Abstract. Arctic sea ice has been declining rapidly in recent decades. We investigate how poleward transport of moisture and heat from lower latitudes through atmospheric rivers (ARs) influences Arctic sea ice variations. We use ERA5 hourly reanalysis data for 1981-2020 at $0.25°$ x $0.25°$ resolution to examine meteorological conditions and sea ice changes associated with ARs in the Arctic. In years 2012 and 2020, which had extremely low summer Arctic sea ice extent, we show that individual AR events associated with large cyclones initiate rapid sea ice decrease through turbulent heat fluxes and winds. We further carry out statistical analysis of meteorological conditions and sea ice variations for 1981-2020 over the entire Arctic Ocean. We find that on weather timescales atmospheric moisture content anticorrelates significantly with sea ice concentration tendency almost everywhere in the Arctic Ocean, while dynamic sea ice motion driven by northward winds further reduces sea ice concentration.

1 Introduction

Atmospheric rivers (ARs) are long, narrow, and transient corridors of strong horizontal water vapor transport as defined in the Glossary of Meteorology (American Meteorological Society, 2017). ARs are an important form of extreme horizontal water vapor transport on weather and synoptic scales. ARs account for 90% poleward water vapor transport at midlatitudes (Zhu and Newell, 1998). Poleward water vapor transport by ARs plays a critical role in atmospheric moisture content and precipitation variations at high latitudes (e.g., Nash et al, 2018).

The Arctic has experienced rapid sea ice decrease especially in summer in recent decades. This decrease has been quantified using satellite observations since 1979, with the record low summer sea ice minimum occurring in 2012 (Parkinson and Comiso, 2013). Rapid Arctic sea ice loss leads to global climate change and weather extremes, such as increasing occurrence of ARs near the North American west coast (Ma et al., 2021). The imminence of the seasonal sea ice free Arctic Ocean in the coming few decades (Peng et al., 2020; Notz et al., 2020; Guarino et al., 2020) has important implications for marine ecosystems, shipping, resources, and conservation.

Many processes and feedbacks contribute to sea ice variations in the Arctic across different temporal and spatial scales. Previous studies show that poleward atmospheric energy transport is a key factor driving Arctic sea ice variations (e.g., Olonscheck et al., 2019; Hofsteenge et al., 2022). In particular, moisture transport into the Arctic influence the surface energy budget by strengthening downward longwave radiation and sensible heat flux,

40 especially in winter (Doyle et al., 2011; Mortin et al., 2016; Woods and Caballero, 2016; Johansson et al, 2017; Woods et al., 2017; Hegyi et al., 2018; Olonscheck et al., 2019; Ali and Pithan, 2020; Wang et al., 2020; Fearon et al., 2020). Those studies are mostly on large spatial scales such as considering zonal mean moisture transport (e.g., Papritz et al., 2022; Hofsteenge et al., 2022) and total Arctic sea ice loss (e.g., Wernli and Papritz, 2018) and over long time scales such as interannual variability (e.g., Olonscheck et al., 2019) and trends (e.g., Woods and

45 Caballero, 2016). ARs are one form of extreme moisture transport on weather and synoptic scales at low levels. However, the direct impact of ARs through both thermodynamic and dynamic processes on Arctic sea ice variations at high temporal and spatial resolutions still needs better understanding (Hegyi et al., 2018; Wang et al., 2020; Papritz et al., 2022).

50 ARs transport moisture and heat from lower latitudes into the Arctic with considerable potential to drive sea ice reduction (e.g., Baggett et al., 2016; Hegyi et al., 2018; Vázquez et al., 2018; Wang et al., 2020; Papritz et al., 2022). Though the upstream moisture source and transport pathways of ARs reaching the Arctic have been examined (Vázquez et al., 2019; Harrington et al., 2021; Papritz et al., 2022), the downstream interaction between ARs and sea ice requires further investigation. As low level jets associated with ARs come in close contact with sea ice surface

55 near sea ice margins, they can have direct impacts on sea ice through intense surface energy, momentum, and mass exchanges between the atmosphere and ice/ocean (Hegyi et al., 2018; Wang et al., 2020). Furthermore, the warm and moist air masses brought by ARs are forced upward by cold air to form precipitation and clouds with associated latent heat release into the upper air (e.g., Komatsu et al., 2018).

60 This study investigates the relative contribution of surface heat flux components and the relative importance of thermodynamic and dynamic processes in sea ice changes associated with Arctic ARs. One novel aspect of this study reveals the important roles of turbulent heat fluxes under ARs and the ARs' wind effect on sea ice on weather timescales. Another novel aspect of this study is the method of extraction of high frequency signals representing extreme weather events such as ARs, without mean seasonal cycle, interannual variability and trends. Furthermore,

65 we find that the covariation between ARs and sea ice holds for the whole Arctic Ocean through the entire seasonal cycle. This comprehensive analysis provides better understanding of physical processes governing the interactions between ARs and sea ice with implication on short term sea ice prediction.

The goal of this study is to explore how ARs contribute to Arctic sea ice variations. We examine sea ice changes in

70 relation to AR forcing by thermodynamic surface heat fluxes as well as dynamic winds. First, we show two case studies to examine physical processes through spatial pattern and time series analysis. Second, we carry out statistical analysis for 1981-2020 over the entire Arctic Ocean.

2 Data and Methods

75

ERA5, the fifth-generation European Re-Analysis, is the most recent atmospheric reanalysis from ECMWF, with data assimilation system IFS Cycle Cy41r2 with 4D-Var (Hersbach et al., 2020). ERA5 uses boundary conditions of sea ice concentration and sea surface temperature based on satellite observations (HADISST2 before 1979, OSI SAF (409a) for 1979-Aug 2007, OSI SAF operational from Sep 2007). ERA5 has high temporal (hourly) and spatial (~31km horizontally, 137 model levels vertically) resolutions suitable for studying extreme weather events such as ARs. Its long and consistent records are also appropriate for studying climate change and variability.

ERA5 atmospheric reanalysis over Arctic sea ice has been evaluated with in-situ observations (Graham et al., 2019; Batrak et al., 2019; Renfrew et al., 2020). ERA5 accurately represents integrated water vapor (IWV) and downward longwave radiation, and correlations between ERA5 and in-situ observations are high for meteorological variables such as IWV, 2-m temperature, 10-m wind speed, and sea level pressure (Graham et al., 2019). Noticeably, ERA5 improves estimate of the Arctic energy budget in terms of closure (Mayer et al., 2019). However, ERA5 has a warm bias near the Arctic sea ice surface, which is large in winter and small in summer (Graham et al., 2019; Batrak et al., 2019).

We use ERA5 hourly reanalysis data for 1981-2020 at 0.25º x 0.25º resolution in the Arctic. First of all, we study two AR events associated with cyclones during summertime of 2012 and 2020, which are periods of record low Arctic sea ice extent. We examine spatial patterns and time series of meteorological conditions, surface energy budget, and sea ice variations related to the AR events. Furthermore, for each grid box of the entire Arctic Ocean, we investigate the statistical relationship between anomalous meteorological conditions and sea ice variations on weather timescales during 1981-2020. We extract high frequency variations on weather timescales and identify extreme moisture anomalies as approximate ARs which are validated by Guan and Waliser's AR catalog version 3 from 6-hourly 0.625° x 0.5° Modern-Era Retrospective Analysis for Research and Applications, Version 2 (MERRA-2) reanalysis data for 1980-2020 (Guan and Waliser, 2019).

3 Results

3.1 Two Case Studies in 2012 and 2020

Atmospheric rivers transport moisture and heat from lower latitudes into the Arctic at low levels on weather timescales. Those episodic extreme events of water vapor transport can have a large impact on Arctic sea ice variations with important implications for short term sea ice prediction. Here we show two examples of AR events occurring in the summertime of 2012 and 2020 in the western Arctic Ocean associated with rapid sea ice changes through turbulent heat fluxes, longwave radiation, and winds. These case studies of AR events reveal important physical processes and give context to the statistical analysis shown later.

3.1.1 The Atmospheric River Event of August 2012

Deleted: -

130   In September 2012 the Arctic sea ice extent reached the lowest in the satellite record (Parkinson and Comiso, 2013). This was preceded during August 5-12, 2012 by a severe Arctic cyclone, one with the lowest central pressure (966 hPa) in August since 1979 (Simmonds and Rudeva, 2012). On August 5, 2012, when the cyclone first reached the Arctic Ocean, an associated AR arrived in the western Arctic Ocean.

135   Sea ice concentration decreased substantially in the Chukchi Sea and the East Siberian Sea between Aug 4-6, 2012 (Figure 1a). The AR entered the western Arctic from Siberia on Aug 4, 2012, reached its highest intensity on Aug 5, 2012, with integrated water vapor transport (IVT) values exceeding 250 kg m^{-1} s^{-1} (maximum in the core around 500 kg m^{-1} s^{-1}), and was still present in the Arctic Ocean on Aug 6, 2012 (exceeding 250 kg m^{-1} s^{-1}) (Figure 1b). Concurrently, strong northeastward surface winds (inferred from sea level pressure from geostrophic balance)

140   beneath the AR core pushed sea ice away from the sea ice edge towards the pole. This coincided with strong downward sensible and latent heat fluxes near the sea ice edge, driven by warm and moist air and high wind speed at low levels within the AR (Figure 1cd). Net longwave radiation (incoming longwave radiation minus outgoing longwave radiation) near the sea ice edge was also downward, but the magnitude is much weaker than turbulent heat fluxes (Figure 1f). In contrast, net shortwave radiation (incoming shortwave radiation minus outgoing shortwave

145   radiation) is reduced over sea ice (Figure 1e). The radiation patterns, reduced net shortwave radiation and enhanced net longwave radiation, were consistent with clouds and precipitation that formed when the AR arrived (not shown). This major event provides evidence that turbulent heat fluxes may be the dominant terms in surface energy budget during an AR. This is in contrast to prior studies, which emphasize dominance of downwelling longwave radiation related to water vapor and clouds (Doyle et al., 2011; Mortin et al., 2016; Woods and Caballero, 2016; Johansson et

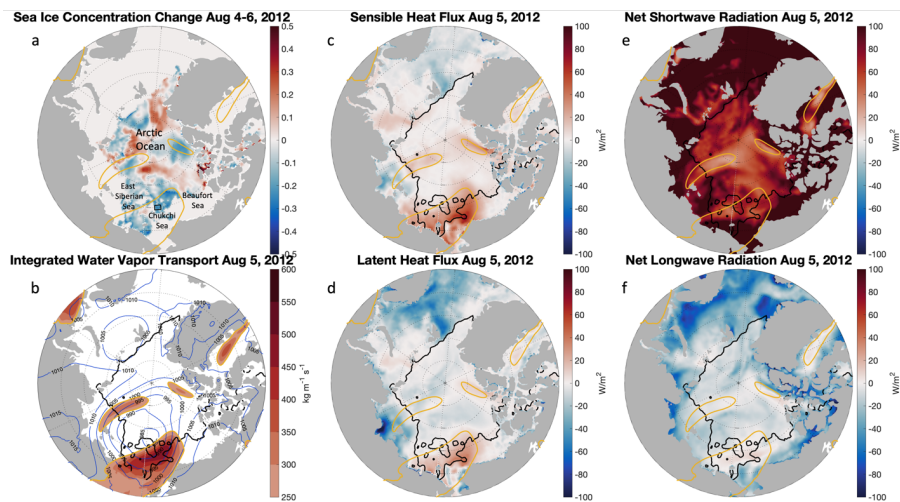
150   al, 2017; Woods et al., 2017; Hegyi et al., 2018; Wang et al., 2020), though some studies reveal an important role of surface sensible heat flux (e.g., Stern et al., 2020).


Figure 1: a Sea ice concentration change during Aug 4-6, 2012 (sea ice concentration on Aug 6, 2012 minus sea ice concentration on Aug 4, 2012). Extent of atmospheric rivers (250 kg m⁻¹ s⁻¹ contour of integrated water vapor transport) on Aug 5, 2012 is represented as yellow lines (same in b c d e f). The black box will be used in Figure 3. b Magnitude of integrated water vapor transport on Aug 5, 2012. Sea ice edge (15% contour of sea ice concentration) on Aug 5, 2012 is represented as black lines (same in c d e f). Sea level pressure on Aug 5, 2012 is represented as blue contours. c Sensible heat flux (positive downward) on Aug 5, 2012. d Latent heat flux (positive downward) on Aug 5, 2012. e Net shortwave radiation (positive downward) on Aug 5, 2012. f Net longwave radiation (positive downward) on Aug 5, 2012.

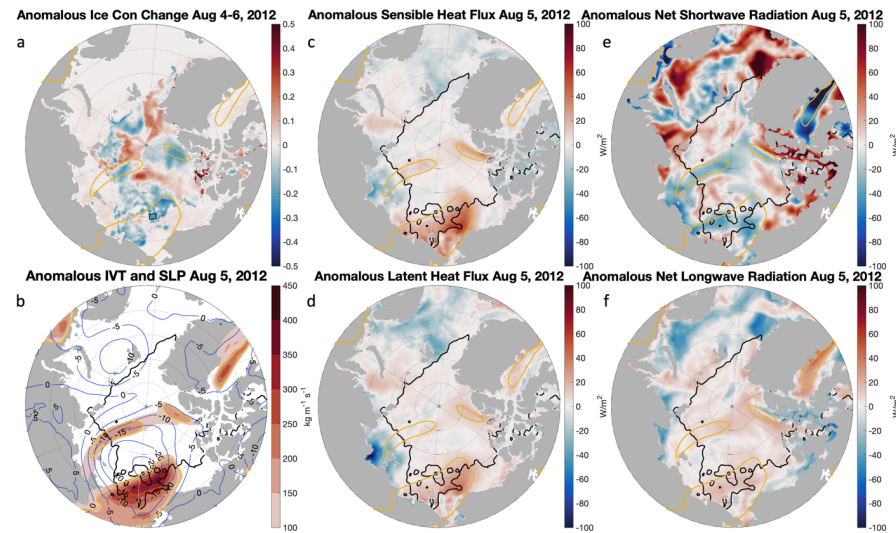
Figure 1 shows the original fields to demonstrate the magnitude of the event. However, the seasonal cycle can impact the interpretation of the event, as radiative and turbulent fluxes change their relative importance throughout the year. We therefore further investigate this event using anomalies (Figure 2). Anomaly is defined as difference between original field and the daily 1981-2020 climatology for the case study here. Indeed, Figure 2 removes the mean radiative component features, and doesn't reveal significantly large radiative anomalies collocated with anomalous IVT. As expected, shortwave is reduced and longwave is enhanced in regions of anomalous IVT, but the magnitudes are similar to anomalies found elsewhere in the region. The most significant anomalous flux component collocated with IVT is sensible heat flux. This positive flux anomaly is augmented by additional anomalous heating from latent and longwave components. However, like shortwave anomalies, longwave anomalies associated with increased IVT are not as notable in the domain. In the Chukchi Sea, substantial anomalies of the turbulent heat flux during the event collocated with IVT anomalies (Figure 2), whereas significant radiative anomalies occurred throughout the domain especially for the shortwave component.


Figure 2: Same as Figure 1 but using anomalous fields (original fields minus climatologies) on Aug 5 (Aug 4-6 for sea ice concentration change) during 1981-2020. Note that sea ice edge in black lines and extent of atmospheric rivers in yellow lines are based on original fields.

To study the total effect of the cyclone on sea ice, we examine time integrated surface heat fluxes, time integrated IVT, and sea ice concentration change through the life cycle of the cyclone (Appendix Figure A1). During Aug 5-12, 2012, sea ice is reduced substantially over broad areas of the Chukchi Sea and the East Siberian Sea, corresponding with strong time integrated IVT there (maximum around 1.5 kg m⁻¹ over 7 days). Strong sensible heating, weak latent heating, weak net longwave radiation cooling, and weak net shortwave radiation heating are seen there. In the western Arctic Ocean , the cyclone extensively reduces sea ice over its life cycle, corresponding to strong IVT, atmospheric warming (enhanced sensible/latent heat fluxes and longwave radiation) as well as sea ice advection driven by winds. Here we only consider local atmospheric forcing of sea ice changes during the cyclone, though other processes such as ocean-ice heat flux are also important in sea ice melt during the cyclone (Zhang et al., 2013; Stern et al., 2020; Finocchio et al., 2020; Lukovich et al, 2021). Note that ARs initiate the cyclones and happen at the early stage of the life cycle of the cyclones, as shown in this case. While our study focuses on ARs and their effect on Arctic sea ice, the roles of cyclones/anticyclones in sea ice change are very complicated, varying between seasons and regions. For example, Wernli and Papritz (2018) showed that enhanced sea ice melt during Arctic summer is related to polar anticyclones as well as extratropical cyclones, however, overall cyclones seem to have less effect on sea ice than long wavelength atmospheric waves (Hofsteenge et al., 2022).

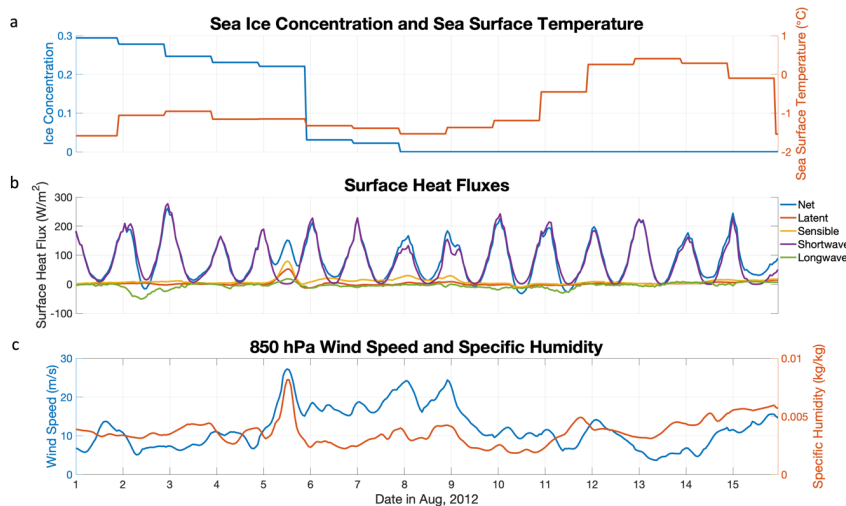
We examine hourly time series of surface heat fluxes and meteorological conditions and daily time series of sea ice concentration and sea surface temperature for Aug 1-15, 2012 area averaged over the black box (with an area ~100000 km^2) as shown in Figure 1a (Figure 3). The location of the black box was chosen due to its proximity to the summer sea ice edge in the western Arctic Ocean. This study area was partially covered by sea ice before the arrival of the cyclone and became sea ice free after the cyclone. Sea ice concentration and sea surface temperature from ERA5 are daily based on satellite observations, while other variables from ERA5 are hourly in Figure 3. The sea ice concentration drops abruptly around Aug 5, 2012 when the AR arrives (Figure 3a). Correspondingly, large downward sensible and latent heat fluxes and moderate downward net longwave radiation into ice/ocean occurred within one day, peaking at midnight with nearly zero net shortwave radiation on Aug 5, 2012 (Figure 3b). The dominant latent and sensible heat fluxes were related to the high moisture and heat content associated with the AR, while high wind speed further enhanced turbulent heat fluxes. Over the black box, the Aug 5, 2012 AR event is categorized as an AR Cat 2 (Moderate) with maximum IVT magnitude 867 kg m^{-1} s^{-1} and duration of 18 hours (IVT>250 kg m^{-1} s^{-1}) (AR scale is defined in Ralph et al., 2019). We further partition IVT into moisture and wind components to separate into thermodynamic and dynamic components of AR. The specific humidity at 850 hPa peaks prominently on Aug 5, 2012 (Figure 3c). The 850 hPa wind speed is the strongest at the same time as the largest specific humidity on Aug 5 and continues to be strong for the next 3 days (Figure 3c). Wind direction is northward on Aug 5, 2012, and then turns eastward on Aug 6-10, 2012 (not shown). Near surface conditions in humidity and wind are also examined and show similar results (not shown). In summary, simultaneous maxima in moisture and wind speed cause intense downward turbulent heat fluxes and subsequent rapid sea ice decrease as the AR arrived on Aug 5, 2012.


Figure 3: a Sea ice concentration (blue) and sea surface temperature (red) daily during Aug 1-15, 2012 averaged over the black box in Figure 1 a. b Latent heat flux (red), sensible heat flux (yellow), net shortwave radiation (purple), net longwave radiation (green), and net surface heat flux (blue) hourly during Aug 1-15, 2012 averaged over the black box in Figure 1 a. c Wind speed (blue) and specific humidity (red) at 850 hPa hourly during Aug 1-15, 2012 averaged over the black box in Figure 1 a.

Sea surface temperature at this location decreased slightly after the AR during the first half of the cyclone and increased substantially near the end of the cyclone (Figure 3a). The spatial pattern of sea surface temperature change during the life cycle of the cyclone revealed significant ocean warming in newly formed open ocean which was covered by sea ice before the cyclone (Appendix Figure A2). This ocean surface warming was related to strong air-sea interaction during the cyclone with shortwave radiation as the dominant term in surface heat fluxes. Wind induced ocean mixing could also bring subsurface warm water upward during the cyclone (Zhang et al., 2013; Stern et al., 2020).

3.1.2 The Atmospheric River Event of July 2020

The second lowest summer sea ice extent in 2020 (based on the NSIDC sea ice index (Fetterer et al., 2017)) is also investigated for its relation to AR forcing. The summer 2020 sea ice deficit occurred largely in the western Arctic Ocean (Liang et al., 2022). The reasons causing the record low Arctic sea ice in 2020 involve several processes across different temporal and spatial scales. The Siberian heat wave associated with local atmospheric warming occurred during January-June 2020 (Overland and Wang, 2020) before the extremely low summer sea ice extent in the East Siberian Sea. The record low Arctic sea ice extent in July, 2020 has also been attributed to horizontal transport of heat and moisture during April-June, 2020 (Liang et al., 2022). Here we show an example of the contribution of strong water vapor transport by ARs on weather timescales to rapid sea ice changes during summer of 2020.

In the western Arctic Ocean, a large cyclone occurred during July 25 - Aug 2, 2020, reaching lowest central pressure (968 hPa) on July 28, 2020. Strong advection of heat and moisture (with large gradient of temperature and moisture) from Siberia to the Arctic Ocean occurred on July 26, 2020 (not shown). An AR event with maximum IVT around 600 kg m^{-1} s^{-1} in the core and strong northward winds happened near the sea ice edge on July 27, 2020 (Figure 4b). Corresponding to the AR timing and location over sea ice, strong sensible/latent heat fluxes and net longwave radiation are directed from the atmosphere into the ice/ocean, and net shortwave radiation is reduced by clouds (Figure 4cdef). Meanwhile, strong northeastward winds reduce sea ice concentration near the sea ice edge (Figure 4ab). The wind direction is northward before the AR and becomes eastward after the AR (not shown). This suggests wind-driven meridional water vapor transport at the early stage of the cyclone life cycle and intensified IVT as the AR propagates eastward along the coast later.

Time is in UTC.

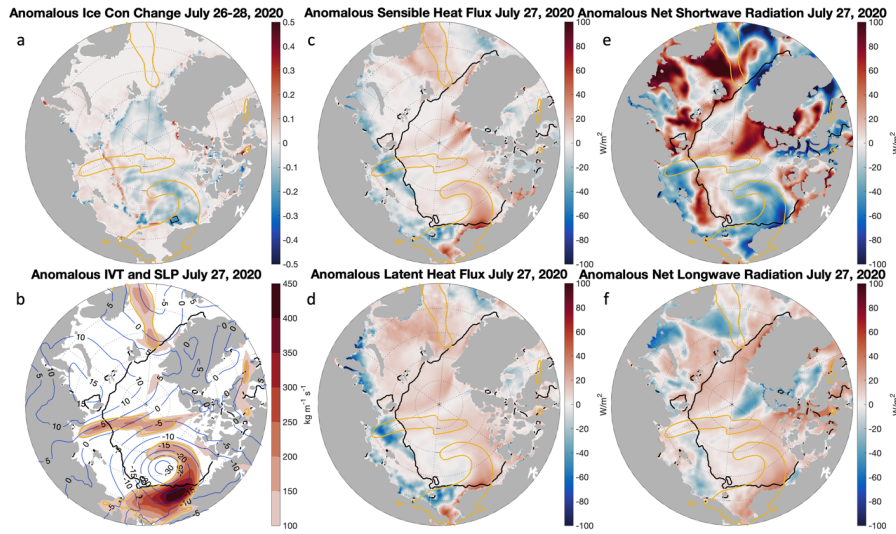
As in Figure 2, we also investigate this event with respect to difference from the daily 1981-2020 climatology. This highlights the spatial extent of anomalies of surface heat fluxes are collocated well with anomalous IVT (Figure 5). Like the event discussed earlier, the most striking anomalous fluxes are the turbulent fluxes: the sensible heat flux is greatest where the IVT is greatest, and the latent heat flux is negative over much of the domain, but strongly positive over the locations of high anomalous IVT. The radiative fluxes show the influence of the IVT anomaly, but these flux anomalies are large in many parts of the domain.


Figure 5: Same as Figure 4 but using anomalous fields as departures from climatology on July 27 (July 26-28 for sea ice concentration change) during 1981-2020. Note that sea ice edge in black lines and extent of atmospheric rivers in yellow lines are based on original fields.

Next, we examine time series of sea ice concentration, sea surface temperature, surface heat fluxes and AR conditions during the life cycle of the cyclone area averaged over the black box (with an area ~100000 km²) as shown in Figure 4a (Figure 6). We choose this study area in the Beaufort Sea because it experiences the most significant sea ice reduction during the life cycle of the cyclone (July 25-Aug 2, 2020). At this location, sea ice concentration decreases gradually from 72% to 19% in one week throughout the cyclone, while the most rapid sea ice decrease happens immediately after the AR. Sea surface temperature increases immediately after the AR and persistently during the cyclone, indicating increasing ocean-ice heat flux for bottom and lateral sea ice melt. Culminating downward turbulent heat fluxes and weak downward net longwave radiation occur on early July 27, 2020 when the AR arrives. For this AR event on July 27, 2020, peaking moisture content, along with high wind speed, generates peaking downward turbulent heat fluxes. This AR event is categorized as AR Cat 1 (Weak) (Ralph et al., 2019) with maximum IVT magnitude 502 kg m⁻¹ s⁻¹ and duration of 16 hours (IVT>250 kg m⁻¹ s⁻¹). The major difference between this case and the case in Aug 2012 is that sea ice concentration decreases gradually, lasting for a few days during the cyclone, which might be related to ocean's role due to warming of sea surface temperature and constant high wind speed during the cyclone.

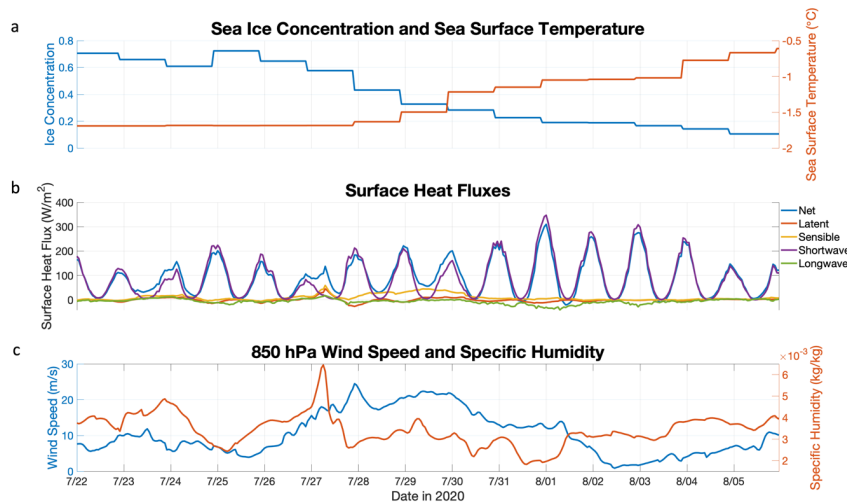

Figure 6: a Sea ice concentration (blue) and sea surface temperature (red) hourly during July 22-Aug 5, 2020 averaged over the black box in Figure 4 a. **b** Latent heat flux (red), sensible heat flux (yellow), net shortwave radiation (purple), net longwave radiation (green), and net surface heat flux (blue) hourly during July 22-Aug 5, 2020 averaged over the black box in Figure 4 a. **c** Wind speed (blue) and specific humidity (red) at 850 hPa hourly during July 22-Aug 5, 2020 averaged over the black box in Figure 4 a.

In summary, for the years 2012 and 2020, which experienced record low summer sea ice extent in the Arctic Ocean since 1979, AR related atmospheric water vapor transport from lower latitudes triggered rapid sea ice melt in the western Arctic Ocean through turbulent heat fluxes. Another extreme event with the 3rd lowest summer Arctic sea ice minimum in 2007 has also been attributed to atmospheric heat and moisture transport from the Pacific with enhanced downwelling longwave radiation and turbulent fluxes (Graversen et al., 2011). Our results of surface energy budget of sea ice are generally consistent with in situ observations (Tjernström et al., 2015; Tjernström et al., 2019) and coupled atmosphere/ocean/ice models (Stern et al., 2020) showing the dominant role of turbulent heat fluxes under ARs.

3.2 Statistical Analysis of Meteorological and Sea Ice Variations for 1981-2020

The case studies in the previous section reveal linkages between AR-related atmospheric forcing and rapid sea ice changes. We extend to a general study spanning four decades over the entire Arctic Ocean. We carry out statistical analyses to examine the relationships between meteorological conditions and sea ice changes in the Arctic Ocean using ERA5 reanalysis for 1981-2020. We explicitly separate thermodynamic and dynamic effects of ARs on sea ice changes. We consider IWV, surface latent and sensible heat fluxes as thermodynamic variables, near-surface

northward wind as a dynamic variable, and sea ice concentration tendency on a daily basis. Because ERA5 has good performance of IWV (Graham et al., 2019) and sea ice concentration is daily based on satellite observations, it is reasonable to examine the relationship between IWV and sea ice concentration tendency on the daily basis to study how ARs influence sea ice changes thermodynamically. In addition, we use northward wind as the driving force to approximately study ARs' dynamic effect on sea ice. The partial sea ice cover with sea ice concentration < 85% we consider is in free drift with small internal sea ice stress (Heorton et al., 2019). Sea ice velocity in free drift is strongly correlated with wind forcing especially on weather timescales. We find that sea ice concentration tendency has significant anticorrelation with IWV, northward wind, and turbulent heat flux on weather timescales almost everywhere in the Arctic Ocean.

3.2.1 Seasonal Variations in 2012 at One Location in the Chukchi Sea

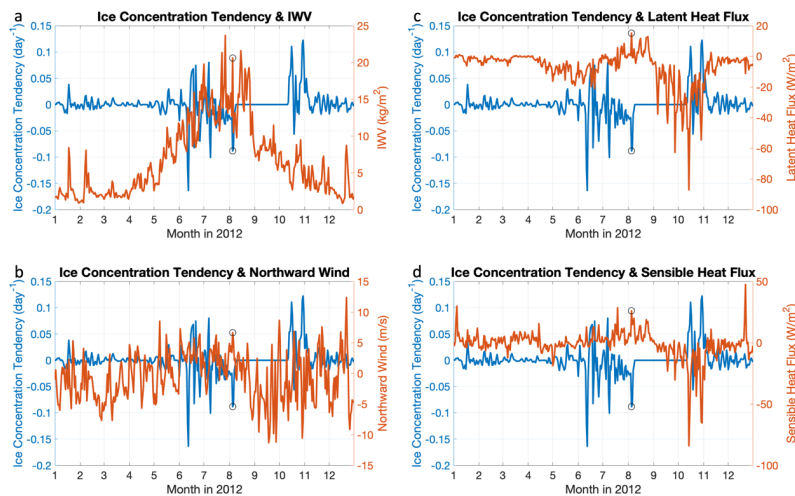
To put the AR event on Aug 5, 2012 in the context of longer time scales, we first extend the time series to the full calendar year 2012 for the same study area shown as the black box in Figure 1a. We examine 2012 daily IWV, sea ice concentration tendency, latent heat flux, sensible heat flux, and northward wind averaged over that study area (Figure 7). Since satellite observed sea ice concentration is available at daily resolution, we consider daily mean IWV, latent/sensible heat fluxes, and northward wind. The conditions of the extreme event on Aug 5, 2012 are marked with black circles (Figure 7). For this extreme event, substantial sea ice concentration decrease corresponds to large atmospheric moisture content, strong latent and sensible heating from the atmosphere, and high northward wind. Note that those variables show dominant seasonal cycles and high frequency fluctuations imposing on seasonal cycles. Those high frequency variations on weather timescales are the focus of this study.


Figure 7: a Variations in sea ice concentration tendency and IWV in 2012. b Variations in sea ice concentration tendency and northward wind in 2012. c Variations in sea ice concentration tendency and latent heat flux in 2012. d Variations in sea ice concentration tendency and sensible heat flux in 2012. All variables are averaged over the black box in Figure 1 a. The AR event on Aug 5, 2012 is marked with black circles.

3.2.2 Statistical Analysis for 1981-2020 at One Location in the Chukchi Sea

We expand our time series analysis to four decades for 1981-2020. We focus on variations on weather timescales in this study. We use a high pass filter with period <30 days to remove time-varying seasonal cycles from the daily time series for 1981-2020. We define those high frequency variations (period <30 days) as anomalies in the statistical analysis here. We only consider time periods when sea ice cover is partial (sea ice concentration between 15% and 85%). This is in general consistent with the definition of marginal ice zone with sea ice concentration between 15% and 80% (https://www.npolar.no/en/themes/the-marginal-ice-zone). Also, sea ice is in free drift for sea ice concentration less than 85%. The reason for this choice is that sea ice concentration can only change substantially in response to atmospheric forcing when sea ice concentration is partial.

We find significant rank correlation between anomalies of sea ice concentration tendency and IWV, northward wind, latent heat flux, and sensible heat flux for 1981-2020 (Figure 8). Rank correlation between sea ice concentration tendency and IWV anomalies is -0.30, and it is -0.28 for latent heat flux, -0.30 for sensible heat flux, and -0.34 for northward wind), all with p-values <0.01 for Spearman's rho. The negative correlations are moderate,

but significant due to the large sample size (14610). The AR event on Aug 5, 2012 (big red dot in Figure 8a) stands out as an extreme event during 1981-2020.

465

Figure 8: Scatter plots at one location in the Chukchi Sea (black box in Figure 1 a) from daily time series for 1981-2020 when sea ice cover is partial. a Scatter plot of anomalies of IWV and sea ice concentration tendency (blue dots), with small red dots representing extreme IWV anomalies exceeding 90% percentile. b Scatter plot of anomalies of northward wind and sea ice concentration tendency c Scatter plot of anomalies of latent heat flux and sea ice concentration tendency d Scatter plot of anomalies of sensible heat flux and sea ice concentration tendency. Big red dots in abcd represent the AR event on Aug 5, 2012.

470

Next, we identify all extreme moisture anomalies from ERA5 during 1981-2020 in this study area as proxies for AR events and validate them with a global AR catalog. We define extreme moisture anomalies as IWV anomalies exceeding the 90% percentile based on the daily time series during 1981-2020. We only consider extreme events over partially covered sea ice in this study. For this study area, we identify 553 extreme moisture anomalies with 20% frequency when sea ice cover is partial during 1981-2020. The mean IWV anomalies of those extreme events is 5.21 kg/m^2, and the mean sea ice concentration tendency anomalies of those extreme events is -1% day^{-1}. In Figure 8a, small red dots represent extreme moisture anomalies using ERA5 data, while the big red dot represents the AR event on Aug 5, 2012 (Figure 1 and Figure 3). We validate extreme moisture anomalies identified by our method with ARs identified by Guan and Waliser's AR catalog version 3 (Guan and Waliser, 2019). Among extreme moisture anomalies exceeding 90% percentile over partial sea ice cover, 72% have a corresponding AR identified from the catalog around the same date (+/-12h) at the same location. For 2012, this ratio is 91%. For large extreme events, these two methods agree very well. The consistency of results using methods based on IWV and IVT

475

480

485

respectively implies that extreme IWV anomalies in the Arctic are due to water vapor transport by ARs from lower latitudes. In summary, consistency of ARs identified by 2 methods confirms that it is reasonable to use extreme moisture anomalies to approximate ARs in our study, but our method of detecting daily extreme moisture anomalies is simple and efficient for large datasets from ERA5. Additionally, our method of identifying extreme moisture anomalies is similar to moist-air intrusions defined in Papritz et al., 2022, except that we examine moisture evolution for each grid box accounting spatial variations while they consider zonal mean moisture transport (Papritz et al., 2022).

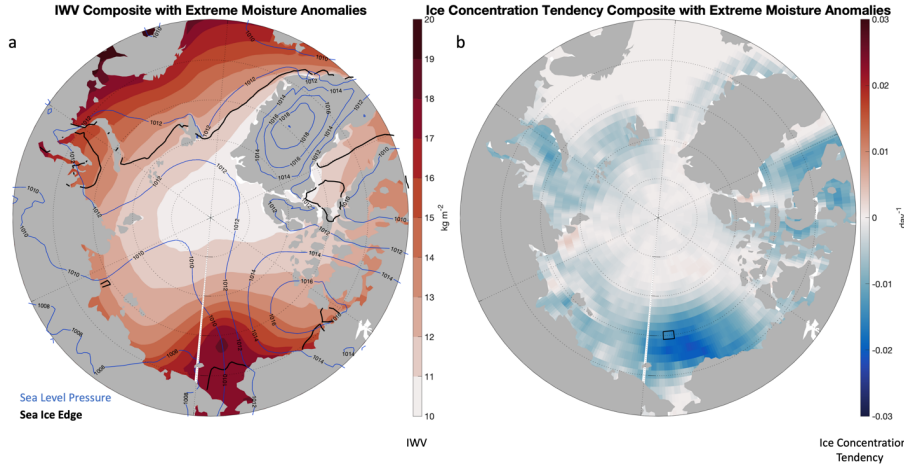
We further examine composite meteorological and sea ice conditions on dates with extreme IWV anomalies identified from 1981-2020 ERA5 data in the same study area. As shown in Figure 9a, a prominent feature of IWV is moisture intrusion onto sea ice cover over the Chukchi Sea. Simultaneously, a very strong northward wind pattern around the same region can transport water vapor from the Pacific to the Arctic (consistent with Baggett et al., 2016; Horvath et al., 2021). Correspondingly, substantial sea ice loss occurs over a broad area where moisture reaches sea ice (Figure 9b). Those extreme events mainly happen during the summer season when sea ice cover is partial. We also examine composites on dates with extreme IWV anomalies and ARs from AR catalog. The spatial patterns of IWV, sea level pressure and sea ice concentration tendency composites with ARs are consistent with composites with extreme moisture anomalies, but the magnitudes are stronger (Appendix Figure A3).


Figure 9: a Composites of IWV, sea ice edge (black lines), and sea level pressure (blue contours) b Composite of **sea** ice concentration tendency when extreme IWV anomalies (>90% percentile) during 1981-2020 occur over partial **sea** ice cover in the black box in the Chukchi Sea.

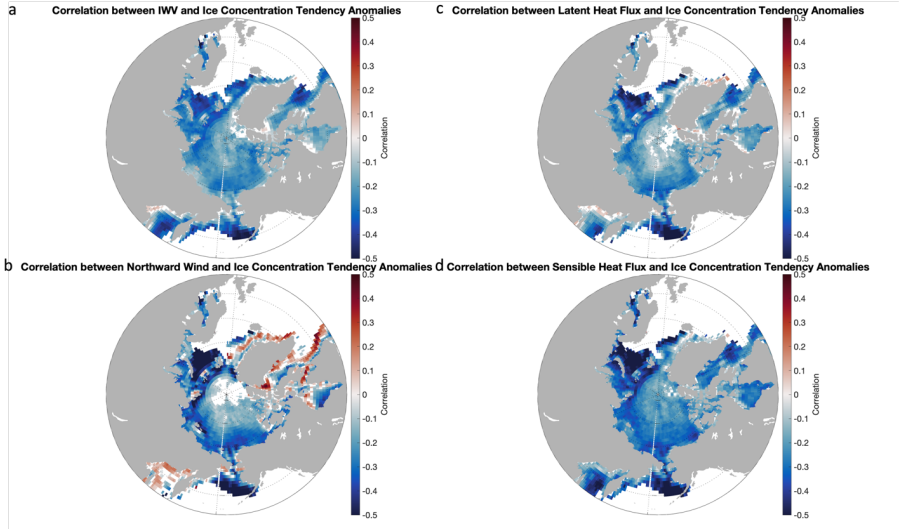
3.2.3 Statistical Analysis for 1981-2020 Everywhere in the Arctic Ocean

515

We further expand our analysis from one location in the Chukchi Sea to all grid boxes in the Arctic Ocean on the daily basis during 1981-2020. We find that anomalies of IWV and sea ice concentration tendency have significant anticorrelation almost everywhere when sea ice cover is partial (Figure 10). Correspondingly, latent and sensible heat flux anomalies anticorrelate with sea ice concentration tendency anomalies. Dynamically, northward wind

520 anomalies have negative correlation with sea ice tendency anomalies for the majority of the Arctic Ocean and have positive correlation with sea ice tendency anomalies near land margins, e.g., around Greenland. The synergy of thermodynamical and dynamical components of atmospheric forcing indicates the importance of horizontal advection of heat and water vapor from lower latitudes through ARs in causing rapid sea ice changes. Note that only time periods with partial sea ice cover with sea ice concentration between 15% and 85% are included in the analysis,

525 which are different at different locations. The marginal ice zone advances and retreats across different seasons. Thus, we consider different seasons for different regions. For instance, correlations are during the summer season in the central Arctic, while correlations are during the winter season in the southeast Bering Sea.


530 **Figure 10: a Rank correlation between anomalies of IWV and sea ice concentration tendency. Only significant correlations are plotted. b Rank correlation between anomalies of northward wind and sea ice concentration tendency. c Rank correlation between anomalies of latent heat flux and sea ice concentration tendency. d Rank correlation between anomalies of sensible heat flux and sea ice concentration tendency.**

535 Next, we examine mean anomalous conditions when extreme moisture anomalies occur for each grid box in the Arctic Ocean (Figure 11). We identify dates with extreme moisture anomalies specific for each grid box and calculate mean anomalies on those dates locally over that grid box. Note that extreme moisture anomalies are daily

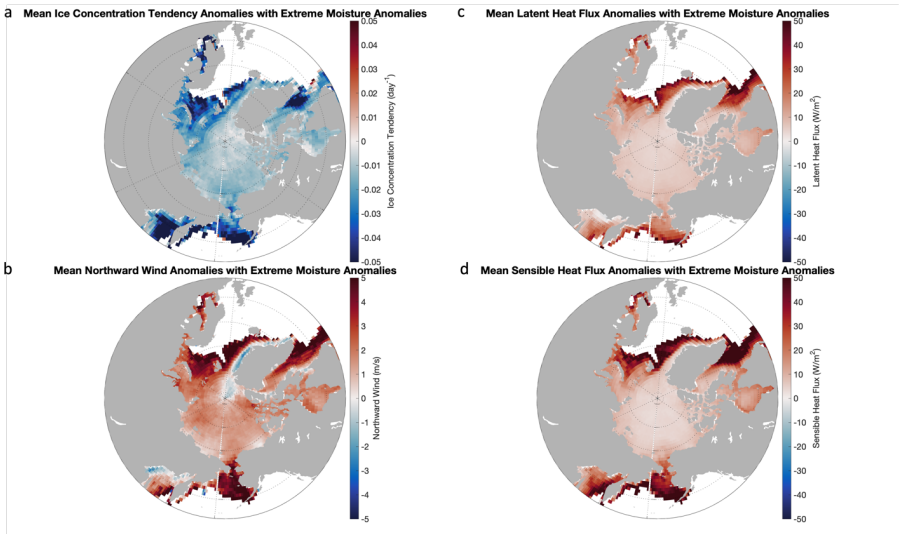
while AR events have varied duration, but mean anomalies with extreme moisture anomalies and AR events are the same. When extreme moisture anomalies (approximate AR events) happen over partial sea ice cover, mean sea ice concentration tendency anomalies are negative almost everywhere in the Arctic Ocean. Correspondingly, mean latent and sensible heat flux anomalies are positive, and mean northward wind anomalies are positive (except certain locations near land margins). It is noted that the strength of mean extreme moisture anomalies is similar over the entire Arctic Ocean (Appendix Figure A4). However, sea ice response shows large spatial variations: magnitudes of sea ice concentration tendency anomalies are much larger in subarctic seas (e.g., the Bering Sea) than in the central Arctic, indicating that partial sea ice cover in subarctic seas is more sensitive to moisture forcing than in the central Arctic.


Figure 11: a Mean sea ice concentration tendency anomalies with extreme moisture anomalies. b Mean northward wind anomalies with extreme moisture anomalies. c Mean latent heat flux anomalies with extreme moisture anomalies. d Mean sensible heat flux anomalies with extreme moisture anomalies.

4 Discussion and Conclusion

Poleward moisture transport from lower latitudes through ARs has large impacts on Arctic sea ice variations. ARs bring moist and warm air and strong winds into the Arctic. When ARs reach regions covered by sea ice they can trigger rapid and substantial sea ice loss on weather timescales. Sensible and latent heat fluxes are the dominant terms in surface energy budget associated with ARs. These fluxes are enhanced by warm and moist air and strong winds associated with ARs. Due to clouds and precipitation associated with ARs and large atmospheric water vapor

content, net longwave radiation is enhanced moderately, and net shortwave radiation is reduced. Additionally, sea ice motion driven by strong near-surface winds under ARs further reduces sea ice concentration near sea ice margins. Note that the relationship between ARs and sea ice change is similar and even stronger in winter (not shown here), though the case studies shown in this paper are in summer.

An analysis over the entire Arctic Ocean shows sea ice concentration tendency has significant anticorrelation with IWV, northward wind, and turbulent heat flux anomalously almost everywhere. This occurs year-round. The coherence over the entire Arctic Ocean of anticorrelation between anomalous moisture/winds and sea ice variations on weather timescales provides important implications for Arctic sea ice prediction. The documented anomalies and statistical relationships found in this work helps explain the physics governing the observed sea ice variability associated with ARs. In particular, ARs are characterized by a low level jet and this study demonstrates the important role that associated with winds play in driving sea ice motion and thus sea ice variability.

Our conclusions are in general consistent with the dominant role of atmospheric temperature in driving sea ice change mainly through advection at low levels (Li et al., 2014 a b; Olonscheck et al., 2019), though over different time scales. Our study shows that near-surface atmospheric temperature and moisture induced sensible and latent heat fluxes from ARs to sea ice are most important terms in surface energy budget on weather timescales (Olonscheck et al., 2019). ARs large impact on sea ice variations on weather timescales also suggests that ARs provides one mechanism of bottom amplified warming with important implications for Arctic amplification (e.g., Woods and Caballero, 2016).

Though we have added novel analysis regarding the interaction between ARs and sea ice, there is still much to do. Our future work will examine the relative contribution of water vapor/heat transport and local warming/moistening in sea ice decline in the Arctic. In addition, the role of the ocean and ocean feedbacks should be examined, possibly using coupled atmosphere-ocean- sea ice models. Remote sensing is challenging in the presence of ARs, but nevertheless future work could also aim to incorporate satellite inferred sea ice velocity into the type of analysis presented here. Moreover, while we have shown that individual AR events can have large impacts on the Arctic sea ice variations in the short term, the integrated effect of ARs including frequency and strength on the Arctic sea ice budget deserves further study. It is important to understand the extent to which the Arctic sea ice decline can be attributed to AR activity, possibly using climate models.

Acknowledgements

We appreciate ECMWF for providing ERA5 atmospheric reanalysis data. We also thank editor and reviewers for their contributions for improving this work. Funding of this study is provided by Center for Western Weather and Water Extremes, Scripps Institution of Oceanography, University of California, San Diego, US.
