximately Gaussian relation with distance due to the influence of the sink on NO<sub>2</sub>. This comparison demonstrates the

sensitivity of the relation between  $XNO_2/XCO$  ratio and downwind distance to the  $NO_2$  lifetime, which we want to exploit to  
355 quantify OH. When including the background, the shapes of the functions in Figure 3c change (not shown), because the  
relative weights of the background and city contributions to the ratio vary with distance of the city centre. In summer, the WRF  
RATIO is higher by ~15 % close to centre of city TROPOMI due to the overestimation of  $XNO_{2\ WRF}$  in WRF (see Fig. 3d).  
However in the downwind plume, at a distance of 100 km WRF RATIO is higher by 20 % to 50 % compared to TROPOMI.

In winter,  $Ratio_{without\ OH}$  and  $Ratio_{with\ OH}$  show relations with downwind distance that are similar to summer, confirming  
360 that an OH sink leads to a Gaussian structure of the ratio (see Fig. S14). The winter WRF RATIO is 40 % to 60 % higher than  
TROPOMI due to the overestimation of  $XNO_2$  by 40 % to 50 %. The WRF RATIO close to the centre of city is also 20 %  
higher in winter than in summer, due to higher winter  $XNO_{2\ WRF}$  than in summer (see Fig S12 and S15). In contrast, TROPOMI  
shows a higher ratio in summer compared to winter (see Fig S15). These differences between TROPOMI and WRF-derived  
ratios offer an opportunity to address uncertainties in CTM computed urban OH and emission inventories, which will be  
365 explored next.

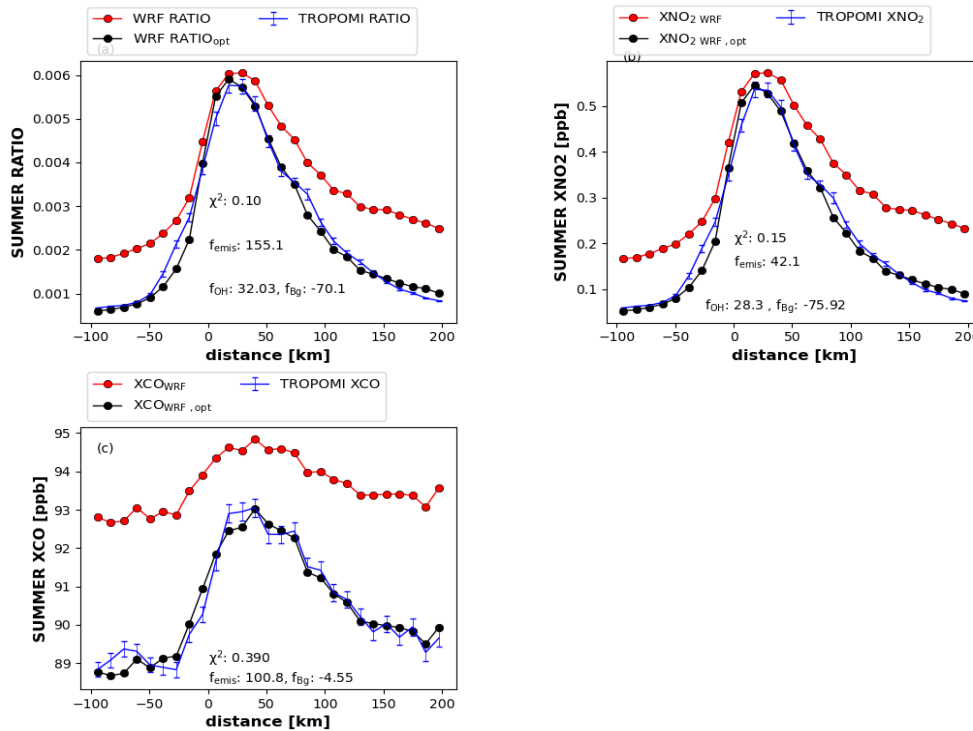

### 3.3 WRF optimization using synthetic data

To translate the discrepancies between TROPOMI and WRF derived ratios of section 3.2 into implied differences in emissions, OH and background, the least squares optimization method has been used as described in section 2.6. Before optimizing WRF using TROPOMI, pseudo data experiments in WRF have been carried out to test if the optimization method is capable of recovering true emissions and OH levels. To this end, changes in OH concentrations, emissions and background by known scaling factors have been applied to the WRF prior simulation to create a synthetic dataset. This process is repeated multiple times to create thousands of synthetic datasets. Subsequently, the scaling factors are obtained in the inversion procedure. These tests reveal that the estimation errors for  $f_{\text{emis}}$ ,  $f_{\text{OH}}$  and  $f_{\text{Bg}}$  are less than 2.5 % (see Fig. S16). This confirms that the least square optimization method works, with two iterations leading to a sufficient accuracy, and can be used to estimate emissions and OH from TROPOMI data. Using TROPOMI data, estimation errors for  $f_{\text{emis}}$ ,  $f_{\text{OH}}$  and  $f_{\text{Bg}}$  are expected to be higher due to atmospheric transport errors, simplified chemistry, and XCO and XNO<sub>2</sub> retrieval uncertainties. These errors did not play a role in the pseudo-data experiments, in which perfect transport and sampling was assumed.

To obtain a more realistic estimate of the uncertainty in least squares optimized OH, TROPOMI data have been replaced by NO<sub>2</sub>, CO and NO<sub>2</sub>/CO ratio derived from WRF-chem using the Carbon Bond Mechanism Z (CBM-Z) gas-phase chemical mechanism (Zaveri and Peters, 1999). EDGAR based VOCs, NO<sub>x</sub> and CO emission have been used in combination with boundary condition for NO, NO<sub>2</sub>, CO, ozone (O<sub>3</sub>) from CAMS to run WRF-chem for August 17<sup>th</sup>, 2018 and November 18<sup>th</sup>, 2018 representing a summer and winter day, respectively. For August 17<sup>th</sup>, 2018, the ratio and XNO<sub>2</sub> optimization increase the CAMS based prior OH of  $1.19 \times 10^7$  moleculescm<sup>-3</sup> by 15.7 % and 13.4 %, respectively (see Fig S17). In the fully coupled online chemistry with WRF simulation, the boundary layer averaged OH for the box of 300 km x 100 km amounts to  $1.33 \times 10^7$  moleculescm<sup>-3</sup>, which is <5 % lower than the optimized OH value that is derived using our method. The optimized NO<sub>x</sub> and CO emissions differ by <11 % from the emission input used in the full chemistry version WRF. In winter, the optimization increases CAMS based OH of  $1.03 \times 10^7$  moleculescm<sup>-3</sup> by 19.4 %. The OH derived from WRF with full online chemistry is  $1.07 \times 10^7$  moleculescm<sup>-3</sup> and lower by 15.2 % than the optimized OH value. The component wise optimization increases the EDGAR NO<sub>x</sub> and CO emissions by 23.1 % and 10.5 %, respectively (see Fig S18). Overall, the uncertainty in optimized NO<sub>x</sub>, CO emission and OH derived from this test is <11 % in summer and 10 % to 23 % in winter. Since the lifetime of NO<sub>x</sub> is determined by other reactions in addition to the oxidation to HNO<sub>3</sub> considered in our method, it is expected to overestimate the real OH value. The test using WRF full chemistry confirms that this is indeed the case. The uncertainty for OH, NO<sub>x</sub> emission and CO emission are in good agreement with the CLASS computations explained in detail in Text S6.

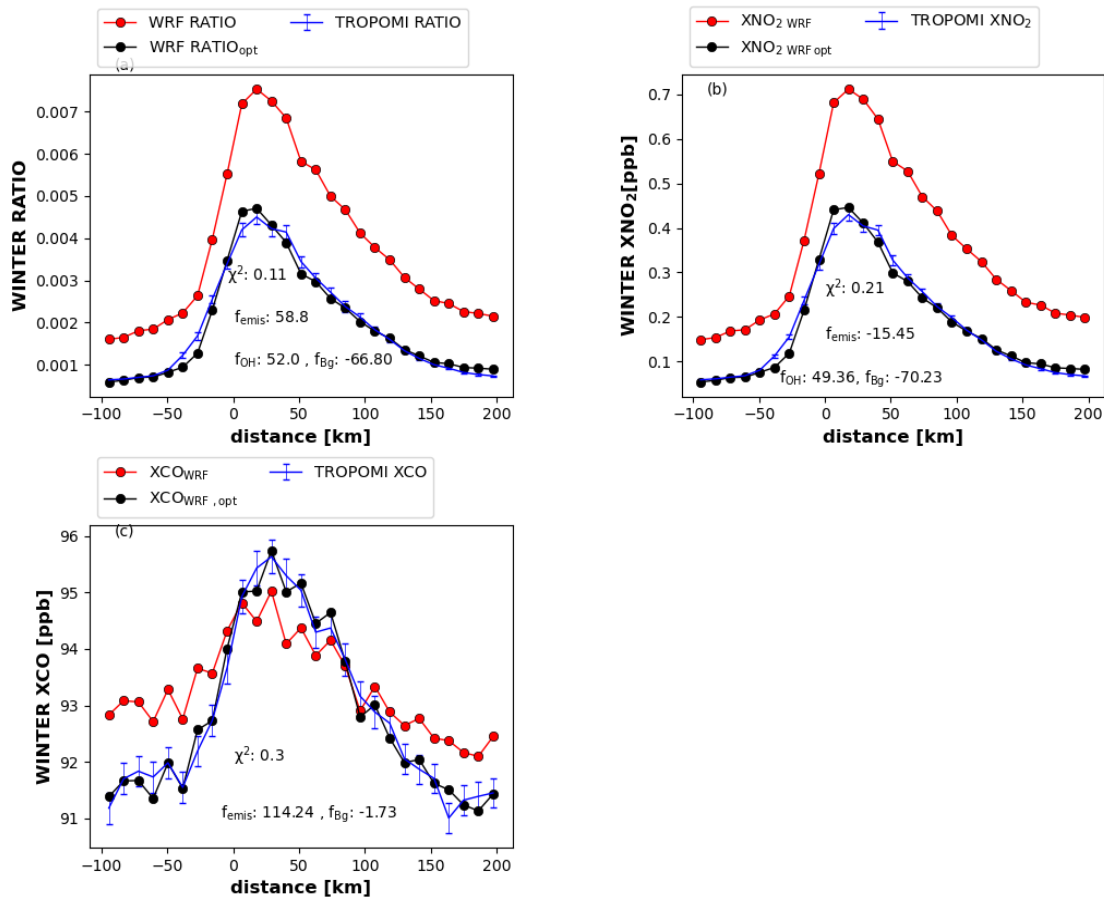

The results for summer are summarized in Figure 4, showing the optimized fit to the TROPOMI data as well as the corresponding scaling factors  $f_{\text{emis}}$ ,  $f_{\text{OH}}$  and  $f_{\text{Bg}}$  that are estimated. The optimized emission, OH and Bg obtained from the 2<sup>nd</sup> iteration is divided by prior to derive the  $f_{\text{emis}}$ ,  $f_{\text{OH}}$  and  $f_{\text{Bg}}$  (see Text S5 for details). The convergence of the iterative procedure is shown in Fig S19 and S20. The estimated uncertainties for the scaling factors  $f_{\text{emis}}$ ,  $f_{\text{OH}}$  and  $f_{\text{Bg}}$  are derived by summing the contribution of wind speed, length and width of the box, NO<sub>2</sub> bias, CO bias and the different pathways of NO<sub>x</sub> loss in quadrature (see Text S6, Tables S1 and S2). For summer and winter, the uncertainties of the optimized OH concentrations is <17 % and <29 % respectively. For NO<sub>x</sub> and CO emissions, the uncertainty is <29 % in summer and winter. Figure 4a shows WRF ratios for summer in comparison to TROPOMI, before and after optimizing the OH concentration. The optimized WRF ratios fit the TROPOMI ratios well with  $\chi^2 = 0.1$  (for the derivation of  $\chi^2$  see section Text S7). The prior and optimized

**Figure 4.** Comparison between TROPOMI and WRF, before and after optimization for Summer (averaged over June to October, 2018). a) XNO<sub>2</sub>/XCO ratio, b) XNO<sub>2</sub> and c) XCO in comparison to TROPOMI.  $f_{\text{OH}}$ ,  $f_{\text{emis}}$  and  $f_{\text{Bg}}$  are optimized scaling factors obtained iteratively for OH, emissions and background by least square optimization method.  $f_{\text{emis}}$ ,  $f_{\text{OH}}$  and  $f_{\text{Bg}}$  are derived by accounting the total change in emission, OH and background using the corresponding scaling factors obtained from 1<sup>st</sup> and 2<sup>nd</sup> iterative step. The unit of scaling factor is in percent (%).

405 emission ratio, OH concentration and background ratio obtained from component and ratio optimization for summer and winter is provided in Table S4. According to the ratio optimization, the emission ratio and CAMS OH are underestimated by  $155 \pm 26 \%$  and  $32 \pm 5.3 \%$  respectively (see Table S4). The optimized CAMS background ratio is lower by  $70 \pm 6.5 \%$  compared to prior. It should be realized here that the ratio optimization does not estimate the absolute emission of  $\text{NO}_2$  and CO, but only their ratio.

410

**Figure 5.** As Figure 4, for Winter (averaged over November, 2018 to March, 2019)

To derive the absolute emission, we performed component-wise optimizations of WRF-derived  $\text{XCO}_{\text{WRF}}$  and  $\text{XNO}_{2\text{WRF}}$ . Optimized  $\text{XCO}_{\text{WRF}}$  and  $\text{XNO}_{2\text{WRF}}$  fit well to the TROPOMI data (see Fig. 4b and 4c). In the  $\text{XNO}_2$  optimization, the EDGAR NO<sub>x</sub> emission is increased by  $42.1 \pm 8.4 \%$  and the CAMs background is reduced by  $75.9 \pm 10.0 \%$ . CAMS OH is increased

by  $28.3 \pm 3.9$  % which is close to the results obtained from the ratio optimization (see Table S4). In the XCO optimization,  
415 EDGAR CO emissions are roughly doubled and the background is reduced by  $4.5 \pm 0.7$  % compared to CAMS (see Table S4).

The summer optimized NO<sub>x</sub>/CO emission ratio derived from the component wise optimization is  $0.55 \pm 0.09$ . The optimized  
emission ratio from ratio optimization is larger by factor 3.6 compared to component wise optimization (see Table S4). The  
difference between two estimates can be explained by different constraints on the solution in the two methods. In particular,  
the ratio inversion allows emission adjustment in a fixed relation between NO<sub>2</sub> and CO emissions whereas the component wise  
420 has the full flexibility to adjust CO and NO<sub>2</sub> emission. The NO<sub>2</sub>/CO ratio over a city is the sum of the contributions of the  
background and the city emission. The relative weight of the two is determined by the absolute background levels and absolute  
emissions of CO and NO<sub>2</sub>. Therefore, the emission ratio estimated by ratio optimization is sensitive to the XNO<sub>2Bg</sub>. However,  
the difference between the two estimates is larger than expected but does not affect the OH estimation. Lama et al., (2020)  
inferred an NO<sub>2</sub>/CO emission ratio over Riyadh of  $0.47 \pm 0.1$  for 2018 from TROPOMI favoring the Monitoring Atmospheric  
425 Chemistry and Climate and CityZen (MACCity) emission ratio over that of EDGAR. The optimized emission ratio obtained  
from component wise optimization is consistent to Lama et al., (2020) and MACCity summer emissions. This shows that for  
the accurate estimation of the emission and emission ratio, the component wise optimization method is preferable.

Figure 5 presents optimization results for winter, where optimized WRF is in similar good agreement with TROPOMI as for  
summer with  $X^2 = 0.11$ . For winter, the ratio optimization increases emission ratio by  $58.8 \pm 33$  % and OH by  $52.0 \pm 14$  %.  
430 The ratio and component-wise optimizations again show similar OH adjustments, demonstrating the robustness of our method.  
The background ratio is reduced by  $66.8 \pm 11$  %. The XNO<sub>2</sub> optimization reduces the EDGAR NO<sub>x</sub> emission by  $15.45 \pm 4.1$   
% and the CAMS background by  $70.2 \pm 6.1$  %. For XCO, the WRF XCO<sub>Bg</sub> is reduced by  $1.74 \pm 0.1$  % in combination with a  
doubling of the EDGAR CO emission. The optimized emission ratio (NO<sub>x</sub>/CO) derived from component wise optimization  
is 0.36 which is lower by 4.0 times than optimized emission ratio obtained from ratio optimization (see Table S4).

**Table 2.** Overview of WRF optimized OH and NO<sub>x</sub> emissions for Riyadh and comparison to the EMG method. The estimated uncertainty for EMG and WRF derived NO<sub>x</sub> emission and OH concentration is the sum of the contribution of wind speed, length and width of box and NO<sub>2</sub> bias correction provided in Table S1, S2 and S3.

Parameter	Summer WRF Optimization		Summer EMG	Winter WRF Optimization		Winter EMG
	Prior	Optimized		Prior	Optimized	
NO <sub>x</sub> emission (kg/second)	8.2	11.6±2.3	8.6±1.3	9.4	7.9±2.1	5.3±1.2
OH (10 <sup>7</sup> , molecules/cm <sup>3</sup> )	1.3	1.7 ± 0.32	1.53± 0.16	0.86	1.3 ±0.38	1.2± 0.16
NO <sub>x</sub> lifetime (hr)	3.1	2.4 ± 0.46	2.26 ± 0.3	4.9	3.3 ± 0.9	2.98 ± 0.4
NO <sub>x</sub> background (ppb)	0.22	0.053± 0.007	0.079±0.01	0.15	0.049±0.006	0.057±0.008

### 3.5 WRF optimization using a single TROPOMI overpass

To demonstrate the application of our WRF optimization method to single TROPOMI overpasses, results are presented in this subsection for August 18<sup>th</sup>, 2018. This date was selected for clear sky conditions with most of the TROPOMI NO<sub>2</sub> and CO pixels passing the data quality filter. During this day, the urban plume is transported in southwestern direction over Riyadh. The spatial distribution of XNO<sub>2</sub><sub>WRF</sub> (r<sup>2</sup> = 0.76) and XCO<sub>WRF</sub> (r<sup>2</sup>= 0.65) matches quite well with TROPOMI (see Fig S21). The optimized ratio, XNO<sub>2</sub> and XCO for a single day fit well with TROPOMI ( X<sup>2</sup> = 0.1, 0.3 and 0.7) comparable to the summer averaged plumes indicating that the optimization method can be applied to single TROPOMI overpass. The ratio optimization increases the emission ratio and CAMS OH respectively by 111 ± 18.4 % and 37.9 ± 6.2 % respectively, whereas the background is reduced by 51.5 ± 5.2% (see Fig S22 a). The XNO<sub>2</sub> optimization increases the EDGAR NO<sub>x</sub> emission by 25.5 ± 5.1 % and CAMS OH by 32.3 ± 4.4 %, whereas the NO<sub>x</sub> background is reduced by 54.4 ± 7.0 % (see Fig S20 b). The CO optimization doubles the EDGAR CO emission and reduces the background by 6.1 ± 0.97 % (see Fig S20 c). The optimized NO<sub>x</sub> and CO emission for August 18<sup>th</sup> is 8.9 ± 1.7 kg/s and 18.9 ± 4.0 kg/s respectively and differs by <25 % with the summer optimized emission (see Table 2 and S5). The optimized OH derived from a single TROPOMI overpass is 1.73x10<sup>7</sup> ± 0.3 molecules cm<sup>-3</sup> differs by < 5 % from the summer averaged OH i.e. 1.7 x 10<sup>7</sup> ± 0.3 moleculescm<sup>-3</sup> confirming that the method yields realistic results for a single overpass.

### 3.6 WRF optimization Vs the EMG method

455 To investigate the consistency between our method and the EMG method, the derived NO<sub>x</sub> lifetimes, emissions and OH concentrations using both methods are listed in Table 2 for winter and summer. Our optimization and the EMG method agree well on the seasonal change in NO<sub>x</sub> emission and OH concentration. Both methods result in higher NO<sub>x</sub> emissions and shorter lifetimes in summer; lower NO<sub>x</sub> emissions and longer lifetimes in winter. Riyadh has dry and warm summer days and the increase in power consumption due to the use of air conditioning contributes to the higher emission in summer than in winter (Lange et al., 2021). During the summer, EMG and the WRF optimization method both increase the NO<sub>x</sub> emission and OH concentration compared with the prior. The size of the NO<sub>x</sub> emission and OH concentration increase, obtained using the WRF optimization method is higher than the EMG method by 10% to 29 %. However, the difference between the EMG method and the component optimization method are smaller compared to the uncertainty of the emission and OH concentration derived for the optimization method. For winter, the difference between the EMG and WRF-optimized results are smaller than the difference between the EMG results and the prior. The NO<sub>x</sub> emission after optimization differs from the EMG method by 33 %. Optimized OH concentration and NO<sub>x</sub> lifetime differs by <10 % compared to EMG method. In general, the difference between the EMG and optimization results is within the uncertainty range of 20 to 30 %, confirming their consistency and strengthening the confidence in the estimates that are obtained from TROPOMI data. In contrast to EMG method, the optimization method can be used for a single TROPOMI overpass (see Section 3.6) and does not require yearly averaged NO<sub>2</sub> data, allowing analysis of day-by-day OH, NO<sub>x</sub> and CO emission (see Section 3.3). Segregation and averaging of NO<sub>2</sub> urban plume by wind sector is not required in the optimization method. The effect of transport cancels out in taking the NO<sub>2</sub> /CO ratio and loss of NO<sub>2</sub> is mostly governed by OH during the mid-day. In this study, NO<sub>x</sub> emission and OH concentration is estimated iteratively whereas the EMG method arrives at the solution in a single step. However, since our optimization method requires a WRF model simulation it is computationally more expensive. Uncertainties in transport may create mismatches with the satellite observations, leading to errors in the optimized fit. This influences the quality of derived emission estimates (Dekker et al., 2017). Therefore, finding a simplified approach using satellite data to derive the emission ratio and to estimate OH concentration in urban plumes will be our focus in the future. In the future, the accuracy of our method can be further improved by accounting other NO<sub>x</sub> removal pathways.

### 3.7 WRF optimized emissions and emission trends

480 It should be realized that the a priori EDGAR emissions and TROPOMI optimized estimates represent different years (2012 and 2018, respectively). To check whether the emission differences that are found may be explained by trends in emissions, we compare EDGARv5.0 2012 NO<sub>x</sub> and CO emissions with 2018 accounting for seasonal and diurnal emission variations using temporal emission factors by van der Gon et al., (2011). EDGAR 2018 NO<sub>x</sub> and CO emissions are derived by linear extrapolation using emission from 2000 to 2015 (see Figure S23). For summer mid-day NO<sub>x</sub> emissions, the EDGAR emissions increased by 16.7 % from 2012 to 2018, which is lower than our optimization results. For winter, mid-day NO<sub>x</sub> emissions

increase in EDGAR by 15.2 % from 2012 to 2018, whereas the WRF optimization yields reductions by 15.6%. In EDGAR, summer and winter CO emissions increased from 2012 to 2018 by 38.5 %. However, the WRF optimization suggests that the EDGAR CO emissions for summer and winter need to be doubled (see Table S4). Borsdorff et al., (2018b) mentioned that EDGAR CO emissions have to be increased significantly to match with TROPOMI CO observations over middle eastern cities such as Tehran, Yerevan, Tabriz and Urmia. Overall , this points to a significant uncertainty in the EDGAR emission inventory at the city scale.

To test the accuracy of the linear extrapolation of EDGAR data, we compare the relative change in NO<sub>x</sub> and CO emission in 2012 to 2018 using CAMS Global (CAMS–GLOB) anthropogenic v4.2 emission datasets (<https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset/cams-global-emission-inventories?tab=overview>). CAMS –GLOB shows that for summer and winter NO<sub>x</sub> emission increases by 26 % from 2012 to 2018, which is higher by a factor 1.7 than EDGAR. CAMS-GLOB based summer and winter CO emission increases by 20 % from 2012 to 2018 which differs by ~40 % compared to EDGAR. In general, the relative increase in CO and NO<sub>x</sub> emission from EDGAR and CAMS-GLOB is much smaller compared to the difference with our optimization method.

#### 4. Discussion

The TROPOMI retrieved XNO<sub>2</sub>/XCO ratio is useful for estimating mid-day OH over isolated localized sources, such as the city of Riyadh, showing a clear contrast between the urban plume and the background. Such TROPOMI derived OH estimates offer a new opportunity to evaluate urban photochemistry in chemistry transport models. OH depends non-linearly on NO<sub>x</sub> and VOC emission, meteorological conditions, etc.(Sillman, 1990) , which vary substantially between cities that are monitored by TROPOMI. Therefore, the application of our method to the global and multi-year dataset that is available could contribute substantially to the understanding of urban photochemistry and the development of effective pollution mitigation strategies. In addition, the method requires local sources with NO<sub>2</sub> and CO emissions that are large enough to be detected by TROPOMI. Especially in European cities with lower CO emission where TROBabic, L., Braak, R., Dierssen, R., Kissi-Ameyaw, J., Kleipool, ´ J., Leloux, J., Loots, E., Ludewig, A., Rozemeijer, N., Smeets, S., and Vacanti, G.: Algorithm theoretical basis document for the TROPOMI L01b data processor Erwin Loots Quintus Kleipool, 2017.

POMI cannot detect the CO enhancement along with NO<sub>2</sub> this method cannot be applied.

We realise that our method only considers the first order loss of NO<sub>2</sub> by OH forming HNO<sub>3</sub>. In reality, the NO<sub>2</sub> lifetime is influenced by more spatially and temporally varying factors such as temperature, ozone, and radiation (Lang et al., 2015; 725 Romer et al., 2018). In cities, the loss of NO<sub>2</sub> via the formation of alkyl and multifunctional nitrates (RONO<sub>2</sub>) are also important reactions influencing the lifetime of NO<sub>2</sub> (Browne et al., 2013; Sobanski et al., 2017). For CO, secondary production from short-lived volatile organic compounds can also play an important role in urban pollution plumes. The application of full chemistry that includes all the sources and losses of NO<sub>2</sub> and CO could therefore further improve the accuracy of OH estimates. For cities at higher latitudes, especially in winter, it becomes more critical to account for the contribution of other pathways of 730 NO<sub>x</sub> loss than OH oxidation. Isolated tropical and subtropical cities are therefore best suited for application of our current method.

A sensitivity test has been performed in which  $XNO_{x,Bg}$  is lost by OH. In this case the optimized NO<sub>x</sub> emission and OH for summer and winter differ by < 7 % from the default method where the background is treated as an inert tracer (see Table S6). Furthermore, a sensitivity test has been performed in which the prior emission has been changed. The optimized emission 735 varied by < 5 %, demonstrating robustness of the method to the choice of prior (see Fig S24). This also indicates that the optimization method can be used to study emission changes. Figure S25 shows that power plants and manufacturing industries are the largest pollutant emitter over Riyadh (Beirle et al., 2019). In this study, NO<sub>x</sub> and CO anthropogenic emissions are introduced at the surface, whereas the emission height of different sources is expected to vary in reality. The different emission heights for NO<sub>x</sub> and CO emission sources can also influence the result. In the future, realistic emission heights should also be 740 incorporated in WRF for accurate estimation of OH. Moreover, the temporal emission factors that have been used by van der Gon et al., (2011) are based on European countries. The comparison of van der Gon et al., (2011) with the Copernicus Atmosphere Monitoring Service TEMPORal profiles (CAMS-TEMPO) (Guevara et al., 2020) suggests that temporal emission factors for weekend road transport and monthly residential combustion are different in Riyadh compared to European countries CAMS-TEMPO is expected to provide a more accurate representation of emission variation due to the information on 745 temporal, spatial variations that is included. Road transport, CO emission has the largest contribution ~75 % to the total emission over Riyadh, whereas NO<sub>x</sub> emission from road contributes by 24 % to the total NO<sub>x</sub> emission. Residential combustion has the smallest contribution of ~0.3 to 0.4 % to total NO<sub>x</sub> and CO emissions (see Fig S25 ). In the future, the application of accurate diurnal emission factors for road transport (see Fig S26) can further improve the accuracy of urban OH concentrations estimated using TROPOMI derived  $XNO_2/CO$  ratios. In addition, the seasonality for NO<sub>x</sub> and CO emissions 750 is different in Riyadh than in Europe, which should be accounted for in future studies also.

## 5. Conclusions

In this study, a new method is presented for estimating OH concentrations in urban plumes using TROPOMI observed XNO<sub>2</sub>/XCO ratios in combination with WRF simulations of the downwind pollution plume of large cities. Our new method has been tested for the city of Riyadh using synthetic as well as real TROPOMI data. Seasonal emissions and OH concentrations have been estimated for summer (June to October, 2018) and winter (Nov, 2018 to March, 2019).

WRF is well able to reproduce the spatial distribution of TROPOMI retrieved XNO<sub>2</sub> and XCO plumes over Riyadh during the summer and winter seasons. However, before the optimization, WRF overestimates XNO<sub>2</sub> by 15 % to 30 % in summer and 40 % to 50 % in winter compared to TROPOMI. In both seasons, TROPOMI XCO agrees within 10 % with WRF. The WRF derived XNO<sub>2</sub>/XCO ratio is higher by 15 % to 30 % in summer and 40% to 60 % in winter compared to TROPOMI, explained mostly by differences in XNO<sub>2</sub>.

The differences between WRF and TROPOMI observations have been used to optimize emissions and the NO<sub>2</sub> lifetime. To this end, scaling factors for the city emissions, OH and the background level have been optimized iteratively using a least squares method. Ratio and component wise optimizations have been compared to test the overall consistency of the method. In summer, the ratio and XNO<sub>2</sub> optimization for XNO<sub>2</sub> suggest that the OH prior from CAMS is underestimated by  $32 \pm 5.3$  %. The OH estimates obtained from the ratio and NO<sub>2</sub>-only optimization differs by <10 %, demonstrating the robustness of the method. Summertime emissions of NO<sub>x</sub> and CO from EDGAR are increased by  $42.1 \pm 8.4\%$  and  $101 \pm 21 \%$ . For winter, the ratio and component wise optimizations increase OH by  $\sim 52 \pm 14 \%$  to fit TROPOMI inferred ratios. In the optimization of winter data, NO<sub>x</sub> emissions are reduced by  $15.5 \pm 4.1 \%$  and CO emissions are doubled. In the future, the remaining differences between TROPOMI observations and WRF simulations could be reduced further by the use of precise temporal and monthly emission factors, emission heights and full chemistry to account for secondary sources and sinks of CO and NO<sub>2</sub>.

TROPOMI inferred OH concentrations obtained from the least squares optimization method have been compared to the EMG method. For the summer and winter, the optimized OH concentrations differ by 10% between two methods. These results confirm that urban emissions and OH concentrations can robustly be estimated from TROPOMI data. With our method, single TROPOMI overpasses can be used to estimate OH whereas EMG method requires averaging of urban NO<sub>2</sub> plume by wind sector. The iterative approach allows to test the factors i.e.  $f_{\text{emis}}$ ,  $f_{\text{oh}}$  and  $f_{\text{bg}}$  obtained from optimization method, whereas EMG method does not allow such flexibility.

An important remaining uncertainty is the bias correction of the TROPOMI XNO<sub>2</sub> retrieval. Following the recommended procedure, the air mass factor AMF is recalculated by replacing the tropospheric AMF based on TM5, that is provided with the data, with WRF-chem. The TROPOMI XNO<sub>2</sub> bias correction increases the mixing ratio in the urban plume of Riyadh by 5 % to 10 % in summer and 25 % to 30 % in winter. The background is less affected by the bias correction. Without TROPOMI XNO<sub>2</sub> bias correction, the uncertainty in scaling factor for OH can vary up to 20 % and NO<sub>x</sub> emission to 60 % over Riyadh.

## Appendix A: AMF recalculation

The air mass factor (AMF) used in the retrieval of TROPOMI XNO<sub>2</sub> has been re-calculated by replacing the tropospheric AMF, calculated from the NO<sub>2</sub> column simulated by TM5, with its WRF-chem equivalent, as described by Lamsal et al. (2010) and Boersma et al. (2016) using the following Eq. (16),

$$M_{trop, WRF} = M_{trop, TM5} \times \frac{\sum_{l=1}^L A_{trop,l} x_{l,WRF}}{\sum_{l=1}^L x_{l,WRF}} \quad (16)$$

where,  $M_{trop,WRF}$  and  $M_{trop,TM5}$  are the tropospheric air mass factors derived from WRF and TM5, respectively.  $A_{trop,l}$  is the tropospheric averaging kernel, ranging from the surface to the uppermost layer of the troposphere in the TM5 model (l).  $x_{l,WRF}$  is the equivalent NO<sub>2</sub> column density in model layer l, based on WRF.  $A_{trop}$  in Eq. (16) is derived using  $A_{trop} = A \times \frac{M}{M_{trop}}$ , where M and  $M_{trop}$  are the total and tropospheric AMF's respectively. Finally, the bias corrected NO<sub>2</sub> vertical column density is computed using,

$$NO_{2, \text{ bias corrected}} = \frac{M_{trop, TM5}}{M_{trop, WRF}} \times NO_2$$

where,  $NO_2$  is the TROPOMI tropospheric NO<sub>2</sub> vertical column density and  $NO_{2, \text{ bias corrected}}$  is the bias corrected

TROPOMI tropospheric NO<sub>2</sub> vertical column density.

## Appendix B: XCO component wise optimization

The component wise optimization of XCO<sub>WRF</sub> to estimate the emission and background of CO uses the following equation,

$$XCO_{TROPOMI} = XCO_{WRF} + \Delta XCO_{emis} * \frac{f_{emis}}{10} + \Delta XCO_{Bg} * \frac{f_{Bg}}{10}$$

$$XCO_{WRF} = XCO_{emis} + XCO_{Bg}$$

$$\Delta XCO_{emis} = 0.10 * XCO_{emis}$$

$$\Delta XCO_{Bg} = 0.10 * XCO_{Bg}$$

Here,  $XCO_{TROPOMI}$  is TROPOMI XCO,  $XCO_{WRF}$  is the WRF simulated XCO accounting for emissions and background CO,  $XCO_{emis}$  is the XCO contribution from the urban CO emission and  $XCO_{Bg}$  is the CAMS-derived XCO background.  $\Delta XCO_{emis}$  is the change in XCO due to emission and  $\Delta XCO_{Bg}$  is the change in the XCO background level.

*Data Availability Statement.* TROPOMI CO and NO<sub>2</sub> data can be downloaded from <https://cophub.copernicus.eu/s5pexp>.  
805 EDGAR emission data is available at [https://edgar.jrc.ec.europa.eu/emissions\\_data\\_and\\_maps](https://edgar.jrc.ec.europa.eu/emissions_data_and_maps). CAMS data can be  
downloaded from <https://ads.atmosphere.copernicus.eu/cdsapp#!/dataset/cams-global-reanalysis-eac4?tab=form>. WRF  
simulations output are available at <https://zenodo.org/deposit?page=1&size=20>

*Author contributions.* SL performed the data analysis, data interpretation, and wrote the paper. SH supervised the study. SH,  
810 FKB, IA, MK and HACDG discussed the results. All co-authors commented on the paper and improved it.
