Abstract Since 1987, more than 13,200 rockfalls have been inventoried by the Québec Ministry of Transport (MTQ) as having impacted the National Road 132 in northern Gaspésie. This natural hazard represents a nearly permanent danger for users. Traditional mitigation measures can be ineffective on poorly consolidated, deformed and highly fractured rockwall such as those found in northern Gaspésie. To address this issue, implementing a preventive risk management based on the factors that trigger rock instabilities could be the most effective method. Earthquake, rainfall and freeze-thaw cycles are commonly considered to be the main rockfall triggering factors. This study aims to better understand the climatic conditions conducive to rockfalls in northern Gaspésie in order to provide knowledge to implement an appropriate risk management strategy. Three rockwalls were scanned with a terrestrial laser scanner (TLS) during specific pre-targeted weather conditions. Over a period of 18 months, 17 surveys have allowed to identify 1287 rockfalls with a magnitude above 0.005 m³ on a scanned surface of 12 056 m². In addition, meteorological instruments and a 550 cm thermistor string have been installed directly on a vertical rockwall. It appears that some weather conditions influence occurrence, frequency, and magnitude of rockfalls. In winter, rockfall frequency is 12 times higher during a superficial thaw than during a cold period in which temperature remains below 0°C. In summer, rockfall frequency is 22 times higher during a heavy rainfall event than during a period mainly dry. Superficial freeze-thaw cycle (< 50 cm) causes mostly a high frequency of small magnitude events while deeper spring thaw (> 100 cm) results in a high frequency of large magnitude events. Influence of weather conditions on rockfall frequency and magnitude is crucial in order to improve risk management since large magnitude events represent higher potential hazards. This study provides a classification of weather conditions based on their ability to trigger rockfalls of different magnitudes. This knowledge could be used to implement a risk management strategy.

1 Introduction

Rockfall is hillslope movement in which blocks detach from the surface of rocky escarpments (Budetta, 2004; Michoud et al., 2012; Piteau and Peckover, 1978; Selby, 1993). Rock mass properties, such as lithology, degree of alteration, discontinuity network characteristics and slope, are predisposing factors in the occurrence, magnitude and failure mode (e.g. planar, wedge or toppling) of rock instabilities (e.g. Selby, 1993; Turner and Schustler, 1996). Although they are spontaneous, rockfalls result from the long term interaction of a series of processes (Schovanec, 2020). They never result solely from the latest visible

change (Draebing and Krautblatter, 2019; Gunzburger et al., 2005). Many factors can contribute to the development of rock instabilities, but two are recurring in the literature: precipitation and freeze-thaw cycles (e.g. Collins and Stock, 2016; Coutard and Francou, 1989; D'Amato et al., 2016; Hungr et al., 1999; Matsuoka and Sakai, 1999; Rapp, 1960; Wieczorek and Jäger, 1996).

35

While there is consensus in the literature on the influence of meteorological variables on rockfall, quantifying their respective roles is often challenging because they are challenging to differentiate (Schovanec, 2020). Studies of rockwall dynamics have long been complicated by the poor accessibility and dangerous nature of the terrain (Abellán et al., 2014). The recent development of remote sensing techniques, particularly LiDAR (Light Detection and Ranging), has considerably improved our ability to study rockwall dynamics (Abellán et al., 2014; Guerin et al., 2014; van Veen et al., 2017). Terrestrial laser scanning (TLS) makes it possible to carry out topographical surveys of vast areas with good accuracy and very high resolution (Abellán et al., 2014; Santana et al., 2012; Williams et al., 2018). By combining the point clouds from several surveys, rock instabilities that occurred between the surveys (e.g. van Veen et al., 2017) and developing future instabilities (e.g. Kromer et al., 2018; Oppikofer et al., 2008, 2009; Royán et al., 2014) can be identified.

45

Given the unpredictability of rock instabilities, evasive action is near impossible when an event occurs (Volkwein et al., 2011). Rockfall is a daily occurrence in mountainous areas (Dorren, 2003). The literature describes many examples of the resulting infrastructure damage and human mortality (e.g. Badger and Lowell, 1992; Badoux et al., 2016; Bunce et al., 1997; Chau et al., 2003; Hilker et al., 2009; Porter and Orombelli, 1980). To reduce this risk to infrastructure and human life, a better understanding of this hazard is needed (Dorren, 2003; Erismann and Abele, 2001). TLS is a key tool in achieving that objective. It can help identify unstable rockwall portions that require monitoring (e.g. Kromer et al., 2018; Oppikofer et al., 2008; Royán et al., 2014) and improve our understanding of rockfall triggering factors (e.g. Kromer et al., 2018; Oppikofer et al., 2008; Royán et al., 2014).

50

55

This study looks at the influence of weather conditions on the rockfall dynamics of rockwalls in Haute-Gaspésie (Quebec, Canada). Composed of Cloridome Formation sedimentary rock (flysch) (Slivitzky et al., 1991), these rockwalls are poorly consolidated, deformed and highly fractured. Weidner and Walton (2021) showed that in similar geology in Colorado, mitigation activities including mechanical scaling, stabilization with reinforcement rock bolts, wire mesh installation and polyurethane resin injections could be ineffective. They even observed a higher frequency of rockfall after mitigation measures were implemented. Some measures, such as mechanical scaling, were unsuited to highly altered rockwalls. Following scaling operations, the newly exposed rockwall could be just as altered and unstable as the previously exposed surfaces. Traditional mitigation measures are ineffective on low and moderate magnitude ($<1 \text{ m}^3$) instabilities, which corresponds to the magnitude of instabilities caused by weather processes (Weidner and Walton, 2021; Wyllie and Mah, 2004). For highly altered rockwalls

60

such as those found in Haute-Gaspésie, implementing hazard mitigation methods based on the factors that trigger rock instabilities could therefore be the most effective method of limiting hazards associated with rockfall.

Recent literature illustrates significant advances in our understanding of the impact of weather variables on rockfall (D'Amato et al., 2016; Delonca et al., 2014; Macciotta et al., 2015; Matsuoka, 2019; Pratt et al., 2019; Ravanel and Deline, 2011; Weidner and Walton, 2021). The primary objective of our study is to strengthen this knowledge for a geological context neglected by the literature and fill in its main gaps:

- LiDAR data makes it possible to accurately quantify rock instabilities, but they are not always linked to suitable weather data. For example, freeze-thaw cycles are often derived from air temperature without consideration of the influence of solar radiation, even on south-facing rockwalls (e.g. Weidner and Walton, 2021). Furthermore, air temperature provides no insight on freezing front depth in the rock. This makes it difficult to relate spring thaw to the rockfalls that occur (e.g. Macciotta et al., 2015).
- The relationship between rock instabilities and weather conditions is often studied at the monthly or seasonal scale (e.g. Kromer et al., 2018; Macciotta et al., 2017). While this temporality can reveal interesting trends, it cannot differentiate the respective impacts of different meteorological events on rockfall dynamics. For example, on a monthly scale, the respective roles of precipitation events and freeze-thaw cycles cannot be easily distinguished since their occurrences can overlap. Consequently, this temporality is not useful in the preventive hazard management of rock instability triggers.
- Many studies highlight the strong relationship between rockfall frequency and magnitude (e.g. Guerin et al., 2014, 2020; Rosser et al., 2005; Santana et al., 2012; van Veen et al., 2017; Williams et al., 2018). However, studies into the influence of weather variables on rockwall dynamics focus almost exclusively on rockfall frequency. One exception is Matsuoka (2019), who investigated the relationship between weather conditions and rockfall magnitude. From the perspective of managing natural hazards, the relationship between the magnitude of rock instabilities and their triggering factors is an essential area of study since the damage caused by instabilities is proportional to their magnitude.

Our study therefore aims to link rockfall dynamics to specific adequately measured weather conditions. We use TLS to quantify the frequency and magnitude of rock instabilities for each targeted weather condition. We also propose a classification of weather conditions based on their level of concern in preventive hazard management.

2 Study sites

In Haute-Gaspésie, Route 132 is the sole transportation corridor linking a number of villages to the rest of the region. For the local population, it is critical infrastructure for accessing essential services. The highway runs along the Gulf of St. Lawrence

shoreline and is subject to coastal flooding and erosion (e.g. Drejza et al., 2014). The rockwalls that tower above the road expose it to other natural hazards: snow avalanches (Fortin et al., 2011; Héту, 2007), falling ice blocks (Gauthier et al., 2017), debris flows (Fortin et al., 2015), and rockfall. Those same rockwalls make moving the roadway inland from the shore unfeasible. To limit risk to road users, the Ministère des Transports du Québec (department of transportation) created a 24/7 patrol to monitor the 70 km of highway that run along the rockwall of Gaspé's uplands. The patrol is also responsible for clearing the road when it is obstructed by rock, snow or ice from hillslope movements. Between 1987 and 2020, the patrol responded to 13,261 rockfall events along the 25 km where rockwalls overhang Route 132 (Ministère du Transport du Québec, 2021).

LiDAR was used to monitor three rockwalls (Figure 1, A1 and A2) that overhang Route 132 in Haute-Gaspésie. From east to west, the sites are near the villages of Manche-d'Épée (MAE), Gros-Morne (GMO) and Marsoui (MAR). The total area scanned was 12,056 m². Rockwalls were selected using five criteria: 1) structural and lithologic characteristics representative of Haute-Gaspésie rockwalls; 2) frequent rockfall incursions onto the highway; 3) year-round accessibility; 4) general morphology (verticality, height) and microtopography (roughness) compatible with LiDAR acquisition from the highway; and 5) absence of vegetation (occlusion) and drainage (signal reflection). The three sites are sedimentary rockwalls (flysch) with horizontal or subhorizontal bedding planes. The easternmost study site, MAE, covers an area of 3154 m². It has a vertical (>80°) natural rockwall that is 35 m high and is oriented north-northwest (350°). It rises over an unvegetated 30 m long scree slope with an average gradient of 38°. The rockwall is primarily composed of siltstone (50%), shale (30%) and greywacke (20%). Rockfall of greywacke blocks is most likely to reach the highway, which runs about 10 m from the base of the scree slope. GMO is a rockwall with alternating spurs and re-entrants. On that site, three rock spurs with a total area of 5370 m² were scanned, most of which have been dynamited. The orientation of the spurs ranges from 330° to 20°, and their gradients range between 70° and 90°. Their bases do not have scree slopes, and rockfall regularly reaches the highway. Only the lower 25 m of the three spurs were scanned to limit occlusion as much as possible. The rock spurs are composed of greywacke (50%), siltstone (40%) and shale (10%). Lastly, MAR is a vertical (90°) dynamited rockwall composed primarily of sandstone (70%), siltstone (20%) and shale (10%). The thickness of the siltstone strata tends to result in decimeter sized instabilities. Since the highway runs right along the base of the rockwall (no scree slope is present), these instabilities regularly reach the roadway. However, its low height (<30 m) and verticality limit the distance of rockfall travel from the rockwall.

Haute-Gaspésie has a humid continental climate with short cool summers, according to the Köppen climate classification system. During the period 1991–2020, it had an annual mean temperature of 3.9 °C. The mean temperatures of the warmest (July) and coldest (January) months were 16.3 °C and -9.2 °C, respectively. Over those same 30 years, average annual precipitation was 888 mm, 33% of which fell as snow (Environment Canada, 2021).

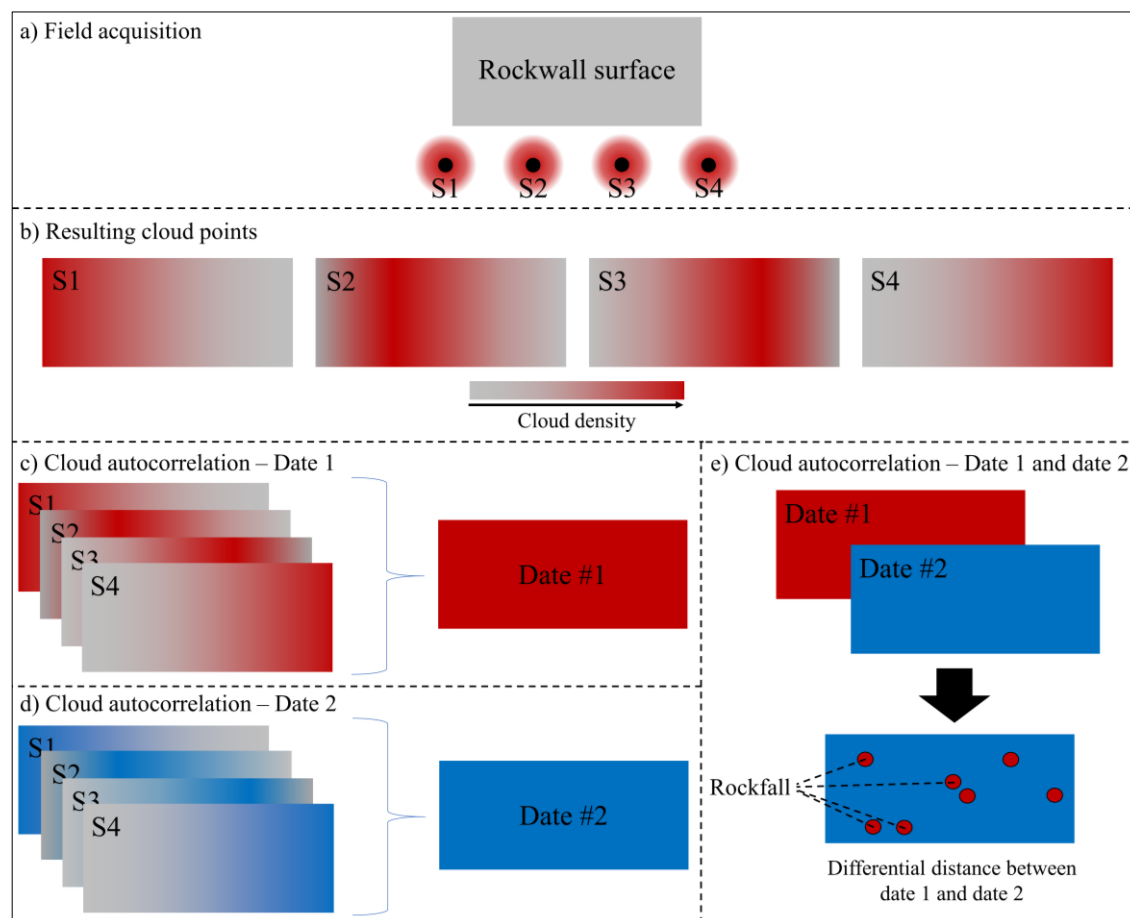

Figure 1. Location of the study sites.

130 3 Methodology

Over the 554 d period of 14 June 2019–December 2020, 17 LiDAR surveys were performed. Two TLS were used for data acquisition. The four first surveys used a Leica Geosystems ScanStation C10. A RIEGL VZ-400i was used for the 13 subsequent surveys. To obtain dense point clouds with the fewest possible occlusions, multiple surveys were conducted to adequately cover the scanned surfaces at each site (Figure 2(a) and Figure 2). Depending on site morphology and surface area, 135 four to twelve 360° surveys were needed. The resulting point clouds were merged using Leica HDS Cyclone software, producing point clouds with a centimeter-level density for each survey of every rockwall. The same function was used to align the point clouds corresponding to a given acquisition date (Figure 2(c) and Figure 2(d)). The CloudCompare M3C2 plugin was then used to compare surface differences and quantify rockfall volumes during the target periods (Figure 2(e)).

140 **Figure 2. Protocol used to identify and quantify rockfalls from point clouds.**

To study the influence of weather conditions on rock instability frequency and magnitude, sufficiently high spatial resolution is needed to identify all events at the lowest quantified magnitude (Abellán et al., 2014). This study considered that instabilities of a volume exceeding 0.005 m^3 can be identified. Smaller-scale events were not analyzed since their volume make them
 145 difficult to distinguish from other processes such as the wind erosion of snow cover from rock slop surfaces. Regarding the temporal resolution, Barlow et al. (2012) showed that a 19 month interval between surveys leads to an underestimation of small scale events. With overly long intervals, several distinct but spatially overlapping events can be erroneously interpreted as a single larger scale event. Williams et al. (2018) compared rockfall frequencies detected at temporal resolutions of one hour and of 30 days. They found that the number of low magnitude events ($<0.1 \text{ m}^3$) detected was three orders of magnitude
 150 greater at a temporal resolution of one hour. However, to achieve this high temporal resolution, a fixed scanner is required. This leads to other issues, such as greater occlusion on the rockwall surface and more limited scanned areas. Barlow et al. (2012) showed that while environmental factors influence rockfall, defining a constant frequency is not necessary for data

acquisition. LiDAR surveys must be more frequent during periods when a greater rock instability frequency is expected. Conversely, intervals between surveys can be longer surveys during periods with a lower rockfall frequency. The protocol we
155 implemented was designed to limit the scanning effort by targeting selected periods rather than performing regular scans. This resulted in an inconsistent survey frequency that is justified by the influence of weather conditions on rockslide dynamics. The scanning periods were selected based on knowledge of the weather conditions that cause major surface deformations on the rockwalls and are likely to result in rockfall (Birien and Gauthier, 2022). This study's LiDAR surveys made it possible to quantify instabilities over 16 distinct periods (Figure 3). Target periods could run over several dozen days (dry period, rainy
160 period, autumn period with near-daily freeze-thaw cycles and cold winter period) or monitor specific meteorological events (heavy and high intensity rainfall, winter freeze-thaw cycles and spring surface, 1 m deep and full rockwall thaws).

The periods to scan were determined over the course of the study using Environment Canada weather forecasts and then validated with local weather measurements. A Campbell TE525WS-L rain gauge was used to measure precipitation (mm). In
165 winter, it was equipped with a CS705 adapter to measure the water equivalent of solid precipitation. A thermistor string (with a GeoPrecision data logger operating at 915 MHz) inserted into a horizontal borehole measured the temperature (°C) every 30 cm to a depth of 550 cm. Using linear interpolation between the thermistors, we produced a temperature profile at different depths over time, quantified the number and depth of freeze-thaw cycles and tracked the depth of the freezing front in winter and the thawing front in spring (Figure 4). All weather instruments took data readings every 15 minutes.

170 Of the 16 targeted periods, three totaling 104 d with a mean precipitation of 1.4 mm d⁻¹ were defined as dry periods (DRY). Two periods totaling 100 d and a mean precipitation of 4.1 mm d⁻¹ were defined as rainy (RAINY) periods. Two periods totaling 93 d with a mean air temperature below the freezing point (-6.2 °C) and very low winter freeze-thaw frequency (0.02 thaws d⁻¹) were defined as cold winter periods (WIN. <0 °C). The autumn periods (AUT. FT) experienced the first freeze-thaw
175 cycles after summer. Two autumn periods totaling 79 days were scanned. The specific meteorological events that were monitored included a heavy (54 mm) and high intensity (4 mm h⁻¹ for 12 h 45 min) rainfall event (HEAVY RF) in September 2019 and two winter freeze-thaw cycles (WIN. FT) in winter 2020. Lastly, four LiDAR surveys were used to segment the spring thaw (SPR. MELT) into three periods. The change in rock temperature during these three periods is shown Figure 4. The first phase corresponds to the initiation of the thawing season including two freeze-thaw events reaching a depth of 50 cm
180 from the rockwall surface (SPR.0:50). The second phase is characterized by a thaw that penetrates to a depth of 95 cm and by a thaw of 77 cm from depth (SPR.50:100). The third phase corresponds to the complete thaw of the rockwall (SPR.100:350). The 25 May–16 September 2020 period experienced a range of weather conditions too varied for categorization (Figure 3).

Figure 4. Rock temperature evolution along a perpendicular profile from surface to 360 cm depth, 21 March 2020–6 May 2020. Dark time series are for freeze-thaw depth (0 °C). Vertical lines delimit scan periods.

4 Results

4.1 Frequency-magnitude

Over the study period, 1287 rockfalls over 0.005 m^3 in volume were identified and their volumes measured. Rockfall frequency decreased rapidly with magnitude (Figure 5(a)). The frequency-magnitude curves generally fit a power law (Guerin et al., 2014, 2020; Hungr et al., 1999; Rosser et al., 2005; Santana et al., 2012; van Veen et al., 2017; Williams et al., 2018). In this case, it can be defined as:

$$f(V) = 0.0168V^{-1.06}$$

where $f(V)$ is the mean daily frequency of rockfalls with a volume greater than or equal to V over the entire study period for the $12,056 \text{ m}^2$ of scanned rockwalls. This frequency is the equivalent of 2.2 rockfalls d^{-1} for events greater than or equal to 0.01 m^3 , 0.2 rockfalls d^{-1} for events greater than or equal to 0.1 m^3 , and 0.02 rockfalls d^{-1} for events greater than or equal to 1.0 m^3 .

Where the frequency or spatial resolution of the LiDAR surveys is insufficient, low magnitude instabilities are underrepresented (Barlow et al., 2012; Guerin et al., 2014; Malamud et al., 2004). The absence of a rollover in the logarithmic frequency-magnitude distribution obtained in this study makes it possible to validate whether a suitable instability detection threshold was chosen (Figure 5(b)). This result confirms that the selected survey frequency and spatial resolution were appropriate for individually identifying the large majority of events with a volume exceeding 0.005 m^3 .

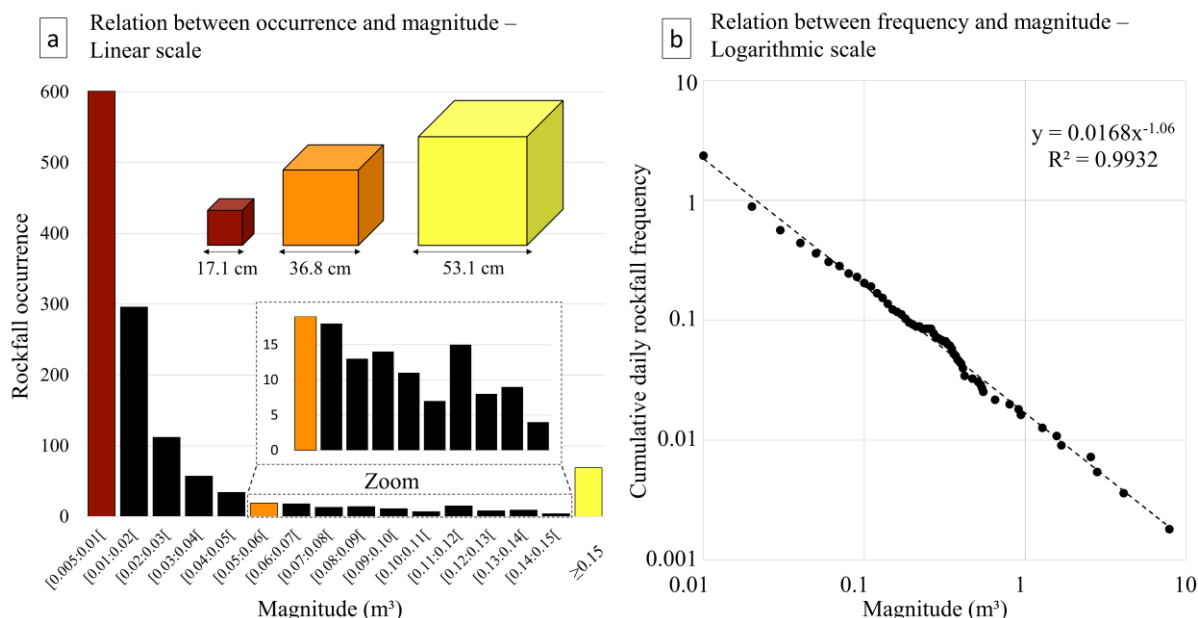

Figure 5. Relationship between rockfall occurrence and magnitude (a) and between cumulative daily rockfall frequency and magnitude (b).

210

4.2 Global rockwall retreat rate

The annual rockwall retreat rates and the rockfall frequency were calculated using the entire 554 d time series of two summers and two autumns but only one winter and one spring. The 1287 recorded rockfalls were distributed across the three study sites as follows: 363 at MAE, 486 at GMO and 438 at MAR. Figure 6, A1 and A2 show the surface differential at the three study sites between the first survey in June 2019 and the last survey in December 2020. Over the 554 d period, many changes were visible on the rockwall surfaces. Most of the positive changes (in green) to the rockwall and scree slope are explained by low snow accumulation during the last LiDAR surveys on 18 December 2020. These positive changes can also be attributed to the development of rock instabilities large enough to be detected by LiDAR (Kromer et al., 2018; Oppikofer et al., 2008, 2009; Royán et al., 2014). For example, measurements taken at MAE show that between the months of June 2019 and December 2020, a rock mass measuring 3 m high separated from the rockwall by 4 to 5 cm at its top and 1 to 2 cm at its base (Figure 6(a)). The increased rate of displacement at the top of the rock mass suggests a toppling failure. This type of pre-rupture movement was not considered in the rockfall volume calculation. Only rockfalls that produced negative change in the surface differential (shown in red in Figure 6, A1 and A2) were considered in the retreat rate calculation. It is important to recall that what appears to be a high magnitude event over the entire study period may correspond to several successive smaller-scale events (Figure 6(b)) (Abellán et al., 2014; Barlow et al., 2012; van Veen et al., 2017; Williams et al., 2018).

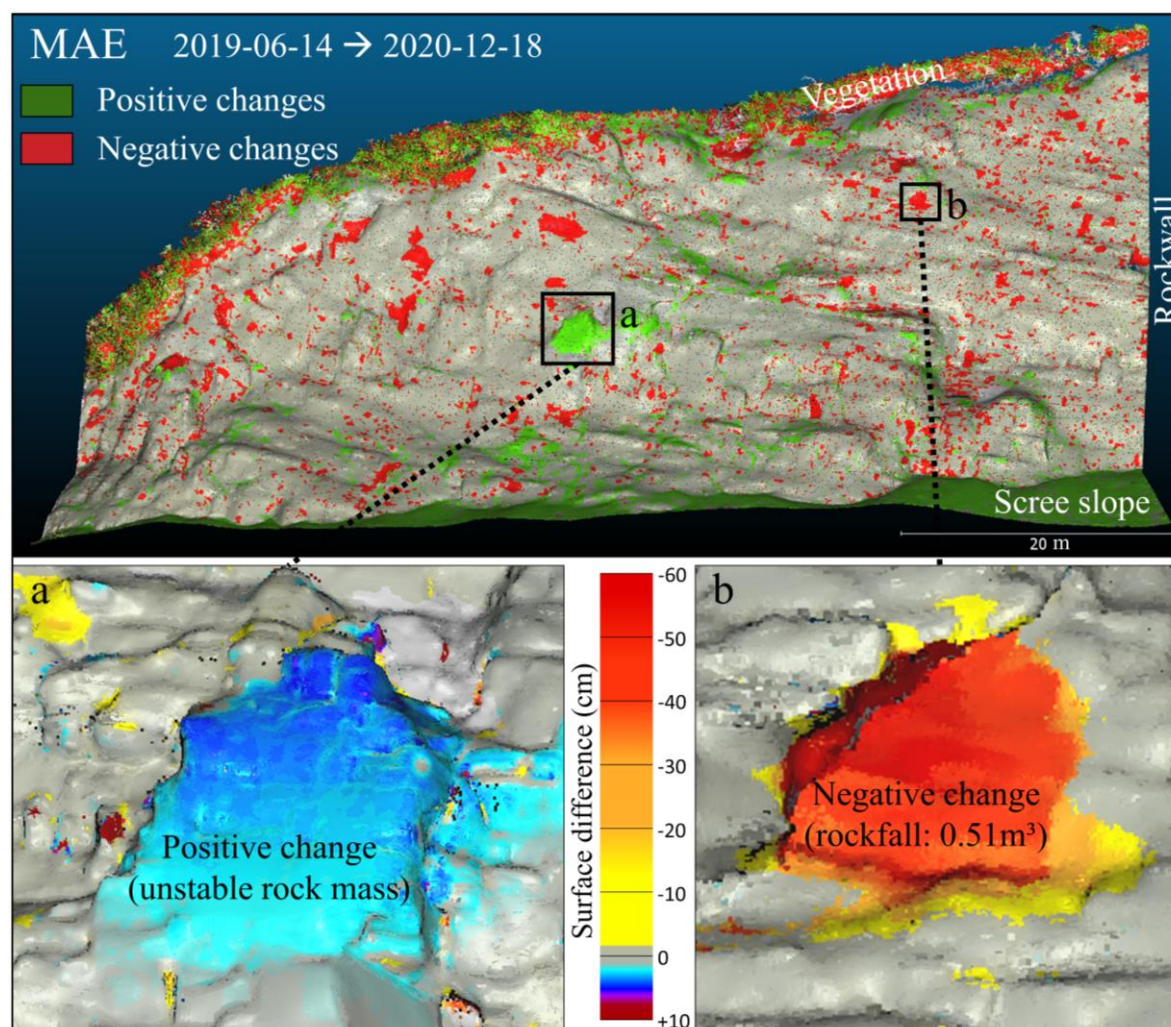

Figure 6. Point clouds of main changes (MAE rockwall) between the first (14 June 2019) and last (18 December 2020) scan surveys. Positive changes are mainly relative to unstable rock mass (a) and negative changes highlight rockfall (b).

230

Considering the scanned surfaces separately, all three sites had fairly similar annual rockfall frequencies: 0.08 rockfalls m^{-2} for MAE and MAR, 0.06 rockfalls m^{-2} for GMO (Figure 7(a)). In contrast, the differences between the erosion rates of the three rockwalls were more pronounced. Over the study period, the retreat rate was higher for MAR (5.4 mm y^{-1}) than for MAE (3.0 mm y^{-1}) or GMO (2.8 mm y^{-1}) (Figure 7(b)). Therefore, despite comparable rockfall frequencies, MAR had a higher

235 retreat rate than the other sites. This distinction shows that on average, MAR experienced higher magnitude events. This is borne out by the fact that in the entire time series, five of the seven recorded events with a volume of over 1 m^3 occurred at MAR. These seven events account for 33% of the total volume lost by the three rockwalls in the study period. At MAR, the eight largest magnitude events contributed as much to the erosion rate of the studied surface as the 430 lower magnitude events.

Meanwhile, at GMO and MAE, the five and 20 highest magnitude events represented the volume of the 481 and 343 smallest events, respectively. Clearly, high magnitude events substantially affected the erosion rate of the rockwalls (Figure 7(c)).

Figure 7. Mean annual rockfall frequency (a), rockwall erosion rate (b) and total volume of rockfall for the overall studied period (c).

4.3 Periods of rockfall occurrence and risk assessment

This study quantified rockfall in three dry (DRY), three spring thaw (SPR. MELT), two rainy (RAINY), two autumn (AUT. FT), two cold (WIN. <0 °C), two winter freeze-thaw (WIN. FT) and one high magnitude and high intensity rain (HEAVY FR) periods (Figure 3). In decreasing order, 241 rockfalls were associated with RAINY periods, 178 with AUT. FT periods, 145 with DRY periods, 120 with SPR. MELT periods, 97 with WIN. <0 °C periods and 91 with the HEAVY RF period and 44 with WIN. FT periods (Figure 8(a)). However, rockfall occurrence under these meteorological conditions is not representative of the dynamics of rockwall instability since some of those conditions occur over a much longer period than others. For example, DRY periods total 104 days, while WIN. FT periods total just four. Considering rockfall frequency rather than occurrence revealed different meteorological conditions as triggering factors of instabilities. WIN. <0 °C and DRY were associated with the lowest daily rockfall frequencies, respectively 0.9 and 1.4 events d⁻¹ across the full scanned surface area (12,056 m²). This frequency tended to double under AUT. FT (2.2 events d⁻¹), RAINY (2.4 events d⁻¹) and SPR. MELT (2.6 events d⁻¹) conditions. Winter freeze-thaw cycles (WIN. FT) and heavy rainfall events (HEAVY RF) produced the highest rockfall frequencies. Frequencies for WIN. FT and HEAVY RF were 11.0 and 30.3 events d⁻¹, respectively (Figure 8(b)). Compared to a cold winter period (WIN. <0 °C), rockfall frequency was multiplied by a factor of 1.5 during DRY periods, 2.3 in AUT. FT periods, 2.8 in SPR. MELT periods, 11.7 in WIN. FT periods and 32.3 in HEAVY RF periods.

Figure 8. Rockfall occurrence (a) and frequency (b) for each scanned survey period, grouped by targeted weather conditions for all sites.

For each scanned survey period, precipitation intensity and freeze-thaw cycles were compared with rockwall erosion rates and rockfall frequency (Figure 9). The erosion rate and frequency shown for each period are relative to their respective mean values over the entire time series (standard score). Where values for a period were under one, the rockwall erosion rate and rockfall frequency were less than the time series mean. On 7 September 2019, Category 5 hurricane Dorian arrived in the Gulf of St. Lawrence as a post-tropical storm. It dropped 54 mm of heavy rain (4 mm h⁻¹ for 12 h 45 min) on the study site. Between 1987 and 2021, only 16 precipitation events of over 50 mm were recorded in Haute-Gaspésie, which represents a return period of 776 days (Environment Canada, 2021). The heavy rain event resulted in a rockwall erosion rate and rockfall frequencies that were 9.3 and 13.8 times the mean, respectively (Figure 9). Calculated for the full 72 h period between the two surveys (7 and 10 September 2019), those values would undoubtedly have been higher had they had been based solely on the actual duration of the event (14 h).

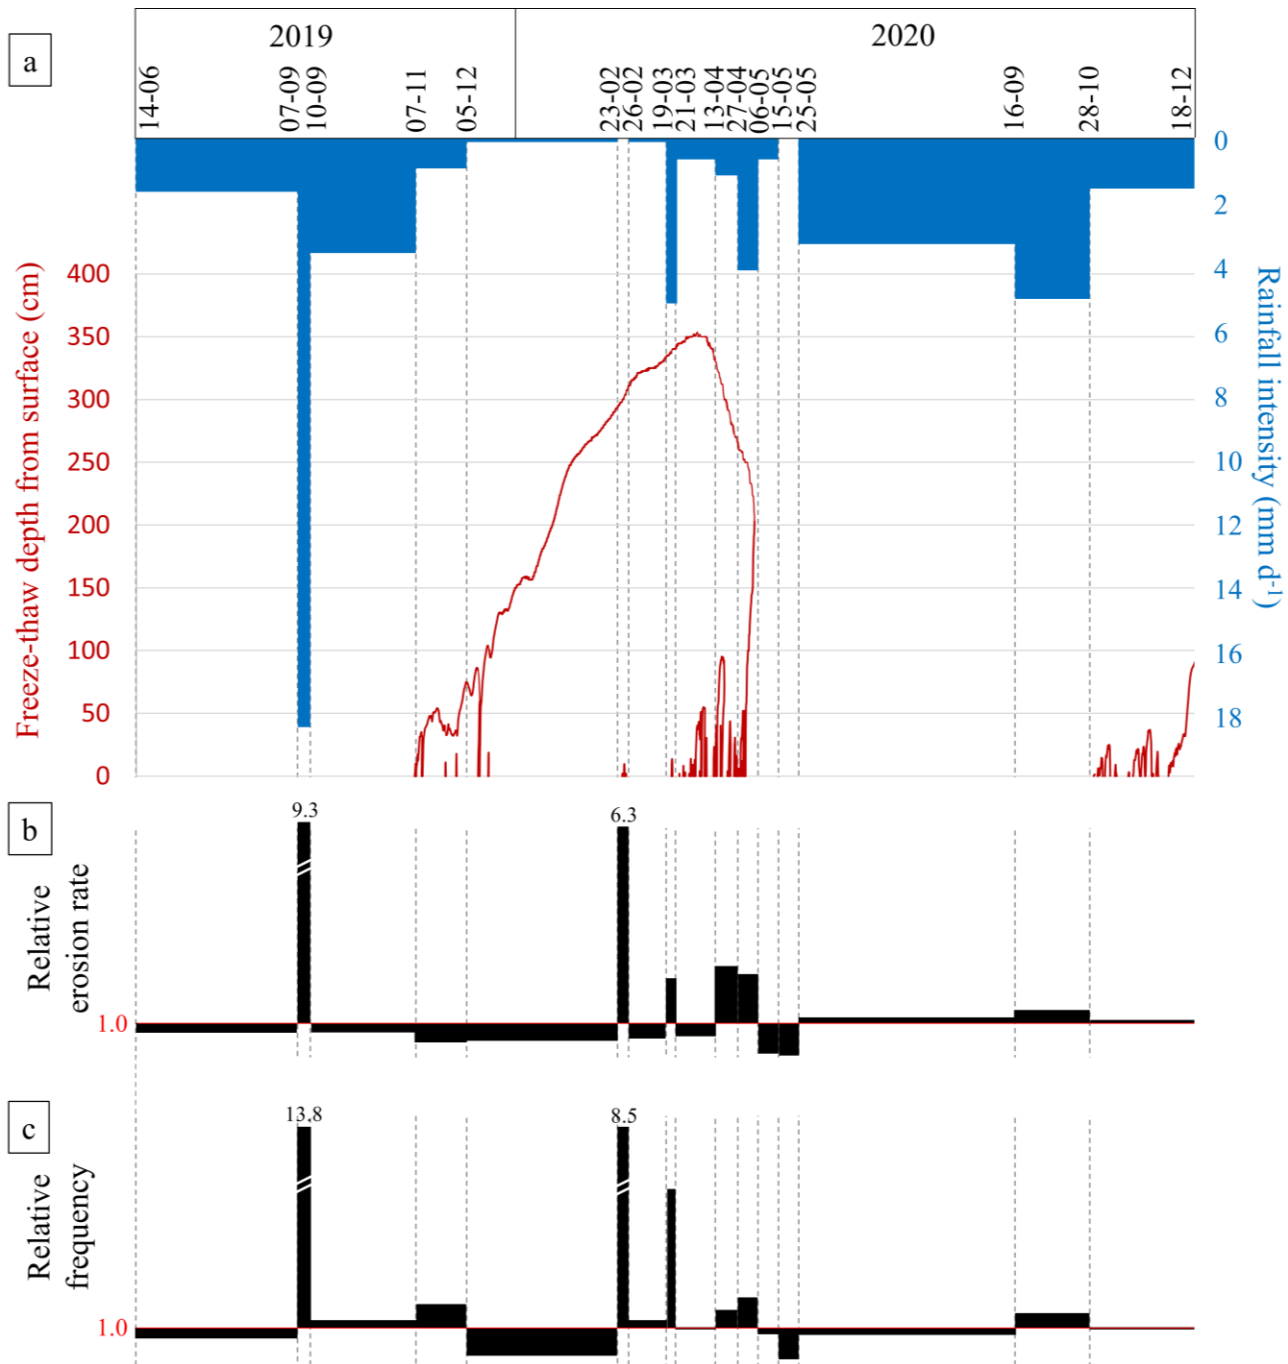

275

Between 23 and 26 February 2020, a series of three freeze-thaw cycles occurred (Figure 9). They followed a long period (70 days) of below freezing point temperatures. During these three freeze-thaw cycles, the air temperature rose to 3.1 °C, 8.3 °C

and 2.1 °C, respectively, separated by 8 h periods around -2 °C. They resulted in a thaw 10 cm depth from rockwall surface. The rockwall erosion rate and rockfall frequency were 6.3 and 8.5 above the mean, respectively. The absence of rain during this period highlights the leading role of surface thaws in rockslide dynamics (Figure 9). The air temperature remained below the freezing point until 20 March 2020 before rising above zero for 24 hours, briefly reaching a high of 8.1 °C. This produced a surface thaw to a depth 14 cm accompanied by rockwall retreat and rockfall frequency rates of 2.3 and 4.4 times the mean, respectively (Figure 9). In the spring, the frequency and magnitude of freeze-thaw cycles increased (Figure 4Figure 9). Rockfall frequency remained fairly low and lower than during the last winter freeze-thaw event (1.7 times more than the mean). In contrast, erosion rates were higher than during the freeze-thaw event on 23 and 26 February and remained high for a period of 24 days (2.5 times more than the mean). This combination of a high erosion rate and fairly low rockfall frequency indicates an increased mean rockfall volume during the spring thaw.

Over the study period, the weather conditions that most contributed to rock instability dynamics were the winter freeze-thaw cycles, the spring thaw and the heavy and high intensity rainfall event (Figure 9). In contrast, other weather conditions were associated with high stability in the studied rockwalls. In the period 5 December 2019–23 February 2020, both the rockwall erosion rate and rockfall frequency were very low – 0.6 and 0.3 times less than the mean, respectively (Figure 9). Temperatures remained below freezing point on all but two days of this 81 d period. The 19 d period 6–25 May 2020 had very low rockwall erosion rates and rockfall frequency (0.2 and 0.6 times less than the mean, respectively). During that period, rockwall temperature remained constantly below freezing and only 5.6 mm of rain was recorded. In the study period, the cold winter and dry summer periods experienced the weather conditions associated with the highest stability in the scanned rockwalls (Figure 9).

300 **Figure 9.** Main weather conditions (a), erosion rates (b) and rockfall frequency (c) for each scanned survey period. Erosion rates and rockfall frequency are respectively relative to mean erosion rates and mean rockfall frequency between 14 June 2019 and 18 December 2020.

LiDAR surveys make it possible to quantify rockfall frequency and calculate the individual volume of each rockfall. Using
305 this data, we can study the influence different weather conditions have on rockfall magnitude. Figure 10(a) presents a matrix
of the weather conditions associated with different rockfall frequencies and magnitudes. We defined three classes of “low”,
“intermediate” and “high” magnitudes. The first one includes 1,100 low magnitude ($0.005:0.05 \text{ m}^3$) events. The second class
comprises 119 events of intermediate magnitude ($0.05:0.15 \text{ m}^3$), while the third includes 68 events of the highest magnitude
($\geq 0.15 \text{ m}^3$). We also defined five frequency classes for the matrix: low ($<75\%$ mean frequency for the study period), moderate
310 ($75:125\%$), high ($125:300\%$), very high ($300:500\%$) and extreme ($> 500\%$).

HEAVY RF weather condition coincides with extreme rockfall frequency of both low and high magnitude events. In contrast,
DRY, WIN. $<0^\circ\text{C}$, SPR.0:50 and AUT. FT conditions were associated with low frequency rockfall, irrespective of magnitude.
All of those weather conditions had an impact on rockfall frequency, resulting in either widespread instability (HEAVY RF)
315 or, conversely, widespread stability (DRY, WIN. $<0^\circ\text{C}$, SPR.0:50 and AUT. FT). However, while there is no clear relationship
between those conditions and rock instability magnitude, the WIN. FT, SPR.50:100, SPR.100:350 and RAINY conditions led
to rockfall frequencies that varied by magnitude. WIN. FT is associated with extreme frequencies of low and moderate
magnitude instabilities, but only high frequencies of large instabilities. Similarly, RAINY and SPR.50:100 are associated with
high frequencies of low magnitude events but moderate to low frequencies of high magnitude events. The inverse relationship
320 was observed during the thawing period in depth (SPR.100:350). This critical period was dominated by high magnitude
rockfalls that outnumbered low magnitude ones (Figure 10(a)).

The cumulative daily occurrence of targeted weather conditions is drawing only on data collected during the first year of the
study (14 June 2019–13 June 2020) rather than the entire time series in order to give each season an equal weight
325 (Figure 10(b)). In that year, HEAVY RF and SPR.100:350 periods accounted for just 11 days. There was therefore a low
occurrence of periods with weather conditions favorable to extreme frequency high magnitude events. The WIN. FT, SPR.0:50,
SPR.50:100 and AUT. FT periods were also associated with high frequency or high magnitude rockfall and represent a
cumulative occurrence of 44 days between 14 June 2019 and 13 June 2020 (Figure 10(b)). Lastly, the DRY, WIN. $<0^\circ\text{C}$ and
RAINY periods, which do not coincide with periods of high instability, accounted for 310 days, or 85% of the year
330 (Figure 10(b)). Thus, on an annual scale, the weather conditions that resulted in high frequency or magnitude rockfall are in a
small minority.

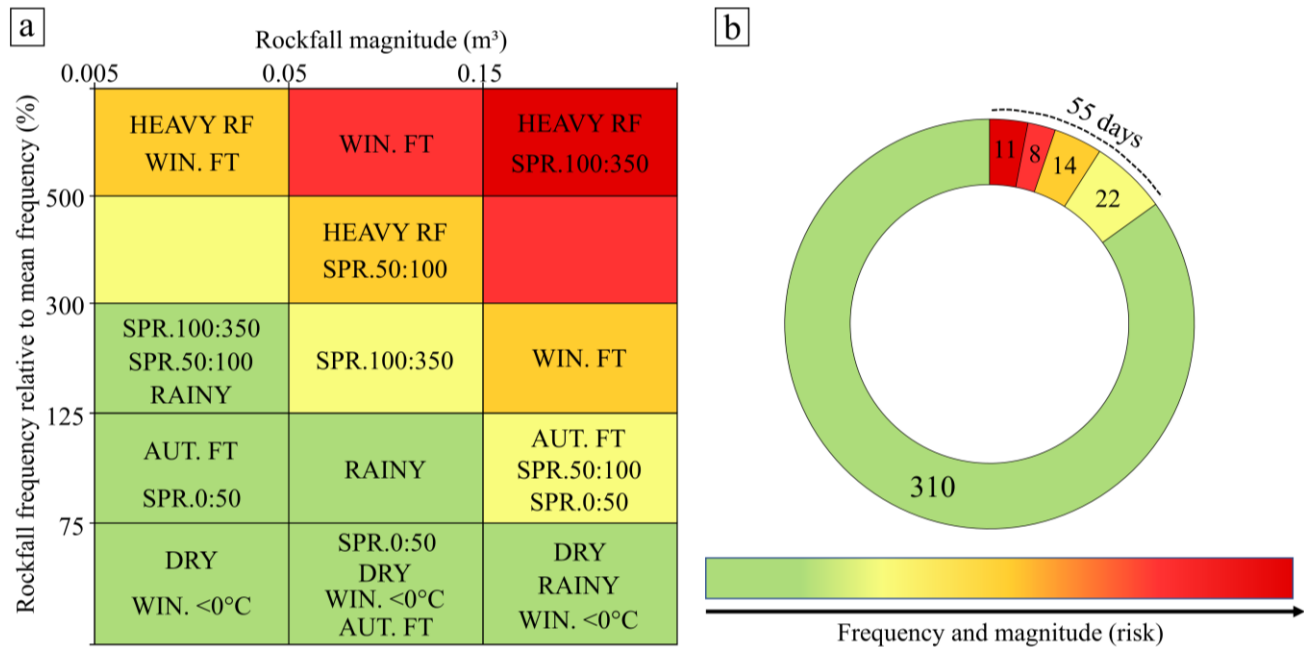

Figure 10. Risk assessment matrix showing the relationship between rockfall magnitude and frequency for specific weather conditions (a) and cumulative daily occurrence of those conditions during the first complete year of this study (14 June 2019 to 13 June 2020) (b).

5 Discussion

5.1 Flysch rockwall retreat rate

The annual retreat rates measured over 554 days for the three flysch rockwalls in Haute-Gaspésie are very high (between 2.8 and 5.4 $mm\ a^{-1}$) compared to reported rates for various lithologies and climate patterns (e.g. André, 1997; Ballantyne, 1984; Curry and Morris, 2004; Hinchliffe and Ballantyne, 1999). They are nonetheless perfectly consistent with those reported by Héту and Gray (2000) for a 40 m flysch rockwall in the same study area (3.2 $mm\ a^{-1}$). Those rates were measured by weighing the sediment accumulated on plastic tarps placed at the foot of rockwalls (Héту and Gray, 2000). Direct measurements by TLS are extremely accurate, making it possible to quantify the retreat rates of rockwalls in their morphoclimatic environments with a greater degree of certainty. The agreement between the results from the two methods demonstrates that they are both valid. However, surveys over very short periods clearly tend to underestimate actual rates by limiting the likelihood of observing very high magnitude events that would have a significant influence on retreat rate (e.g. Korup and Clague, 2009; Krautblatter and Dikau, 2007). Continuing to survey these rockwalls would confirm the accuracy of the retreat rates presented here. TLS is a modern method that merits more widespread use in monitoring projects of this type and to build on our understanding of rockwall retreat and erosional feature dynamics (e.g. Ballantyne and Kirkbride, 1987; Duszyński et al., 2019; Higgins and Coates, 1990; Rapp, 1960).

5.2 Relationship between meteorological conditions and rockfall

Rockfall frequency during RAINY periods was 1.7 times higher than the mean relative to DRY periods. The highest magnitude and strongest intensity rain event (HEAVY RF) was associated with rockfall frequency 9.3 times higher than the study period mean, or 21.6 times higher than during a dry period. Only RAINY conditions led to an increased frequency of low magnitude instabilities, while HEAVY RF conditions resulted in a significant increase in the frequency of high magnitude instabilities (Figure 10). These results agree with those obtained in other geological and climatic contexts. For the limestone rockwalls of Isère, France, D'Amato et al. (2016) showed that rockfall frequency was 2.5 to 3 times higher during rain events than during the dry summer period, up to 7.5 higher during high magnitude rain (> 30 mm) and 27 higher during high intensity rain (> 5 mm h⁻¹). For the rockwalls of Réunion Island, Delonca et al. (2014) showed that high magnitude rain (> 120 mm) resulted in an eightfold increase in the probability of daily rockfall. The lack of a time lag between rain events and instabilities shows that this precipitation has a nearly immediate (< 24 h) triggering effect on rock instabilities. In the Japanese Alps, Matsuoka (2109) demonstrated the impact of liquid precipitation on increased water content and subsequent rockfall triggering. Certain high intensity rain events were associated with instabilities of one to multiple meters in size. These studies, like our own, clearly show that rain events are aggravating and triggering factors of rockfall. However, they do not detail the process by which rainwater contributes to the formation of instabilities or improve our understanding of how water moves through the highly fractured rock layer near rockwall surfaces (Magnin et al., 2021; Stoll et al., 2020). It is well known that an increase in hydrostatic pressure in discontinuities reduces shear strength (Selby, 1993; Wieczorek and Jäger, 1996; Wyllie and Mah, 2004). Groundwater recharge and hydrostatic pressure at depth have been put forward as kinematic factors in large rockslides (Cloutier et al., 2015; Crosta et al., 2013). However, how rainwater influences the development of superficial instabilities is less well documented. In clay-rich rock, it has been shown that water content variations at the rockwall surface lead to irreversible mechanical deformations (Birien and Gauthier, 2022) that could trigger rockfall. Rockwall surfaces can experience wide fluctuations in water content. Rain events result in subsurface runoff in the altered surface layer of rockwalls and represent a significant water input. This input can be amplified when wind spreads a layer of rain water over rockwall surfaces (Sass, 2005). This type of subsurface runoff can clearly contribute to reducing shear strength and trigger rockfall during high intensity rain events (Selby, 1993). Conversely, direct solar radiation on rockwall surfaces can lead to rapid and significant drying of the first decimeters of rock (Burnett et al., 2008). Limited access to rockwalls and the challenge of directly measuring water pressure limit our ability to measure moisture dynamics in this surface layer of rock and interpret its influence on the development of rock instabilities.

In this study, rockfall frequency was 11.7 times higher during winter freeze-thaw cycles (WIN. FT) than during cold periods when the temperature remains below the freezing point (WIN. < 0 °C). We therefore observe that high rockfall frequencies occur during thawing periods (WIN. FT), while rockwalls remain very stable during the phases of the freezing process (WIN. < 0 °C). The freezing phase can cause fractures to open (Birien and Gauthier, 2022; Coutard and Francou, 1989; Matsuoka and

385 Sakai, 1999; Matsuoka, 2008). However, cohesion at the ice-rock interface is generally sufficient to hold newly unstable blocks
of rock in place (Fiorio et al., 2002; Krautblatter et al., 2013). Consequently, rockfalls occur when the ice melts, such as during
winter freeze-thaw cycles. This finding supports those of D'Amato et al. (2016), who showed that in limestone rockwalls in
Isère, France, the frequency of rock instabilities is seven times higher during freeze-thaw cycles. Similarly, Delonca et al.
(2014) found that rockfall frequency was doubled on basalt and granite rockwalls in Auvergne, France, for freeze-thaw cycles
390 with a minimum temperature of -5 °C. Our results also show that freeze-thaw cycles are associated with a very high frequency
of low and moderate magnitude events but that their impact is limited when it comes to higher magnitude events (Figure 10(a)).
This is consistent with the fact that winter freeze-thaw cycles influenced only the first 15 cm from surface (Figure 9(a)).
Autumn freeze-thaw cycles (AUT. FT) do not appear to be as effective at developing rock instabilities as winter freeze-thaw
cycles. Their associated frequency of rockfall is near the annual mean for both low and high magnitude instabilities
395 (Figure 10(a)). This is likely partly due to the fact that autumn freeze-thaw cycles were not studied individually. The two AUT.
FT periods were 28 and 51 days long, respectively. They also coincided with weather conditions unmarked by high rockfall
frequency that decreased the average frequency of rockfall specific to autumn freeze-thaw cycles. Matsuoka (2019) also notes
that even if the temperature fluctuations around the freezing point penetrate to 40 cm in depth, the water in the pores and
discontinuities does not necessarily freeze – or freeze completely – due to its high heat capacity. Lastly, the high intensity
400 autumn rain events that preceded the period of many autumn freeze-thaw cycles (AUT. FT) may have purged the rockwall
surface of its most unstable rock, leaving very little rock in a nearly unbalanced state.

The superficial spring thawing phase (SPR.0:50) does not appear to be a particularly unstable period, even for low magnitude
events (Figure 10(a)). However, the thaw in the first meter of rockwall (SPR.50:100) results in very high frequency of moderate
405 magnitude instabilities. When thawing at depth (SPR.100:350) occurs, the frequency of high magnitude instabilities increases
(Figure 10(a)). This relationship between seasonal freezing depth and rockfall magnitude is widely recognized (e.g. Dramis et
al., 1995; Matsuoka, 2019; Matsuoka and Murton, 2008), but for the first time, this study compares the magnitude of rock
instabilities with measurements of the spring thawing front at depth. The winter freeze-thaw cycles (WIN. FT) that occurred
before the first thawing phase (SPR.0:50) may have been responsible for purging the first decimeters of rockwall surfaces and
410 explain why SPR.0:50 conditions are not associated with an unstable period. This surface thaw phase lasted 23 days. During
that period, negative temperatures continued to dominate (conditions equivalent to WIN. <0 °C) and probably tended to
attenuate rockfall frequency throughout the period. At greater depth, the spring thaw is the only thaw of the year (Figure 4).
Consequently, the mechanical action of this high amplitude freeze-thaw cycle has strong potential to destabilize rock portions
(Dramis et al., 1995; Matsuoka, 2019; Matsuoka and Murton, 2008). The impact of the spring thaw on high magnitude rockfall
415 is amplified by water advection associated with snow cover melting, groundwater recharge and ice melting in rock
discontinuities and pores. As spring progresses, rain precipitation becomes predominant, further increasing water inputs
(Hasler et al., 2011). Large magnitude rockfall is likely to result from the reduced cohesion associated with ice melt and

increases in hydrostatic and interstitial pressure in the altered layer of rockwall surfaces (Matsuoka, 2019; Schovanec, 2020; Wieczorek and Jäger, 1996).

420

Among the contributing factors to rock instability development, the roles of precipitation and freeze-thaw cycles are predominant (e.g. Collins and Stock, 2016; Coutard and Francou, 1989; D'Amato et al., 2016; Hungr et al., 1999; Matsuoka and Sakai, 1999; Rapp, 1960; Wieczorek and Jäger, 1996). To a lesser degree, other weather phenomena can trigger rockfall. Large temperature fluctuations cause expansion and contraction within rock masses that can eventually result in rockfall (Collins and Stock, 2016; Eppes et al., 2016; Matsuoka, 2019). The impact of thermal cycles on the rockfall dynamics of the highly altered north-facing rockwalls of Haute-Gaspésie was considered to be minor and was not quantified in this study.

425

5.3 Preventive rockfall hazard management

The magnitude of rockfalls is a major issue in hazard management. Large dimension blocks tend to travel longer distances (e.g. Dorren, 2003). If they reach part of the natural or built environment that is at risk, they have a larger probability of causing damage. Therefore, in risk management, a high frequency of high magnitude events does not have the same significance as a high frequency of low magnitude events. The rockfall on 16 April 2019 that occurred 1.3 km west of the MAE site resulted in the temporary closure of Route 132 (Figure 11). It took place 18 hours after the first thaw to 60 cm in depth and coincided with the spring thaw (SPR.50:100). It also occurred immediately after a 20.1 mm rainfall event (HEAVY RF). In retrospect, the SPR.50:100 and HEAVY RF conditions meant that extremely high frequency high magnitude rockfall was likely (Figure 10). From a risk management standpoint, forecasting a major event such as the one on 16 April 2019 is possible using the risk assessment matrix developed in this study. High intensity rain (HEAVY RF) and spring thaw SPR.100:350 were identified as the weather conditions of greatest concern for public safety since they result in extreme frequency high magnitude events (Figure 10(a)). In our first full year of data collection (14 June 2019–13 June 2020), these conditions only occurred on 11 days (Figure 10(b)). The other weather conditions that lead to increased rockfall frequency and magnitude (WIN. FT, SPR.0:50, SPR.50:100 and AUT. FT) add 44 more days of concern. From the perspective of rockfall forecasting, it is noteworthy that potentially hazardous conditions are present only 55 days annually for users of Route 132. In the year under study, heightened vigilance was needed only 15% of the days on an annual scale (Figure 10(b)) that has wide seasonal disparities (Figure 9 and Figure 10). The Ministère des Transports du Québec could implement different risk mitigation measures targeted for the weather conditions forecast by the weather models.

430

435

440

445

While RAINY conditions do not stand out in this study for causing high frequency and/or magnitude rock instabilities, rain events should be given special attention. Our methodology did not make it possible to clearly encompass all rain events on an annual scale. Given that HEAVY RF conditions are associated with extreme frequency high magnitude events, moderate intensity rain events must also feed back into frequencies and magnitudes of concern for the safety of Route 132 users. The

450 same reasoning applies to the AUT. FT period. Had it been possible to better monitor fall freeze-thaw cycles, they would likely have shown a frequency of associated rock instabilities more similar to that of winter freeze-thaw cycles (WIN. FT).

455 6 Conclusion

The influence of weather conditions on the occurrence of rock instabilities is now widely recognized in the scientific community. This study proposed the novel technique of quantifying rockfall volume using LiDAR during previously selected weather conditions rather than taking regular surveys (weekly, monthly, seasonal). Using an equivalent number of surveys and therefore for the same effort, this protocol made it possible to efficiently monitor the influence of weather conditions on rockfall frequency and magnitude. Over 18 months, 17 surveys were carried out on three rockwalls with a total area of 12,056 m². They made it possible to monitor a range of weather conditions and identify 1,287 rockfalls. The rockwall retreat rate during that period was 2.8–5.4 mm y⁻¹, which is among the highest in the world but comparable to other observations in this type of lithology.

465 The method presented also made it possible to identify the weather conditions responsible for rockfall. Some of those conditions are associated with marked rockwall stability (dry summer and cold winter periods) while others significantly increase rockfall frequency and/or magnitude (winter freeze-thaw cycles, spring thaw, high intensity rainfall). Winter freeze-thaw cycles and moderate rainfall lead to a marked increase in the frequency of low magnitude rock instabilities. High intensity rainfall and spring thaw coincide with a significant increase in the frequency of large dimension rockfall. In the realm of rockfall prevention, this study showed for the first time the importance of quantifying rockfall magnitude since the relationship between weather conditions and rockfall frequency is not necessarily applicable to rockfall magnitude. The results allow weather conditions to be categorized by their ability to trigger rock instabilities of varying magnitudes. Using this combined with current or forecast weather conditions, different risk mitigation measures to limit safety hazards can be implemented.
