**Abstract.** Arctic sea ice has been declining rapidly in recent decades. We investigate how poleward transport of  
moisture and heat from lower latitudes through atmospheric rivers (ARs) influences Arctic sea ice variations. We  
use ERA5 hourly reanalysis data for 1981-2020 at 0.25° x 0.25° resolution to examine meteorological conditions and  
sea ice changes associated with ARs in the Arctic. In years 2012 and 2020, which had extremely low summer Arctic  
15 sea ice extent, we show that individual AR events associated with large cyclones initiate rapid sea ice decrease  
through turbulent heat fluxes, longwave radiation, and winds. We further carry out statistical analysis of  
meteorological conditions and sea ice variations for 1981-2020 over the entire Arctic Ocean. We find that, on  
weather timescales, atmospheric moisture content anticorrelates significantly with sea ice concentration tendency  
almost everywhere in the Arctic Ocean, while dynamic sea ice motion driven by northward winds further reduces  
20 sea ice concentration.

20

### 1 Introduction

25 Atmospheric rivers (ARs) are long, narrow, and transient corridors of strong horizontal water vapor transport as  
defined in the Glossary of Meteorology (American Meteorological Society, 2017). ARs are an important form of  
extreme horizontal water vapor transport on weather and synoptic scales. ARs account for 90% poleward water  
vapor transport at midlatitudes (Zhu and Newell, 1998). Poleward water vapor transport by ARs plays a critical role  
in atmospheric moisture content and precipitation variations at high latitudes (e.g., Nash et al, 2018).

30 The Arctic has experienced rapid sea ice decrease especially in summer in recent decades. This decrease has been  
quantified using satellite observations since 1979, with the record low summer sea ice minimum occurring in 2012  
(Parkinson and Comiso, 2013). Rapid Arctic sea ice loss leads to global climate change and weather extremes, such  
as increasing occurrence of ARs near the North American west coast (Ma et al., 2021). The imminence of the  
seasonal ice-free Arctic Ocean in the coming few decades (Peng et al., 2020; Notz et al., 2020; Guarino et al., 2020)  
35 has important implications for marine ecosystems, shipping, resources, and conservation.

Previous studies show that moisture intrusions into the Arctic influence the surface energy budget by strengthening  
downward longwave radiation and sensible heat flux, especially in winter (Doyle et al., 2011; Woods and Caballero,  
2016; Johansson et al, 2017; Woods et al., 2017; Hegyi et al., 2018; Ali and Pithan, 2020; Wang et al., 2020; Fearon

40 et al., 2020). However, the direct impact of ARs on Arctic sea ice variations still needs better understanding (Hegyi  
et al., 2018; Wang et al., 2020).

ARs transport moisture and heat from lower latitudes into the Arctic with considerable potential to drive sea ice  
reduction (e.g., Baggett et al., 2016; Hegyi et al., 2018; Vázquez et al., 2018; Wang et al., 2020; Papritz et al., 2022).  
45 As low-level jets associated with ARs come in close contact with sea ice surface near ice margins, they can have  
direct impacts on sea ice through intense surface energy/momentum/mass exchange between atmosphere and  
ice/ocean (Hegyi et al., 2018; Wang et al., 2020). Furthermore, the warm and moist air masses brought by ARs are  
forced upward by cold air to form precipitation and clouds with associated latent heat release into the upper air (e.g.,  
Komatsu et al., 2018). This study investigates the relative contribution of surface heat flux components and the  
50 relative importance of thermodynamic and dynamic processes in sea ice changes when ARs happen in the Arctic.

The goal of this study is to explore how ARs influence Arctic sea ice variations. We examine sea ice changes in  
relation to AR forcing by thermodynamic surface heat fluxes and dynamic winds. First, we show 2 case studies to  
examine physical processes through spatial pattern and time series analysis. Second, we carry out statistical analysis  
55 for 1981-2020 over the entire Arctic Ocean.

## 2 Data and Methods

ERA5, the fifth-generation European Re-Analysis, is the most recent atmospheric reanalysis from ECMWF, with  
60 data assimilation system IFS Cycle Cy41r2 with 4D-Var (Hersbach et al., 2020). ERA5 uses boundary conditions of  
sea ice concentration and sea surface temperature based on satellite observations (HADISST2 before 1979, OSI SAF  
(409a) for 1979-Aug 2007, OSI SAF operational from Sep 2007). ERA5 has high temporal (hourly) and spatial  
(~31km horizontally, 137 model levels vertically) resolutions suitable for studying extreme weather events such as  
ARs. Its long and consistent records are also appropriate for studying climate change and variability.

65 ERA5 atmospheric reanalysis over Arctic sea ice has been evaluated with in-situ observations (Graham et al., 2019;  
Batrak et al., 2019; Renfrew et al., 2020). ERA5 accurately represents integrated water vapor (IWV) and downward  
longwave radiation, and correlations between ERA5 and in-situ observations are high for meteorological variables  
such as IWV, 2-m temperature, 10-m wind speed, and sea level pressure (Graham et al., 2019). Noticeably, ERA5  
70 improves estimate of Arctic energy budget in terms of closure (Mayer et al., 2019). However, ERA5 has a warm  
bias near Arctic sea ice surface, which is large in winter and small in summer (Graham et al., 2019; Batrak et al.,  
2019).

We use ERA5 hourly reanalysis data for 1981-2020 at 0.25° x 0.25° resolution in the Arctic. First of all, we study 2  
75 AR events associated with cyclones during summertime of 2012 and 2020, which are periods of record low Arctic  
sea ice extent. We examine spatial patterns and time series of meteorological conditions, surface energy budget, and

sea ice variations related to the AR events. Furthermore, for each grid box of the entire Arctic Ocean, we investigate the statistical relationship between anomalous meteorological conditions and sea ice variations on weather timescales during 1981-2020. We extract high frequency variations on weather timescales and to identify extreme  
80 moisture anomalies as approximate ARs which are validated by Guan and Waliser's AR catalog version 3 from 6-hourly  $0.625^\circ \times 0.5^\circ$  Modern-Era Retrospective Analysis for Research and Applications, Version 2 (MERRA-2) reanalysis data for 1980-2020 (Guan and Waliser, 2019).

### 3 Results

85

#### 3.1 Two Case Studies in 2012 and 2020

Atmospheric rivers transport moisture and heat from lower latitudes into the Arctic at low levels on weather timescales. Those episodic extreme events of water vapor transport can have a large impact on Arctic sea ice  
90 variations with important implications for short-term sea ice prediction. Here we show 2 examples of AR events occurring in the summertime of 2012 and 2020 in the western Arctic Ocean associated with rapid sea ice changes through turbulent heat fluxes, longwave radiation, and winds. These case studies of AR events reveal important physical processes and give context to the statistical analysis shown later.

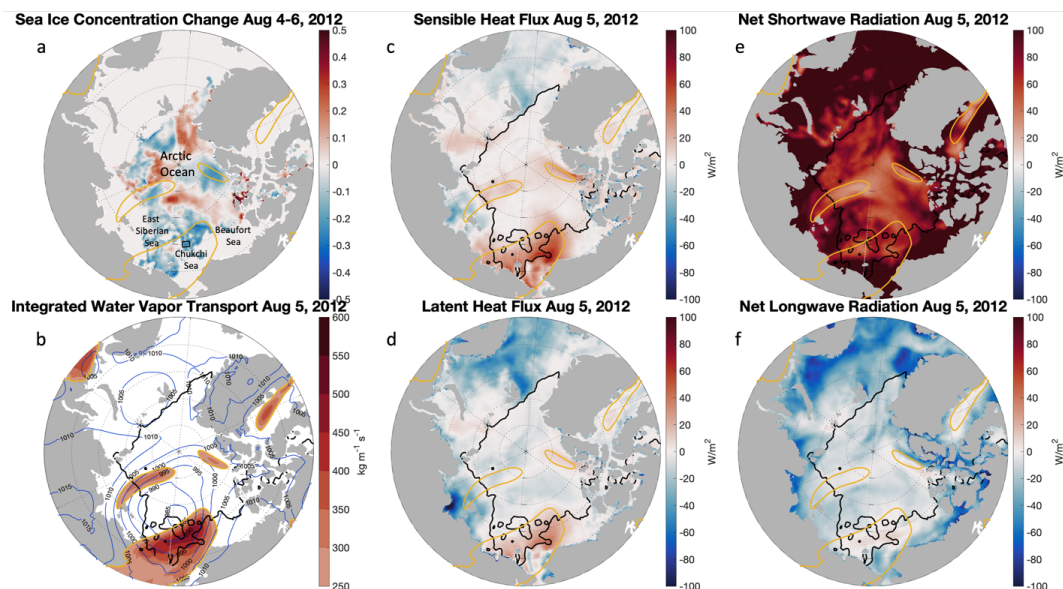

##### 95 3.1.1 The Atmospheric River Event of August 2012

In September 2012 the Arctic sea ice extent reached the lowest ever observed since satellite observations started in 1979 (Parkinson and Comiso, 2013). Before that, an Arctic cyclone with the lowest central pressure (966 hPa) recorded in August since 1979 occurred on August 5-12, 2012 (Simmonds and Rudeva, 2012). On August 5, 2012,  
100 when the cyclone first reached the Arctic Ocean, an associated AR entered the western Arctic Ocean.

Sea ice concentration decreases substantially in the Chukchi Sea and the East Siberian Sea between Aug 4-6, 2012 (Figure 1a). The AR enters the western Arctic from Siberia on Aug 4, 2012, reaches its highest intensity on Aug 5, 2012, with integrated water vapor transport (IVT) values exceeding  $250 \text{ kg m}^{-1} \text{ s}^{-1}$  (maximum in the core around 500  
105  $\text{kg m}^{-1} \text{ s}^{-1}$ ), and is still present in the Arctic Ocean on Aug 6, 2012 (exceeding  $250 \text{ kg m}^{-1} \text{ s}^{-1}$ ) (Figure 1b). Concurrently, strong northeastward surface winds (inferred from sea level pressure) beneath the AR core push sea ice away from the ice edge towards the pole. Coincident with the AR in space and time, strong downward sensible and latent heat flux happens around the ice edge, due to warm and moist air and high wind speed at low levels within the AR (Figure 1cd). Net longwave radiation near the ice edge is also downward, but the magnitude is much  
110 weaker than turbulent heat fluxes (Figure 1f). In contrast, net shortwave radiation is reduced over sea ice cover (Figure 1e). The radiation patterns, reduced net shortwave radiation and enhanced net longwave radiation, are consistent with clouds and precipitation that formed when the AR arrived (not shown). This major AR event gives evidence that turbulent heat fluxes can be the dominant terms in surface energy budget. In contrast, most former

115 studies emphasize dominant downwelling longwave radiation related to clouds, though some studies reveal important role of surface sensible heat flux (e.g., Stern et al., 2020).

120 **Figure 1 a** Sea ice concentration change during Aug 4-6, 2012. Extent of atmospheric rivers ( $250 \text{ kg m}^{-1} \text{ s}^{-1}$  contour of integrated water vapor transport) on Aug 5, 2012 is represented as yellow lines (same in b c d e f). **b** Magnitude of integrated water vapor transport on Aug 5, 2012. Sea ice edge (15% contour of sea ice concentration) on Aug 5, 2012 is represented as black lines (same in c d e f). Sea level pressure on Aug 5, 2012 is represented as blue contours. **c** Sensible heat flux (positive downward) on Aug 5, 2012. **d** Latent heat flux (positive downward) on Aug 5, 2012. **e** Net shortwave radiation (positive downward) on Aug 5, 2012. **f** Net longwave radiation (positive downward) on Aug 5, 2012.

125 We also examine time integrated surface heat fluxes, time integrated IVT, and sea ice concentration change during the life cycle of the cyclone to study the effect of this cyclone on sea ice (Appendix Fig.1). During Aug 5-12, 2012, sea ice cover is reduced substantially over broad areas of the Chukchi Sea and the East Siberian Sea, corresponding with strong time integrated IVT there (maximum around  $1.5 \text{ kg m}^{-1}$  over 7 days). Strong sensible heating, weak latent heating, weak net longwave radiation cooling, and weak net shortwave radiation heating are seen there. The effect of this cyclone on sea ice during its life cycle is extensive sea ice decrease in the western Arctic Ocean, corresponding to strong IVT, atmospheric warming (enhanced sensible/latent heat fluxes and longwave radiation) and sea ice motion driven by winds. Here we only consider local atmospheric forcing of sea ice changes during the cyclone, though other processes such as ocean-ice heat flux are also important in sea ice melt during the cyclone (Zhang et al., 2013; Stern et al., 2020; Finocchio et al., 2020; Lukovich et al, 2021).

135

We examine hourly time series of surface heat fluxes and meteorological conditions and daily time series of sea ice concentration and sea surface temperature for Aug 1-15, 2012 averaged over the black box as shown in Figure 1a

(Figure 2). The location of the black box is chosen due to its proximity to the summer ice edge in the western Arctic Ocean. This study area was partially covered by sea ice before the cyclone and became ice free after the cyclone.

140 Sea ice concentration and sea surface temperature from ERA5 are daily based on satellite observations, while other variables from ERA5 are hourly in Figure 2. The time series shows that sea ice concentration drops abruptly around Aug 5, 2012 when the AR arrives (Figure 2a). Correspondingly, large downward sensible and latent heat fluxes and moderate downward net longwave radiation into ice/ocean occurs within one day, peaking at midnight with nearly zero net shortwave radiation on Aug 5, 2012 (Figure 2b). The dominant latent and sensible heat fluxes are related to

145 the high moisture and heat content associated with the AR, while high wind speed further enhances turbulent heat fluxes. This AR event on Aug 5, 2012 over the black box is categorized as an AR2 (Ralph et al., 2019) with maximum IVT magnitude  $867 \text{ kg m}^{-1} \text{ s}^{-1}$  and duration of 18 hours ( $\text{IVT} > 250 \text{ kg m}^{-1} \text{ s}^{-1}$ ) (not shown). We further partition IVT into moisture and wind components. The specific humidity at 850 hPa shows a prominent peak on Aug 5, 2012 (Figure 2c). The 850 hPa wind speed is the strongest at the same time as the largest specific humidity on

150 Aug 5 and continues to be strong for the next 3 days (Figure 2c). Wind direction is northward on Aug 5, 2012, and then turns eastward on Aug 6-10, 2012 (not shown). Near surface conditions in humidity and wind are also examined and show similar results (not shown). In summary, moisture and wind are both important in contributing to the strong IVT, and subsequent intense downward turbulent heat fluxes/longwave radiation and rapid sea ice decrease when the AR arrives on Aug 5, 2012.

155

**Figure 2 a** Sea ice concentration (blue) and sea surface temperature (red) daily during Aug 1-15, 2012 averaged over the black box in Figure 1 a. **b** Latent heat flux (red), sensible heat flux (yellow), net shortwave radiation (purple), net longwave radiation (green), and net surface heat flux (blue) hourly during Aug 1-15, 2012 averaged over the black box in

160 **Figure 1 a. c Wind speed (blue) and specific humidity (red) at 850 hPa hourly during Aug 1-15, 2012 averaged over the black box in Figure 1 a.**

Sea surface temperature at this location decreases slightly after the AR during the first half of the cyclone and increases substantially near the end of the cyclone (Figure 2a). The spatial pattern of sea surface temperature change  
165 during the life cycle of the cyclone reveals significant ocean warming in newly formed open ocean which was covered by sea ice before the cyclone (Appendix Fig.2). This ocean surface warming is related to strong air-sea interaction during the cyclone with shortwave radiation as the dominant term in surface heat fluxes. Wind induced ocean mixing could also bring subsurface warm water upward during the cyclone (Zhang et al., 2013; Stern et al., 2020).

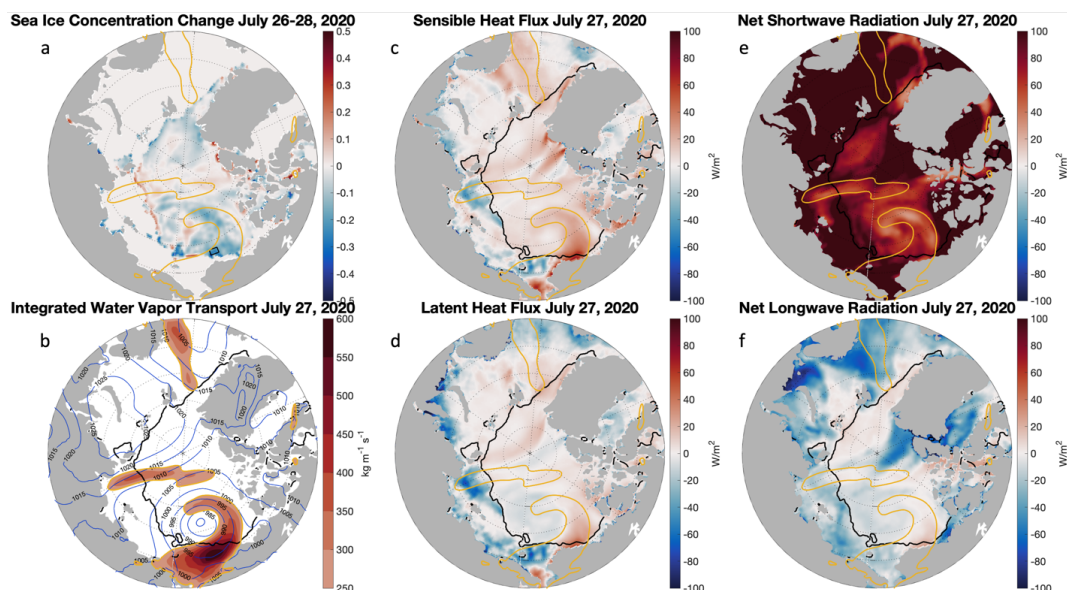

170

### 3.1.2 The Atmospheric River Event of July 2020

We study another extreme event in summer of 2020. 2020 experienced the second lowest summer sea ice extent and the lowest sea ice extent during spring, early summer and fall in the Arctic (NSIDC sea ice index). The summer  
175 2020 sea ice deficit occurred largely in the western Arctic Ocean (not shown). The reasons causing the record low Arctic sea ice in 2020 involve several processes across different temporal and spatial scales. The Siberian heat wave occurred during Jan-June 2020 (Overland and Wang, 2020) before the extremely low summer sea ice extent in the East Siberian Sea. The record low Arctic sea ice extent in July, 2020 has also been attributed to heat and moisture transport during April-June, 2020 (Liang et al., 2021). Here we show an example of the contribution of episodic  
180 strong water vapor transport by ARs to rapid sea ice changes during summer of 2020.

In the western Arctic Ocean, a large cyclone occurred during July 25 - Aug 2, 2020, reaching lowest central pressure (968 hPa) on July 28, 2020. Strong advection of heat and moisture (with large gradient of temperature and moisture) from Siberia to the Arctic Ocean occurred on July 26, 2020 (not shown). An AR event with maximum IVT around  
185  $600 \text{ kg m}^{-1} \text{ s}^{-1}$  in the core and strong northward winds happened near the ice edge on July 27, 2020 (Figure 3b). Corresponding to the AR timing and location over sea ice, strong sensible/latent heat fluxes and net longwave radiation are directed from the atmosphere into the ice/ocean, and net shortwave radiation is reduced by clouds (Figure 3cdef). Meanwhile, strong northeastward winds reduce sea ice concentration near the ice edge (Figure 3ab). The wind direction is southerly before the AR and becomes westerly after the AR (not shown). This suggests wind-driven meridional water vapor transport at the early stage of the cyclone life cycle and intensified IVT as the AR  
190 propagates eastward along the coast later.

195 **Figure 3 a** Sea ice concentration change during July 26-28, 2020. Extent of atmospheric rivers ( $250 \text{ kg m}^{-1} \text{ s}^{-1}$  contour of integrated water vapor transport) on July 27, 2020 is represented as yellow lines (same in b c d e f). **b** Magnitude of integrated water vapor transport on July 27, 2020. Sea ice edge (15% contour of sea ice concentration) on July 27, 2020 is represented as black lines (same in c d e f). Sea level pressure on July 27, 2020 is represented as blue contours. **c** Sensible heat flux (positive downward) on July 27, 2020. **d** Latent heat flux (positive downward) on July 27, 2020. **e** Net shortwave radiation (positive downward) on July 27, 2020. **f** Net longwave radiation (positive downward) on July 27, 2020.

200

Next, we examine time series of sea ice concentration, sea surface temperature, surface heat fluxes and AR conditions during the life cycle of the cyclone averaged over the black box as shown in Figure 3a (Figure 4). We choose this study area in the Beaufort Sea because it experiences the most significant sea ice reduction during the life cycle of the cyclone (July 25-Aug 2, 2020). At this location, sea ice concentration decreases gradually from 72%  
205 to 19% in one week throughout the cyclone, while the most rapid sea ice decrease happens immediately after the AR. Sea surface temperature increases immediately after the AR and persistently during the cyclone, indicating increasing ocean-ice heat flux for bottom and lateral sea ice melt. Culminating downward turbulent heat fluxes and weak downward net longwave radiation occur on early July 27, 2020 when the AR arrives. For this AR event, moisture content is more important than wind speed in strong downward surface heat fluxes and rapid sea ice  
210 decrease. This AR event is categorized as AR 1 Scale (Ralph et al., 2019) with maximum IVT magnitude  $502 \text{ kg m}^{-1} \text{ s}^{-1}$  and duration of 16 hours ( $\text{IVT} > 250 \text{ kg m}^{-1} \text{ s}^{-1}$ ) (not shown).

215 **Figure 4 a** Sea ice concentration (blue) and sea surface temperature (red) hourly during July 22-Aug 5, 2020 averaged  
over the black box in Figure 3 a. **b** Latent heat flux (red), sensible heat flux (yellow), net shortwave radiation (purple), net  
longwave radiation (green), and net surface heat flux (blue) hourly during July 22-Aug 5, 2020 averaged over the black  
box in Figure 3 a. **c** Wind speed (blue) and specific humidity (red) at 850 hPa hourly during July 22-Aug 5, 2020 averaged  
over the black box in Figure 3 a.

220 Another extreme event with the 3<sup>rd</sup> lowest summer Arctic sea ice minimum in 2007 has also been attributed to  
atmospheric heat and moisture transport from the Pacific with enhanced downwelling longwave radiation and  
turbulent fluxes (Graversen et al., 2011).

225 In summary, for the years 2012 and 2020, which experienced record low summer sea ice extent in the Arctic Ocean  
since 1979, AR related atmospheric water vapor transport from lower latitudes triggered rapid sea ice melt in the  
western Arctic Ocean through turbulent heat fluxes and longwave radiation. Our results of surface energy budget of  
sea ice are generally consistent with in situ observations (Tjernström et al., 2015; Tjernström et al., 2019) and  
coupled atmosphere/ocean/ice models (Stern et al., 2020). Our future work will examine the relative contribution of  
water vapor and heat transport and local warming/moistening in sea ice decline in the Arctic.

230

### 3.2 Statistical Analysis of Meteorological and Sea Ice Variations for 1981-2020

While the case studies in the previous section reveal linkages between AR-related atmospheric forcing and rapid sea  
ice changes, here we extend to a more general study for 40 years over the entire Arctic Ocean. We carry out  
235 statistical analyses to examine the relationships between meteorological conditions and sea ice changes in the Arctic

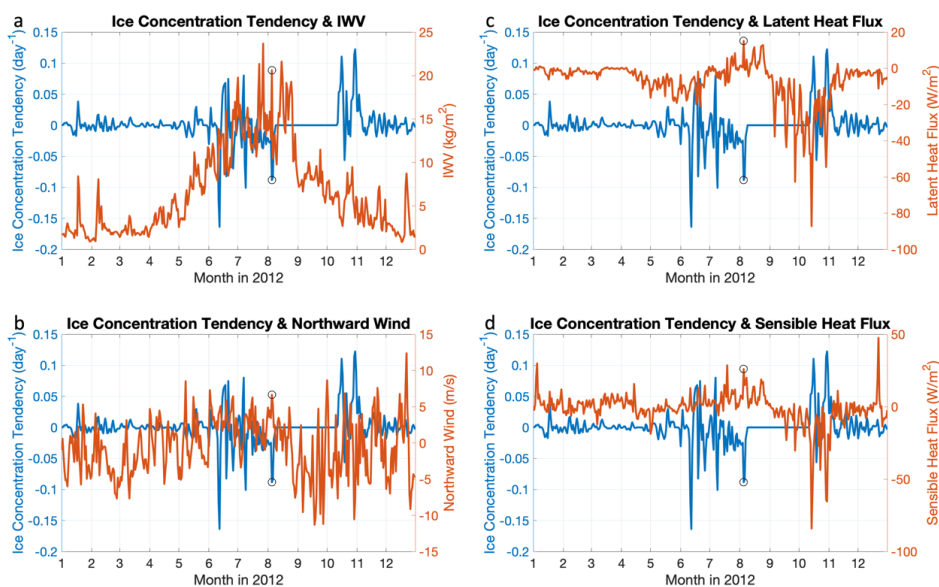

Ocean using ERA5 reanalysis for 1981-2020. We consider IWV, surface latent and sensible heat fluxes as thermodynamic variables, near-surface northward wind as a dynamic variable, and ice concentration tendency on the daily basis. Because ERA5 has good performance of IWV (Graham et al., 2019) and ice concentration is daily based on satellite observations, it is reasonable to examine the relationship between IWV and ice concentration tendency on the daily basis to study how ARs influence sea ice changes. We find that ice concentration tendency has significant anticorrelation with IWV, northward wind, and turbulent heat flux on weather timescales almost everywhere in the Arctic Ocean.

240

### 3.2.1 Seasonal Variations in 2012 at One Location in the Chukchi Sea

To put the AR event on Aug 5, 2012 in the context of longer time scales, we first extend the time series to the full calendar year 2012 for the same study area shown as the black box in Figure 1a. We examine 2012 daily IWV, ice concentration tendency, latent heat flux, sensible heat flux, and northward wind averaged over that study area (Figure 5). Because satellite observed ice concentration is available at daily resolution, we consider daily mean IWV, latent/sensible heat fluxes, and northward wind. The conditions of the extreme event on Aug 5, 2012 are marked with black circles (Figure 5). For this extreme event, substantial sea ice concentration decrease corresponds to large atmospheric moisture content, strong latent and sensible heating from the atmosphere, and high northward wind. Note that those variables show dominant seasonal cycles and high frequency fluctuations imposing on seasonal cycles. Those high frequency variations on weather timescales are the focus of this study.

255

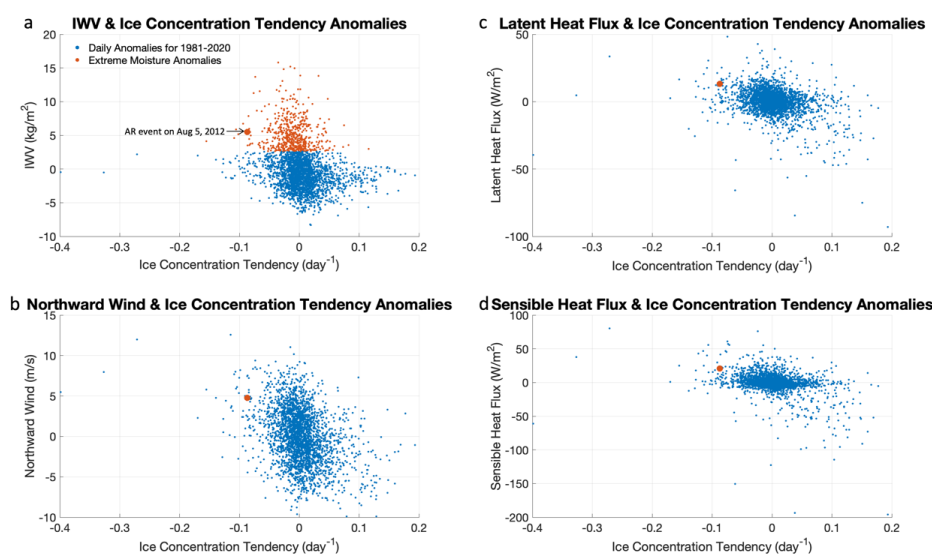

260 **Figure 5 a Variations in ice concentration tendency and IWV in 2012. b Variations in ice concentration tendency and northward wind in 2012. c Variations in ice concentration tendency and latent heat flux in 2012. d Variations in ice concentration tendency and sensible heat flux in 2012. All variables are averaged over the black box in Figure 1 a. The AR event on Aug 5, 2012 is marked with black circles.**

### 3.2.2 Statistical Analysis for 1981-2020 at One Location in the Chukchi Sea

265 We expand our time series analysis to 40 years for 1981-2020. We focus on variations on weather timescales in this study. We use a high pass filter with period  $<30$  days to remove time-varying seasonal cycles from daily time series for 1981-2020. We define those high frequency variations ( $<30$  days) as anomalies. We only consider time periods when ice cover is partial (ice concentration between 15% and 85%). The reason for this choice is that ice concentration can only change substantially in response to atmospheric forcing when ice concentration is partial.

270 We find significant rank correlation between anomalies of ice concentration tendency and IWV, northward wind, latent heat flux, and sensible heat flux for 1981-2020 (Figure 6). Rank correlation between ice concentration tendency and IWV anomalies is  $-0.30$ , and it is  $-0.28$  for latent heat flux,  $-0.30$  for sensible heat flux, and  $-0.34$  for northward wind, all with  $p$ -values  $<0.01$ . The negative correlations are moderate, but significant due to the large sample size (14610). The big red dot in Figure 6a represents the AR event on Aug 5, 2012, which stands out as an  
275 extreme event during 1981-2020.

280 **Figure 6 Scatter plots at one location in the Chukchi Sea (black box in Figure 1 a) from daily time series for 1981-2020 when ice cover is partial. a Scatter plot of anomalies of IWV and ice concentration tendency (blue dots), with small red**

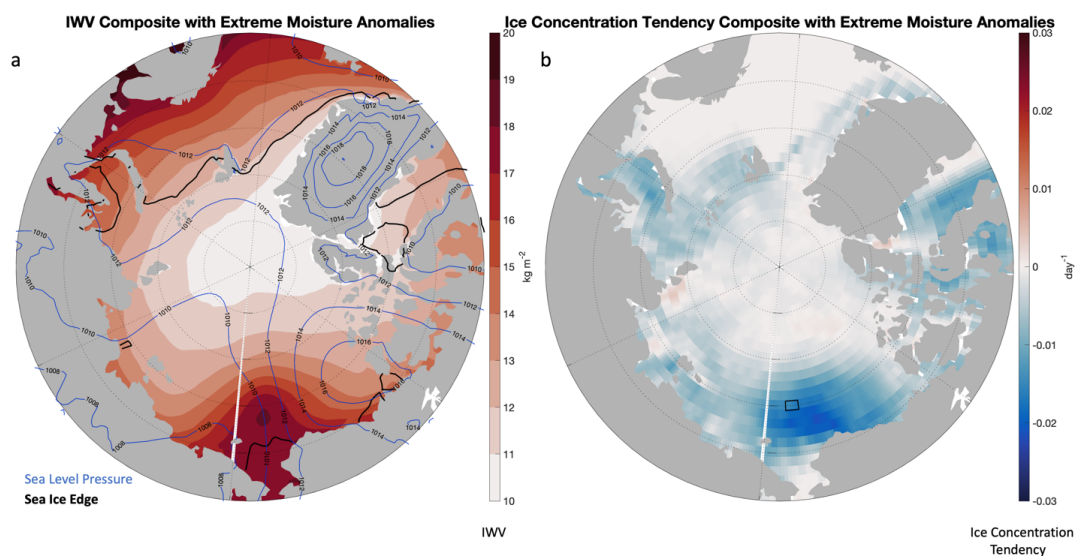

**dots representing extreme IWV anomalies exceeding 90% percentile. b Scatter plot of anomalies of northward wind and ice concentration tendency c Scatter plot of anomalies of latent heat flux and ice concentration tendency d Scatter plot of anomalies of sensible heat flux and ice concentration tendency. Big red dots in abcd represent the AR event on Aug 5, 2012.**

285

Next, we identify all extreme moisture anomalies from ERA5 during 1981-2020 in this study area as approximate AR events and validate them with a global AR catalog. We define extreme moisture anomalies as IWV anomalies exceeding the 90% percentile based on the daily time series during 1981-2020. We only consider extreme events over partially covered sea ice in this study. For this study area, we identify 553 extreme moisture anomalies when  
290 sea ice cover is partial during 1981-2020. The mean IWV anomalies of those extreme events is  $5.21 \text{ kg/m}^2$ , and the mean ice concentration tendency anomalies of those extreme events is  $-1\% \text{ day}^{-1}$ . In Figure 6a, small red dots represent extreme moisture anomalies using ERA5 data, while the big red dot represents the AR event on Aug 5, 2012 (Figure 1 and Figure 2). We validate extreme moisture anomalies identified by our method with ARs identified by Guan and Waliser's AR catalog version 3 (Guan and Waliser, 2019). Among extreme moisture anomalies  
295 exceeding 90% percentile over partial sea ice cover, 72% have a corresponding AR identified from the catalog around the same date ( $\pm 12\text{h}$ ) at the same location. For 2012, this ratio is 91%. For large extreme events, these two methods agree very well. The consistency of results using methods based on IWV and IVT respectively implies that extreme IWV anomalies in the Arctic are due to water vapor transport by ARs from lower latitudes. In summary, good agreement of ARs identified by 2 methods indicates that it is reasonable to use extreme moisture anomalies to  
300 approximate ARs in our study.

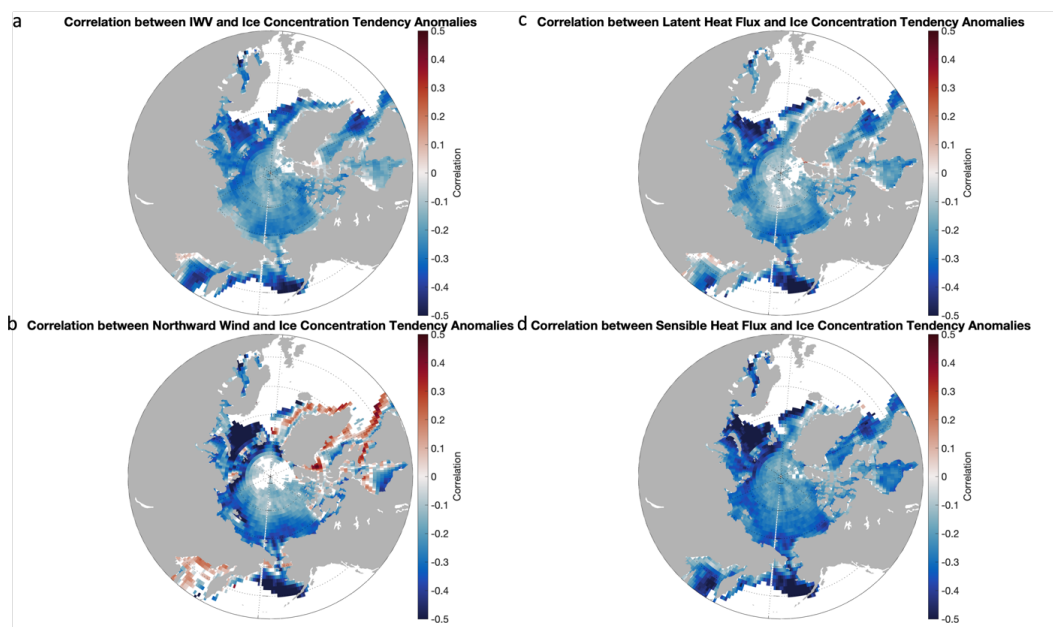

We further examine composite meteorological and ice conditions on dates with extreme IWV anomalies identified from 1981-2020 ERA5 data in the same study area. As shown in Figure 7a, a prominent feature of IWV is moisture intrusion onto sea ice cover over the Chukchi Sea. Simultaneously, a very strong northward wind pattern around the  
305 same region can transport water vapor from the Pacific to the Arctic (consistent with Baggett et al., 2016; Horvath et al., 2021). Correspondingly, substantial sea ice loss occurs over a broad area where moisture reaches sea ice (Figure 7b). Those extreme events mainly happen during the summer season when sea ice cover is partial. We also examine composites on dates with extreme IWV anomalies and ARs from AR catalog. The spatial patterns of IWV, sea level pressure and ice concentration tendency composites with ARs are consistent with composites with extreme moisture  
310 anomalies, but the magnitudes are stronger (Appendix Fig.3).

315 **Figure 7 a Composites of IWV, sea ice edge (black lines), and sea level pressure (blue contours) b Composite of ice concentration tendency when extreme IWV anomalies (>90% percentile) during 1981-2020 occur over partial ice cover in the black box in the Chukchi Sea.**

### 3.2.3 Statistical Analysis for 1981-2020 Everywhere in the Arctic Ocean

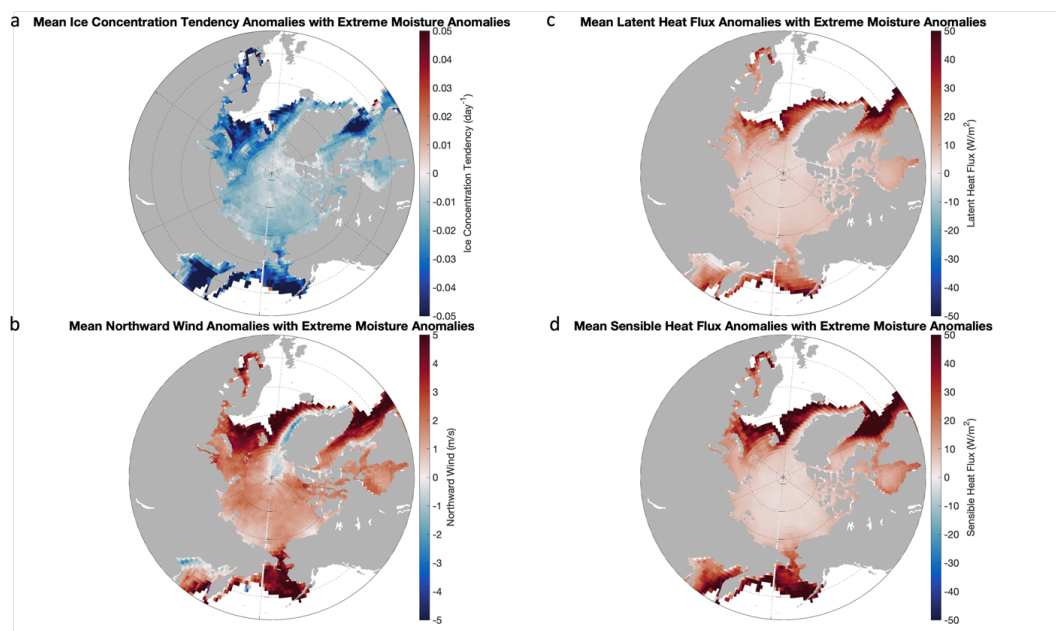

320 We further expand our analysis from one location in the Chukchi Sea to each grid box in the Arctic Ocean on the daily basis during 1981-2020. We find that anomalies of IWV and ice concentration tendency have significant anticorrelation almost everywhere when sea ice cover is partial (Figure 8). Correspondingly, latent and sensible heat flux anomalies anticorrelate with ice concentration tendency anomalies. Dynamically, northward wind anomalies have negative correlation with ice tendency anomalies for the majority of the Arctic Ocean and have positive correlation with ice tendency anomalies near land margins, e.g., around Greenland. The synergy of thermodynamical and dynamical components of atmospheric forcing indicates the importance of horizontal advection of heat and water vapor from lower latitudes through ARs in causing rapid sea ice changes. Note that only time periods with partial sea ice cover with ice concentration between 15% and 85% are included in the analysis, which are different at different locations. The marginal ice zone advances and retreats across different seasons. Thus, we consider different seasons for different regions. For instance, correlations are during the summer season in the central Arctic, while  
330 correlations are during the winter season in the southeast Bering Sea.

335 **Figure 8 a Rank correlation between anomalies of IWV and ice concentration tendency. Only significant correlations are plotted. b Rank correlation between anomalies of northward wind and ice concentration tendency. c Rank correlation between anomalies of latent heat flux and ice concentration tendency. d Rank correlation between anomalies of sensible heat flux and ice concentration tendency.**

Next, we examine mean anomalous conditions when extreme moisture anomalies occur for each grid box in the Arctic Ocean (Figure 9). We identify dates with extreme moisture anomalies specific for each grid box and calculate mean anomalies on those dates locally over that grid box. When extreme moisture anomalies (approximate AR events) happen over partial sea ice cover, mean ice concentration tendency anomalies are negative almost everywhere in the Arctic Ocean. Correspondingly, mean latent and sensible heat flux anomalies are positive, and mean northward wind anomalies are positive (except certain locations near land margins). It is interesting that the strength of mean extreme moisture anomalies is similar over the entire Arctic Ocean (Appendix Fig.4). However, sea ice response shows large spatial variations: magnitudes of ice concentration tendency anomalies are much larger in subarctic seas (e.g., the Bering Sea) than in the central Arctic, indicating that partial sea ice cover in subarctic seas is more sensitive to moisture forcing than in the central Arctic.

#### 355 4 Conclusions

Poleward moisture transport from lower latitudes through ARs has large impacts on Arctic sea ice variations. ARs bring moist and warm air and strong winds into the Arctic, triggering rapid sea ice loss. From the surface energy budget perspective, sensible and latent heat fluxes are enhanced by warm and moist air and strong winds associated with ARs. Due to clouds and precipitation formed by ARs and large atmospheric water vapor content, net longwave radiation is enhanced, and net shortwave radiation is reduced. Additionally, dynamic sea ice motion driven by strong near-surface winds under ARs further reduces sea ice concentration near ice margins.

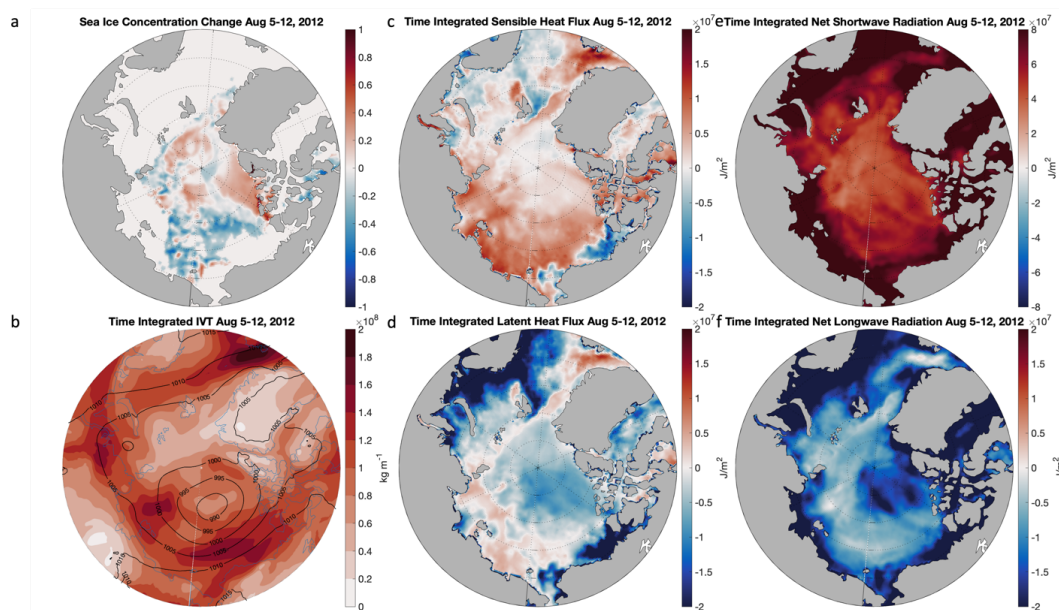

Over the entire Arctic Ocean, ice concentration tendency has significant anticorrelation with IWV, northward wind, and turbulent heat flux anomalously almost everywhere. The coherence over the entire Arctic Ocean of anticorrelation between anomalous moisture/winds and sea ice variations on weather timescales provides important implications for Arctic sea ice prediction.
