13 **Abstract.** The ‘soils of the anthropocene’ are predominately agricultural. To understand them,
14 we analysed agri- and silvicultural intensification of Uruguayan grasslands in a country wide
15 survey on fertility proxies, pH and trace metals in topsoils originating from different land uses.
16 We observed a loss of nutrients, trace metals and organic matter from grassland, crops and
17 timber plantations. As an example, the cation exchange capacity was 160 percent higher in
18 native forests compared to grasslands and lowest in timber plantations, reaching only half of
19 the CEC in grasslands acidification of topsoils continues as three fourth of all samples are
20 'extremely acidic' and 'very strongly acidic' and lowest in timber plantations. Topsoils of
21 riverine forests accumulate more trace metals compared to the other uses. We assume an
22 accumulation in the topsoils of riverine forests, where high levels of nutrients, trace metals and

31 [organic carbon are found](#). The translocation of nutrients and organic matter across the
32 landscape to the erosion base depends on local land use trajectories. Increasing soil
33 acidification is driving a positive feedback loop, and land use intensification is leading to
34 degradation of local black soils within a few decades. Our data raises questions about the
35 resilience and carrying capacity of Uruguayan soils with regard to currently implemented
36 highly productive management forms, including the use of timber plantation for carbon
37 sequestration, and supports more conservative forms of extensive management on the grassland
38 biome.

39 1. Introduction

40 Human activities alter the bio- and pedosphere, leaving a footprint of such a magnitude that it
41 can be verified stratigraphically (Waters et al., 2016). This unprecedented transformational
42 force is intimately related to the expansion of societies and its productive frontiers, causing a
43 loss of biodiversity, habitat and soil degradation and, consequently, to ecosystem modification
44 (Foley et al., 2005, Borrelli et al., 2017). In this context, soil sciences have transitioned from
45 studies on natural soil formation to the science of ‘anthropedogenesis’ (Richter, 2020),
46 focussing on the ‘soils of the anthropocene’ that are predominately agricultural (51 Mio. km²)
47 or urban (1.5 Mio km²; FAO, 2019).

48 The temperate grasslands of South America have historically been characterised by rolling
49 plains and low hills that have been extensively exploited for cattle production and its
50 derivatives since the arrival of European colonization. The Río de la Plata grasslands are one
51 of our planet’s four major black soil regions (Durán et al., 2011; Liu et al., 2012), and some of
52 the most fertile soils in the world. Playing an important role in the global food production, these
53 are characterized by a thick, humus and base cation rich and a high cation exchange capacity

56 throughout their profile. Maintaining their properties are therefore crucial to developing
57 sustainable and productive agriculture (Durán et al., 2011; Liu et al., 2012).

58 Today, the 'Uruguayan savanna' is part of the top-three most critically endangered biomes
59 (Veldman et al., 2015). In recent decades, however, the grassland has decreased due to the
60 expansion of cash crops and *Eucalyptus* plantations, both of which are promoted by national
61 legislation including land grabbing and trans-nationalization (Piñeiro, 2012). This land use
62 intensification, with its increased input of energy, nutrients and pesticides, leads to an overall
63 loss of soil fertility and increasing toxicity related to acidification, salinization and
64 contaminants (Liu et al., 2012; Borrelli et al., 2017). Ecological, economic and cultural
65 functions of soils are severely degraded, and the degradation of black soils in South America
66 is of particular concern because they have only been heavily exploited for a comparatively
67 short period of time (Durán et al., 2011).

68 Since the first decades of the twentieth-century, compared to other disciplines, soil sciences
69 have received an extraordinary amount of attention in Uruguayan academia, governance, the
70 productive sector, and also in the general public, resulting in a national soil inventory program
71 in 1965. The subsequent classification of Uruguayan soils and their productivity (CONEAT
72 Index) remains an important source for today's land taxation and for management plans by the
73 legal conservation regulations, and provides a detailed classification that takes into account soil
74 type, texture, natural vegetation, altitude and geology (Lanfranco and Sapriza, 2011).

75 As soil degradation is extremely relevant for countries like Uruguay, which are
76 socioeconomically dependent on their soils (Zubriggen et al. 2020), it is a topic of discussion
77 for local farmers, academia, and the public. An actualization of the state of the art of soils and
78 related processes is needed (García-Préchac et al. 2004; De Faccio et al. 2021), particularly as
79 there has been little study of the impacts of the Uruguayan grassland intensification on soils
80 properties (Beretta-Blanco et al., 2019). At the same time, while a new paradigm for grassland
81 intensification with a wide set of means including fertilization has been proposed to increase

82 economic and environmental sustainability (Jaurena et al., 2021), it is urgent to get more
83 insights into the dynamics of nutrient in soils of Uruguay and their availability for crops
84 (Beretta-Blanco et al., 2019).

85 Soil classifications are mainly based on subsoils. However, we focus on topsoil as the most
86 relevant and very responsive interface for ecological processes and farmer's management,
87 since understanding the state of the art of topsoils and its processes is crucial for developing
88 recommendations for sustainable land management practices. Due to the diversity of
89 perspectives on soil quality and health and related ecosystem services, operational procedures
90 for evaluation of soil functioning are still lacking (Bonfante et al. 2021). We contribute to a
91 better understanding of globally occurring degradation processes in the field of tension between
92 desired soil productivity, yield limits, especially in erosion sensitive soils, and necessary soil
93 conservation.

94 We therefore explored soil parameters describing current chemical conditions of topsoils that
95 are parts of different soil groups and orders, and Uruguayan soil categories. Specifically, in
96 order to explore the gains and losses of macro and micro-nutrients and soil organic carbon
97 across landscapes and to determine the impact of land use change on acidification and trace
98 metal mobility and related trade-offs with soil degradation and conservation. In detail we
99 address the following question: i) how do fertility proxies such as soil organic carbon and
100 content of nutrients, acidification (pH) and trace metals accumulation in topsoils vary across
101 different land uses? Thus, we expand the knowledge across land uses from more natural to
102 strongly modified uses and discuss the results in light of different degradation processes such
103 as erosion, depletion of nutrients or carbon, acidification and accumulation of pollutants and in
104 the light on current debates on intensification.

120 2. Material and Methods

121 2.1 Study area and design

122 Uruguay covers about 176,000 km², and has a population of 3.5 million, mainly in urban areas.
123 The Western half of Uruguay is dominated by Mollisols, developed on a wide range of
124 sediments from the Devonian to the Cenozoic era (partially associated with Vertisols), while
125 the Eastern plains and wetlands have, in addition to Mollisols, other soil types on the slopes,
126 rocks and on flood plans (i.e. Alfisols, Ultisols, Entisols and Inceptisols; Durán et al. 2011).
127 During a country-wide survey from December 2015 to March 2016, we collected 280 topsoil
128 samples of 0-10 cm depth from 101 plots (50x50m in grassland and crops; 100x100m in native
129 forests and timber plantations) distributed at 28 monitoring sites throughout Uruguay, South
130 America (Fig. 1a-b), using a stratified random design. In the first step, we randomly selected
131 monitoring sites across the country. In the second step, we contacted landowners to explore
132 their willingness to establish a long-term monitoring site. If the owner agreed, plot selection
133 was stratified by different rural land use types: grassland, timber plantations of *Pinus* and
134 *Eucalyptus* species, native forest, and crops. Native forests cover mainly riverine and park
135 forests. The later are a savanna like transition zones between riverine forests and the open
136 grasslands. We subdivided grassland plots according to the intensity of use: (i) undisturbed
137 grassland (without grazing), (ii) partially grazed grasslands (with sporadic grazing and low
138 animal charge), and (iii) highly grazed grassland (with high animal charge). Land use change
139 from 1986 to 2017 follows basically three different trajectories: i) the expansion of timber
140 plantations over grassland leading to a disaggregation of grassland by timber plantations; ii)
141 cropland expansion where crop cover maintains the open landscape character of former
142 grasslands, grassland conservation where large and regularly interconnected riverine forests in
143 a landscape dominated by grasslands (Ramírez and Säumel 2021) and grassland intensification

149 2.2 Analysis of Soil Samples

150 For gravimetric determination of [soil moisture](#), the topsoils samples were dried at 105 °C until
151 constant weight. Next, lumps in the samples were broken down and the remaining plant
152 material was removed before sieving (2 mm) and ground.

hat gelöscht: humidity

hat gelöscht: content

153 We analysed 280 samples regarding macronutrients, pH and trace metals and 80 samples for
154 soluble cations and micronutrients. Among fertility-related variables, we measured the total
155 amount of the macronutrients phosphorus (P), [organic](#) carbon (SOC) and nitrogen (N), so
156 obtaining the C/N ratio. To determine total carbon and nitrogen, the samples were sieved again
157 (0.5 mm) and analyzed using a LECO TruSpec CN (USA) at a combustion temperature of 950
158 °C with ultra-pure oxygen. In addition, the presence of [SOC](#) was tested for by adding
159 concentrated hydrochloric acid, the presence of carbonates was assessed to obtain the amount
160 of [SOC](#).

hat gelöscht: inorganic carbon

hat gelöscht: organic carbon

hat gelöscht: (C_{org})

hat gelöscht: and soil organic matter (SOM) as C_{org} x 2 (Chenu et al. 2015)

161 We determined concentrations of the soluble cations calcium (Ca), magnesium (Mg),
162 potassium (K), sodium (Na), and the micronutrients copper (Cu), zinc (Zn), manganese (Mn)
163 and iron (Fe) by atomic spectroscopy (Unicam AAS Solaar 969, Thermo Electron Corporation,
164 USA), extracting with ammonium acetate (1 mol l⁻¹, pH 7), and with DTPA-CaCl₂-TEA at (pH
165 7.3). We calculated the cation-exchange capacity (CEC). Acidity was measured by adding
166 calcium chloride (0.01M) to the samples in a 2.5:1 proportion, and after shaking and two hours
167 rest, read with a pH meter (HI2550 meter, Hanna Instruments, USA)). For these variables, each

hat gelöscht: mol

178 tenth sample was duplicated. We categorized [acidity](#) using the USDA Natural Resources
179 Conservation Service classification (Kellogg, 1993).

180 To determine the concentrations of arsenic (As), cadmium (Cd), chromium (Cr) and lead (Pb),
181 samples were further sieved as before (0.5 mm), weighed out into a digesting container, and
182 extracted with a mixture of nitric acid (70%) and hydrochloric acid (30%) in a 1:3 proportion.
183 The digestion took place in a Titan MPS (Perkin Elmer, USA) microwave at a programme
184 suitable for this digestion (Method 3051A). During the proceedings, only deionized water Type
185 I ASTM1193 (EC max 0.06 to 0.1 $\mu\text{S}/\text{cm}$) was used. Reagents were used to eliminate traces of
186 other materials and to avoid contamination of the samples. The trace metals were determined
187 by inductively coupled plasma optical emission spectroscopy using the Optima 8000 (Perkin
188 Elmer) with metal-associated wavelengths of 193.696 nm for As, 228.802 nm for Cd, 267.716
189 nm for Cr and 220.353 nm for Pb.

190 Total P concentration of phosphorus was determined calorimetrically after microwave-assisted
191 digestion with Unicam spectrometer at a wavelength of 660 nm. For all these variables, a
192 repetition for each round of the microwave digestion was made.

193 **2.3 Soil classification**

194 We intersected the coordinates of the centre of the plots with maps containing geospatial
195 information on the classification of the Uruguayan soils using ArcGIS 10.3 (ESRI, 2018). For
196 Soil Groups classification, we used the of the World Reference Base for Soil Resources (WRB;
197 IUSS Working Group, 2015); for Soil Orders, the USDA soil taxonomy (Soil Survey Staff,
198 1999); and for the local Uruguayan classification, Soil CONEAT (Comisión Nacional de
199 Estudio Agronómico de la Tierra) Groups categories, which include productive capacity of
200 cattle and sheep (MGAP, [2020](#)). [The CONEAT groups are defined by their productive capacity](#)
201 [in terms of beef, sheep and wool expressed by an index relative to the average productive](#)

hat gelöscht: the values

hat gelöscht: acidity

hat gelöscht: 2021

205 capacity of the country, to which the index 100 corresponds. The classification is based on
206 photo-interpretation at a scale of 1:40,000, field verifications and physico-chemical analysis of
207 the soils. The productivity indices correspond to soil groups. The CONEAT groups have been
208 defined by the dominant and associated soils according to the Soil Classification of Uruguay.
209 The groups are related to the units of the Soil Reconnaissance Chart of Uruguay at a scale of
210 1:1,000,000. For each group, some important soil properties and associated landscape
211 characteristics are indicated. The nomenclature of the CONEAT groups correlates with the Soil
212 Use and Management Zones of Uruguay. The Soil Groups are superimposed on the rural parcel
213 and are represented in the CONEAT cartography at a scale of 1:20,000 (for more details see
214 MGAP, 2020).

hat formatiert: Nicht Hervorheben

215 **2.4 Data Analysis**

216 In a first step, we explored and prepared our database for further analysis. Exploring the
217 distribution of the soil parameters in R (R Core Team 2021), ruled out the normality of the data
218 using the Shapiro-Wilk Test and the homogeneity of variances with the Fligner-Killeen Test.
219 We tested for outliers using the 1.5-3 IQR threshold and the function *outlierTest* from the R
220 package *car* (Fox and Weisberg 2019), reviewing the flagged observations case by case in the
221 experimental context. The variables on soils characteristics showed generally positive skewed
222 distributions, in some cases multimodal, and tests showed evidence contrary to assumptions of
223 spatial autocorrelation, homoscedasticity and normality in most cases (Supplementary
224 Material: Table S1-S2; Fig. S1-S2).

225 Spearman's rank correlations (ρ) were calculated to explore linear associations between soil
226 parameters across all single samples and within different land uses. We used the *adonis*
227 function of the R package *vegan v2.5-7* (Oksanen et al., 2020) with a Euclidean dissimilarity
228 matrix from our normalized soil data to perform PERMANOVA tests with 9999 permutations

229 to analyse the multivariate homogeneity of group dispersions based on differences on soil
230 parameters between land uses.

231 To compare the general effects of land use type on topsoil parameters, non-parametric Kruskal-
232 Wallis tests were carried out in R. When significant ($p \leq 0.05$), we used Pairwise Wilcoxon
233 Rank Sum tests with Benjamini & Hochberg correction to evaluate pairwise differences among
234 land uses.

235 We used non-metric multidimensional scaling (NMDS) as a robust unconstrained ordination
236 method to visualize patterns of top soil characteristics among all samples and within
237 subsamples (intersected with different soil Orders) across different land uses using the Bray-
238 Curtis dissimilarity matrix. The matrix was constructed with the *vegan* package to depict
239 patterns of all soil parameters in two dimensions (Fig.3a, c-f) and for the dataset without soluble
240 cations and micronutrients variables comparing subcategories within single land use types (i.e.
241 within grasslands in ‘undisturbed’, ‘partially grazed’ and ‘highly grazed’ plots; timber
242 plantations in ‘*Eucalyptus*’ or ‘*Pinus*’ plots; Fig. 3b).

hat nach oben verschoben [1]: We subdivided grassland plots according to the intensity of use: (i) undisturbed grassland (without grazing), (ii) partially grazed grasslands (with sporadic grazing and low animal charge), and (iii) highly grazed grassland (with high animal charge).

243 3. Results

244 Nearly 75% of the sampled 101 plots intersected with the soil Group category 'Luvic Phaeozem'
245 (WRB; IUSS Working Group, 2015). A quarter of our plots were distributed among four other
246 Groups (i.e. Haplic Luvisols, Eutric Vertisols, Planosols, Lithic Leptisols; Fig. 1c). Half of our
247 plots intersected with the Orders 'Argiudolls' or 'Argiudolls & Hapluderts' (Soil Survey Staff,
248 1999), and about a quarter with 'Hapludalfs & Hapludults' or 'Argiudolls, Hapludolls &
249 Hapludalfs' (Fig. 1d). Our plots intersected with 32 different CONEAT categories (MGAP,
250 2021). The most frequent categories were '10.2', '9.3' and '2.12' (25% of our plots) and another
251 quarter with '9.1', '8.8', '9.6' and 'G03.11' (Fig. 1e).

252 3.1 General characteristics of Uruguayan topsoils

258 The measured topsoil parameters vary widely across Uruguay, between the different land uses
259 and classification to different soil orders (Table 1, Table A1-A4). The soil organic ~~carbon~~ in
260 topsoils ranged between 0.8 to 16 percent, and was highest in native forests and lowest in timber
261 plantations. The mean of the C/N ratio was about 13, and lowest in crop soils. Phosphorous
262 ranged between 43 to 1009 mg kg⁻¹. We also observed a high variability for the micro- and
263 macronutrients and trace metals. The average cation-exchange capacity (CEC) was 12.41 cmol
264 kg⁻¹, highest in topsoils of native forest, followed by crops and grasslands and timber
265 plantations (Table 1, Table A1-A2).

266 For the whole data set, high correlation was found between P with SOC and Zn ($\rho=0.82$ and
267 0.76, respectively), and between Mg with Ca and Na ($\rho=0.82$ and 0.76, respectively; Fig. 2).
268 Similar results were observed within particular land uses, although in native forests, a negative
269 moderate correlation between Ca and Fe was observed (Fig. S3). There was high correlation
270 between pH and Ca ($\rho=0.89$; Fig. 2). In native forests, we also found similar correlation with
271 other soluble cations like Mg and K (Fig. S3). In park forests topsoils, there was a negative
272 correlation between pH and As and Pb ($\rho=-0.81$ and $\rho=-0.84$, respectively). In highly grazed
273 pastures and crops pH was highly correlated with Cr, and in crops also with As ($\rho=0.93$; Fig.
274 S3). Among trace metals, Spearman correlation was moderate between As with Cr and Pb and
275 high between Cr and Pb (Fig. 2). These correlation trends increased in grasslands, timber
276 plantations and crops. We also found a high correlation between cadmium and Cr in crops
277 ($\rho=0.81$). Phosphorus was highly correlated with Cr and As in pine plantations, while in
278 soybean crops the correlation was between phosphorus with Cr and Pb (Fig. S3).

279 **3.2 Topsoil characteristics clustered by land use**

280 We found differences in multivariate distribution of samples according to the different land
281 uses (i.e., grassland, timber plantations or native forests; Fig. 3a-f; Table S3-S8). All pairwise
282 comparison of land uses showed significant differences with all variables ($p=0.0001$; Fig. 3a;
283 Table S3). We analysed subcategories within a land use type using the dataset without soluble

hat gelöscht: matter

hat gelöscht: SOM

hat gelöscht: organic carbon

287 cations and micronutrients variables, only finding significant differences between *Eucalyptus*
288 and *Pinus* stands ($p=0.0001$; Fig. 3b; Table S4) but not among different grassland subtypes.
289 We also found differences analysing subsamples of different soil order classification to the
290 different land uses (Fig. 3c-f; Table S5-S8). The samples intersected with 'Argiudolls' included
291 all plots on crops, and we found significant differences in all pairwise comparisons of land uses
292 except between grasslands and timber plantation ($p=0.0004$; Fig. 3c; Table S5). We further
293 found differences between timber plantations and native forests at soils of the 'Argiudolls &
294 Hapluderts' Orders ($p=0.0009$; Fig. 3d; Table S6) and between timber plantations and
295 grasslands or native forests in soils of the 'Argiudolls, Hapudolls & Hapludalf' Orders
296 ($p=0.0284$; Fig. 3e; Table S7). Results for samples in 'Hapludalfs & Hapludults' soils were
297 similar to those obtained at country scale ($p=0.0001$; Fig. 3f; Table S8).

298 3.3 Differences in fertility proxies

299 We found significantly higher fertility proxies for **SOC**, P, Ca, Mg and Zn in topsoils from
300 native forests compared to grasslands and timber plantations (Fig. 4b-e, h). Phosphorous was
301 significantly higher in topsoils of grassland compared to those of timber plantations (Fig. 4c).
302 Potassium was significantly higher in topsoils of native forests compared to timber plantations
303 (Fig. 4f). At subcategories level, we found significantly higher amounts of K in partially used
304 grasslands in comparison to samples from highly grazed pastures, and higher **SOC** ($p=0.002$),
305 P ($p=0.059$), Na ($p=0.043$), K ($p=0.012$) and Zn ($p=0.048$) in *Eucalyptus* compared to *Pinus*
306 plantations (Fig. S4). Among native forests, samples from riverine forests contain more Mg
307 ($p=0.023$) and Na ($p=0.023$) in comparison to park forests.
308 Considering all samples within the Order 'Argiudolls', C/N ratio in agricultural topsoils are
309 lower compared to all other land uses. Phosphorus was higher in topsoils of native forests and
310 crops compared to grasslands and timber plantations. Soil organic **carbon** was highest in native
311 forests (Fig. 5a-o; Table A3-A4).

hat gelöscht: values for the

hat gelöscht: SOM

hat gelöscht: organic carbon

hat gelöscht: values of SOM

hat gelöscht: soil organic carbon

hat gelöscht: matter

318 3.4 Soil Acidification

319 Topsoil samples showed a markedly acid profile (median pH=4.66), with nearly 75% classified
320 as 'extremely acidic' and 'very strongly acidic' (Fig. 6a). We found significant differences across
321 land uses, with less acidic native forests, and lower pH in timber plantations (Fig. 6b).
322 Comparing between land uses, we found more samples with neutral acidity in grasslands and
323 more with higher acidity in timber plantations (Fig. 6b-c). In addition, we found lower pH in
324 samples from *Pinus* compared to *Eucalyptus* stands (p=0.018). Results of analysis inside soil
325 Orders showed similar variations observed at country scale, with timber plantations being more
326 acid and native forest closer to neutral pH (Fig. 6d-f).

327 3.5 Trace metal accumulation across land uses

328 For As, Cd, Cr and Pb, we found significantly higher concentrations in topsoils originating
329 from native forests compared to the grassland and timber plantation samples (Fig. 4l-o and 5l-
330 o; Table A1-A4). At the same time, samples from *Eucalyptus* plantations had higher
331 concentrations of both Cr (p<0.005) and Pb (p<0.005) than *Pinus* topsoils, while the same was
332 observed for Cr (p<0.001) and Pb (p<0.05) in riverine forests compared to park forests (Fig.
333 S5).

334 4. Discussion

335 The vicious circle between the wish to stop soil degradation and concurrent increases in land
336 productivity to satisfy the increasing demand for food, fibres and energy has not been broken
337 since green revolution. Socio-economic and conventional management practices that drive soil
338 degradation have generated several traps, such as the 'inputs trap' where a reduced yield per
339 area is followed by higher fertilizer application or the 'credit or poverty trap' where economic
340 pressure forces the farmer to intensification (Gomiero, 2016). Caught in this loop, the soils of

hat gelöscht: values in

hat gelöscht: values

hat gelöscht: content

hat gelöscht: levels

345 the temperate grasslands of Uruguay have suffered strong degradation from erosion,
346 acidification, contamination, salinification and compaction (Zurbriggen et al., 2020). This is
347 clearly reflected in the results of our topsoil survey, which also adds interesting insights from
348 timber plantations, grasslands and native forests to an existing database consisting mainly of
349 crops and pastures samples from 2002-2014, which demonstrated the loss of organic matter by
350 25% and an increasing loss of nutrients (Beretta-Blanco et al. 2019). We contribute deeper
351 insights on fertility, acidification and trace metals accumulation in topsoils from a wide range
352 of different land uses, which is, to our knowledge, unique for the region since the CONEAT
353 classification (CONEAT Index, 1976).

354

355 4.1 Translocation of elements in topsoils within landscape

356 Our data demonstrate the high amounts of organic carbon, nutrients and trace metals in topsoil
357 samples from riverine forests, suggesting transport of soil particles from the surrounding land
358 uses (e.g., grasslands, crop or timber plantations) to the borders of rivers, streams and creeks.

359 Therefore, we assume that organic carbon, nutrients and trace metals are displaced within the
360 landscape and accumulate in the floodplains. Regional soil erosion models estimate the loss of

361 2-5 tons ha⁻¹ year⁻¹ for a third of the country depending on precipitation, topography, soil
362 erodibility and land management (Carrasco-Letelier and Beretta-Blanco 2017). One possible
363 direct impact is the increasing eutrophication reported for larger local rivers, although the
364 models used by these authors did not link Chlorophyll-a concentrations with agricultural land
365 use (Beretta-Blanco and Carrasco-Letelier 2021 and replies). However, other vertical processes
366 and differences across land uses can be hidden deeper in the soil profile, and have not been
367 analysed in this study.

368 Organic carbon content and the exchangeable cations are strongly reduced in topsoils of
369 grasslands, timber plantations and crops compared to native forests (Fig. 4b, d-h and 5b, d-h).

370 Of all the fertility proxies assessed, phosphorus in topsoil was most significantly affected by

hat gelöscht: matter

378 different land uses, being highest in native forests (Fig. 4c and 5c). The cation exchange
379 capacity (CEC) was highest in native forests (more than 160 percent of the CEC in grasslands)
380 and lowest in timber plantations, reaching only half of the CEC in grasslands (Table A1-A2).
381 Lower average nutrient [concentrations](#) and corresponding CEC reported for two timber
382 plantations in the East and one in the Norwest of Uruguay (Hernández et al., 2009 and 2016;
383 Céspedes-Payret et al., 2012) may result from a combined effect of topsoil degradation in
384 timber plantations due to management practices and to soil texture (Sandoval-Lopez et al.,
385 2020). The trees' uptake and the general export of nutrients from fast growing timber
386 plantations through harvesting is higher than the natural input into those systems (Merino et
387 al., 2005). This effect is particularly relevant because timber plantations in Uruguay are on
388 'forestry priority soils', which are generally soils with low fertility, superficial to moderate
389 depth and good drainage (OAS, 1994), so afforestation might reduce even more their soil
390 fertility.

391 Comparing neighbouring sites of grassland and afforested grasslands, our data set shows no
392 significant depletion of nutrients by timber plantations ($p=0.208$) but a slightly higher average
393 of CEC at grasslands (Table A1). In general, plants are expected to compensate the extraction
394 of cations from upper soil by the 'uplift of nutrient' from deeper horizons (Jobbagy and Jackson,
395 2004). This has been questioned for *Eucalyptus* plantations on sandy soils, where, for example,
396 an increase of potassium in the topsoil was not observed compared to the neighbouring
397 grassland (Céspedes-Payret et al., 2012). Phosphorous and cations decline with sand content,
398 so physicochemical factors such as the percentage of sand and organic matter, influence soil
399 fertility (Sandoval-Lopez et al., 2020). A study of *Eucalyptus* plantations in South-East Brazil
400 did not show a significant depletion of nutrients and carbon; in contrast, carbon, potassium and
401 calcium increased in the topsoil after twelve years over one or two harvest and fertilization
402 cycles (McMahon et al., 2019). To sum up, the patterns observed in the various sites in our
403 survey and the other studies indicate very complex interactions of numerous factors. Removal

hat gelöscht: the

hat gelöscht: contents

406 of nutrients by high-yield timber plantations may exceed the capacity of nutrient exchange or
407 turnover of forest litter and wastes. Both stand management and environmental conditions (e.g.,
408 precipitation) influence nutrient and carbon stocks (McMahon et al., 2019; Sandoval-Lopez et
409 al., 2020).

410 The C/N ratio in topsoils ranged within values reported for grassland and timber plantations of
411 the region (see Berthrong et al., 2012). In contrast to that study, however, we observed no
412 differences between grassland and timber plantations (Fig. 4a), but between topsoils of timber
413 plantations, native forests and crops (Fig. 5a). Organic matter and nitrogen decrease in topsoils
414 after grassland afforestation (Berthrong et al., 2009) and C/N ratio increases with plantation
415 age and decreases with precipitation (Berthrong et al., 2012). The topsoils of timber plantations
416 have, on average, lower N [concentrations](#) compared to other land uses (Table A2) and data in
417 literature (Jobbagy and Jackson 2003).

418 Although in cropland, nutrients are regularly compensated for by increased application of
419 fertilizers (Beretta-Blanco et al., 2019), timber plantations are usually fertilized only in the first
420 year of planting (e.g., Binkley et al., 2017; Sandoval-Lopez et al., 2020). The CEC and the
421 average ratio between $K^+(Ca^{2+} + Mg^{2+})^{-1/2}$ in crops and grasslands are in the ranges reported by
422 Beretta-Blanco et al. (2019) with lower availability of potassium for crops. A shortage of
423 potassium and calcium is also most likely for future timber plantations after harvest, especially
424 if the logging process do not include bark stripping on site (Hernández et al., 2009) and due to
425 short time spans between harvest and new planting in the same area (Sandoval-Lopez et al.,
426 2020), but see contrasting results of McMahon et al. (2019). The extraction of nutrients and
427 biomass due to grazing (Fernandez et al., 2017), timber (Hernández et al., 2009 and 2016) and
428 crop production (Beretta-Blanco et al., 2019) lowers organic matter content and exchangeable
429 cations, affects the physical, chemical and biological soil properties, and drives degradation.

430 **4.2 Acidification in Uruguayan topsoils across land uses**

hat gelöscht: contents

hat gelöscht: ¶

433 A further dimension of the soil degradation directly linked to the cation extraction is the
434 acidification of soils. This has been demonstrated for crops and pastures (Beretta-Blanco et al.,
435 2019), and a study site with *Eucalyptus* (Céspedes-Payret et al., 2012) and is now broadly
436 supported by our topsoil samples originating from a wide range of different land uses across
437 Uruguay. The pH of our topsoil samples are mainly in the category of very strongly to
438 extremely acidic and lowest in timber plantations (Fig. 6), which are below the means reported
439 so far (Jobbagy and Jackson, 2003; Céspedes-Payret et al., 2012). Moreover, as our data on
440 topsoil pH fall short compared to the values estimated by the Food and Agriculture
441 Organization of the United Nations and the Intergovernmental Technical Panel on Soils (Caon
442 and Vargas, 2017), acidification and the deterioration of topsoil quality continues.
443 Acidification results from intensified land uses with nitrogen fertilization, with biological N
444 fixation by the legumes both used in the improved pastures (Modernel et al., 2016), or with
445 cation extraction by crop or timber harvest (Jobbagy and Jackson, 2003). So far, although forest
446 soils tend to be more acidic than agricultural soils due to acid-neutralizing treatments in the
447 latter (Baize and van Oort, 2014), we found no differences between topsoils of crops and native
448 forests (Fig. 6d) as the high organic carbon content in native forests buffers the process to a
449 certain extent.

450 4.3 Riverine Forest soils as sink for trace metals

451 In general, the average concentration of Zn, Cu, Cd, Cr, As and Pb in our topsoils were within
452 the expected ranges of samples from crops, pastures and grassland in the region (Lavado et al.,
453 1998, 2004; Roca, 2015). Some samples, especially from orchards and crops, exceeded the
454 background values of copper, cadmium and arsenic (Table A2; Roca, 2015). Little is known
455 about the pedo-geochemical background of the Pampean soils (Roca, 2015): for example, high
456 arsenic concentration in Uruguayan ground waters has been hypothesized to be due to
457 quaternary ash deposits (Wu et al., 2021). In addition, the lateral heterogeneity of Pampean
458 soils over short distances makes separating geochemical and anthropic signatures difficult

hat gelöscht: values

hat gelöscht: with

hat gelöscht: values for

hat gelöscht: so-called "

hat gelöscht: "

hat gelöscht: matter

hat gelöscht: content

466 (Roca, 2015). However, that the main risk of soil contamination in the region is from the
467 application of fertilizers and agrochemicals is uncontested (Kaushal et al., 2018).

468 To our knowledge, there has been no regional study of trace metals in the native riverine forests
469 or timber plantations. Our work thus expands the evidence base for these land uses. The
470 topsoils of riverine forests accumulate [more](#) trace metals compared to those of timber
471 plantations and crops (Fig. 4l-o). The higher amount of soil organic matter in riverine forests
472 favours the retention of cations, including trace metals. Although the origin of potentially
473 harmful elements in forest soils have been primarily attributed to atmospheric deposition
474 (Baize and van Oort, 2014), atmospheric deposition only plays a major role in vicinity of urban
475 or industrial development, and our data from rural sites suggests a different entry path from the
476 surrounding land uses to the riverine forests. High [acidification](#) and low amounts of organic
477 matter reduce the retention of trace metals in the soil of timber plantations, and elements leach
478 out of the soil towards the water table (Baize and van Oort, 2014). The acidification strongly
479 contributes to the overall mobility of base cations into the ‘chemical cocktail of the
480 Anthropocene’ (Kaushal et al., 2018), including trace metals. We thus observe positive
481 feedback in already impoverished soils with high acidity favouring cations solubility, in
482 addition to the uptake by trees intensifies this effect. Timber plantations extract trace metals
483 from soil and also accumulate it in the bark or leaves, so they have been used for
484 phytoremediation (Li et al., 2020). This may explain the higher [concentration](#) of cadmium in
485 grassland compared to timber plantations (Fig. 4m). Differences between *Eucalyptus* and *Pinus*
486 stands may be related to different age classes, as the later may have extracted more lead and
487 chromium from the soil due to their older stand age with rotation periods of about 20 years (Li
488 et al., 2020).

489 **4.4 Carbon storage in topsoils of *Eucalyptus* plantations?**

490 Our study provides evidence that the loss of soil organic [carbon](#) limits not only the productivity
491 of the crops, but also potential carbon sequestration in the region (Beretta-Blanco et al., 2019).

hat gelöscht: levels of

hat gelöscht: values

hat gelöscht: content

hat gelöscht: matter

496 Grassland conversion to cropland decreases soil organic carbon storage compared to adjacent
497 native grasslands (Hernandez-Ramirez et al., 2021).

hat gelöscht: SOC

498 Afforestation of croplands has been also discussed as a carbon sequestration measure to
499 proactively address and effectively mitigate ongoing climate change within a person's lifetime
500 (Hernandez-Ramirez et al., 2021; Mayer et al. 2020). Although carbon stocks of four
501 *Eucalyptus* stands in the Brazilian Cerrados increased but did not change in four *Eucalyptus*
502 stands within the Atlantic Forest (McMahon et al., 2019), this may not be the case for short
503 rotation of *Eucalyptus* plantation on Campos grasslands. In our topsoil samples originating
504 from 28 different stands across Uruguay, organic carbon is lowest in topsoils of timber
505 plantations (Fig. 4b). Similar amounts have been reported for a timber plantation in the East of
506 Uruguay (Céspedes-Payret et al., 2012), and in North-Eastern Argentina (Sandoval-Lopez et
507 al., 2020). Our data therefore provide clear evidence that rather than contributing to carbon
508 sequestration in the topsoil, the carbon release from the transformation of native grasslands to
509 plantation with these fast-growing species has several adverse effects depending on
510 precipitation and soil type (reviewed by Mayer et al., 2020).

hat gelöscht: matter

511 Several trade-offs between carbon sequestration through afforestation and local water yield and
512 soil fertility have been demonstrated, including nutrient and soil organic matter depletion,
513 acidification, and biodiversity loss and corresponding challenges for landscape conservation
514 (e.g., Jackson et al., 2005; Veldman et al., 2015; Friggens et al., 2020). Soil carbon changes
515 dynamically during the first decade of afforestation. Remaining grassland carbon declines,
516 while tree carbon gain starts (e.g. Paul et al., 2002). Although a net gain of carbon is expected
517 when the new forests approached equilibrium after decades (Hernández-Ramirez et al., 2021),
518 in contrast to long-lasting forests, *Eucalyptus* harvest in Uruguay takes place after less than a
519 decade (appr. 7-10 years). Soil organic carbon does not differ between *Eucalyptus* plantations
520 and neighbouring grasslands (Appendix A; Table A1 and A2). Another study near our sites 12
521 and 13 also did not find a significant difference between the soil organic carbon of the upper

hat gelöscht: matter

hat gelöscht: SOC

526 soil (0-30cm) compared to afforested versus native grasslands (Hernández et al., 2016). A study
527 near our sites 7, 8, 10 reported higher top soil carbon of grassland compared with afforested
528 sites in their vicinity only if sand content is lower than sixty percent (Sandoval-Lopez et al.,
529 2020). McMahon et al. (2019) identified a greater carbon gain under *Eucalyptus* stands
530 compared to (potential) carbon losses in neighbouring degraded Cerrado grasslands. There is
531 evidence that the retention of residues after harvest increases the carbon stock in soil (Mayer
532 et al., 2020). Long term monitoring of carbon stocks is needed to verify the influences of
533 management and environmental changes. A regional study on *Eucalyptus* plantations across
534 different biomes in Brazil shows both decreases and no changes depending on precipitation in
535 the dry season, clay content and on the initial stock of carbon in the soil (Cook et al., 2016)
536 The simplistic solution of huge tree plantations to compensate anthropogenic CO₂ emissions
537 has been challenged in the last decade, and some crucial lessons learnt have been summarized
538 (Di Sacco et al., 2020). Since grasslands are more sustainable carbon sinks compared to
539 climate-vulnerable monocultures such as timber plantations (Dass et al. 2018), avoiding
540 afforestation of previously non-forested lands is important. This is the case for *Eucalyptus*
541 afforestation in the originally forestless grasslands of Uruguay: models on carbon sequestration
542 and dynamics in Mollisols and Oxisols under South American grasslands estimated a higher
543 carbon retention efficiency under grasslands compared to afforested sites, suggesting that
544 silvopastoral systems are a potential solution for soil carbon sequestration in tropical soils
545 (Berhongaray and Alvarez, 2019).
546 Connecting or expanding existing forest and using native species for plantings (Di Sacco et al.,
547 2020) is also recommended (see also Alvaro et al. 2020, Ortiz et al. 2020). Our topsoil data
548 indicates that carbon sequestration occurs mainly in the topsoils of native riverine forests that
549 cover less than five percent of the Uruguayan territory. Consequently, the expansion of native
550 forests and the use of native species in forestry project for long term establishment can reduce
551 adverse effects of timber plantations. While there is preliminary evidence that N-fixing tree

552 species can help increase local C stocks of afforestation, because of their potential for invasion,
553 exotic N-fixers should be avoided (Mayer et al. 2020).

554 Recent studies indicated that novel techniques such as perennial grain cropping can help to turn
555 around cropland degradation into beneficial cropland aggradation by using the advantage of
556 perennial vegetation of conserving and even enhancing short term and long-term soil carbon
557 storage and other ecosystems services (Kim et al. 2022).

hat gelöscht: ¶

558 **4.5. Back to more conservative grassland management?**

559 Our soil survey data shows strong soil degradation of Uruguayan black soils from erosion,
560 acidification and contamination, and suggests a translocation of nutrients and organic carbon
561 across the landscape from grassland, timber and crop plantations to the riverine forests. The
562 potential of grasslands as cropland reserve have been largely overestimated (Lambin et al.,
563 2013), and they have already degraded during the last decades by inappropriate land
564 management techniques (Jaurena et al., 2021, De Faccio et al., 2021), lack of mainstreaming
565 soil conservative techniques (García-Préchac, 2004; Fernandez et al., 2017), decoupling of crop
566 and livestock (De Faccio et al, 2021) plus climate change impacts with storm water events and
567 drought, all of which trigger soil erosion (Wingeyer et al. 2015). From the although very limited
568 point of view on topsoils, the concept of conserving ‘old growth grasslands’ with extensive use
569 (Veldman et al. 2015) appears a more promising strategy to put the ‘grasslands at the core’ in
570 the Campos region than the use intensification strategies envisioned by Jaurena et al. (2021).

hat gelöscht: indicates

hat gelöscht: matter

hat gelöscht: f

571 **5. Conclusions**

572 The land use intensification in Uruguay associated with increasing inputs of energy, nutrients
573 and pesticides leads to an overall loss of soil fertility and increasing toxicity related to
574 acidification, salinization and trace metal contaminants. Our data demonstrate the high amounts
575 of organic carbon, nutrients and trace metals in topsoil samples from riverine forests.

580 suggesting transport of soil particles from the surrounding grasslands, crop or timber
581 plantations to the borders of rivers, streams and creeks. Of all the fertility proxies assessed,
582 phosphorus in topsoil was most significantly affected by different land uses, being highest in
583 native forests. Cation exchange capacity was also highest in native forests and lowest in timber
584 plantations, where only half that of grasslands was measured. Our study highlights that soil
585 acidification is ongoing and probably also mobilizing trace metals and their accumulation in
586 riverine forest topsoils.

hat gelöscht: Our study allowed us to corroborate soil acidification processes as a result of soil change. Furthermore, based on the probable accumulation of heavy metals in riverine forests, we infer that management and conservation in the vicinity of productive land uses should be a priority.⁴

587 **Data availability**

588 All data generated or analysed in this study are included in this article (and its supplementary
589 materials). Further data are available from the corresponding authors upon reasonable request.

590 **Author contributions**

591 IS, LRR, ST and MB conceptualized the study, performed the soil sampling and data analysis.
592 EZ advised the laboratory analyses. IS wrote the initial draft. LRR, ST, MB and EZ contributed
593 to generating and reviewing the subsequent versions of the manuscript. IS received the funding
594 for the study.

595 **Competing interests**

596 The authors declare that they have no conflict of interest
