**Abstract.** The alkalinity dynamic in coastal environments controls the global burial of carbonate and modulates the ability of the ocean to trap anthropogenic CO<sub>2</sub>. Eleven high vertical resolution profiles from the temperate Chesapeake Bay estuary during two summers allow precise description of carbonate dynamics over the salinity and redox gradient along with the measurement of the speciation of most redox sensitive elements. In the presence of oxygen, carbonate dissolution, primary production and aerobic respiration are able to explain the evolution of total alkalinity (TA) versus dissolved inorganic carbon (DIC), once corrected for fresh and oceanic water mixing. A significant flooding event in 2018 favoured carbonate dissolution. In oxygen depleted waters, 2.4 mole of DIC is produced per 1 mole of TA production. This substantial DIC increase relative to TA has not been previously reported in the literature, and is consistent over the two years. The stoichiometry of TA and DIC changes suggests this characteristic carbonate signature is produced by MnO<sub>2</sub> reduction followed by Mn carbonate precipitation while direct observation highlights important Mn recycling in the water column. Our results underline that Mn is a critical element of the alkalinity dynamic in the river dominated environment, especially because of its ability to limit the H<sub>2</sub>S oxidation to SO<sub>4</sub><sup>2-</sup> and by favouring sulphur burial.

## 1 Introduction

25 About 30% of anthropogenic CO<sub>2</sub> emission is rapidly trapped by dissolution in the ocean as dissolved inorganic carbon (DIC) which is dominated by bicarbonate ions (HCO<sub>3</sub><sup>-</sup>, Friedlingstein et al., 2019). At the century time scale, atmosphere-ocean exchanges result in oceanic HCO<sub>3</sub><sup>-</sup> enrichment not associated with a cationic enrichment, in contrast to silicate or carbonate weathering (preponderant at thousands to a million year scale, Urey, 1952). This disequilibrium corresponds to an excess of proton release compared to carbonate ions during CO<sub>2</sub> dissolution that is only balanced in the deep ocean by  
30 increasing Ca<sup>2+</sup> production from carbonate dissolution, a process named the chemical carbonate compensation (Boudreau et al., 2018). However, in most shallow waters, where carbonate precipitation largely predominates over dissolution and accounts for 2/3 of buried carbonate (Smith and Mackenzie, 2016), other, localised processes may constrain the carbonate dynamic (Borges et al., 2006; Lohrenz et al., 2010). For example, some calcifying species may slow down their carbonate precipitation in case of pH decrease (so called biological carbonate compensation; Boudreau et al., 2018). As another example, in estuaries,  
35 the seasonality of river flow, temperature and continental erosion modulate CaCO<sub>3</sub> dissolution (e.g. Su et al., 2020b), atmospheric CO<sub>2</sub> exchanges (e.g. Borges et al., 2018) or respiratory activity (e.g. Abril et al., 2003). As recently highlighted (Middelburg et al., 2020), the transfer of carbonate particles over estuaries is poorly estimated due to a sparse dataset (Meybeck, 1987).

In anaerobic environments, sulphate consumption increases the observed alkalinity mainly due to the “charge transfer”  
40 from SO<sub>4</sub><sup>2-</sup> to HCO<sub>3</sub><sup>-</sup> (Hu and Cai, 2011). Although correct, this approach tends to neglect the roles of Fe and Mn oxides (Middelburg et al., 2020) since their transformation from (oxyhydr)oxides into sulphur or carbonate species does not change the charge they bear. However, metal oxides are critical since they are the main H<sub>2</sub>S oxidation pathway that does not regenerate SO<sub>4</sub><sup>2-</sup> but rather produces S<sup>0</sup> instead (Findlay et al., 2014; Avetisyan et al., 2021). Their contribution depends on the solid phases buried in the sediment, but should also be revealed by the specific changes of alkalinity and inorganic carbon they  
45 produce.

To better constrain the carbonate cycle in temperate microtidal estuaries, we sampled a stratified water column in the Chesapeake Bay eleven times over two campaigns with a high vertical resolution (down to 10 cm). This protocol allows a precise description of carbonate dynamics over a redox gradient along with the measurement of the speciation of most redox sensitive elements. Such sampling illustrates carbonate chemistry on transitioning from oxygenated waters to waters devoid  
50 of oxygen as usually only encountered in sediments or in anoxic lakes or seas (*e.g.* Black Sea). The original observed changes of alkalinity versus dissolved inorganic carbon changes are interpreted based on typical geochemical reactions occurring along the redox gradient.

## 2 Materials and methods

### 2.1 Sampling

55 During two sampling campaigns from August 3<sup>rd</sup> to 9<sup>th</sup>, 2017 and July 28<sup>th</sup> to August 3<sup>rd</sup> 2018, eleven profile casts were conducted in a unique station in the Chesapeake Bay with a water depth of 25 m (Station 858, 38°58.54'N; 076°22.22'W). The Susquehanna River is the main tributary of the bay representing on average 2/3 of the fresh water input (Zhang et al., 2015). Despite similar season, the two campaigns occurred at very different river flow with about 850 m<sup>3</sup> s<sup>-1</sup> in 2017 versus 8500 m<sup>3</sup> s<sup>-1</sup> in 2018 due to release of flood waters from the Conowingo Dam. The August 2018 condition corresponds to  
60 flooding which occurs on average every 3.5 years (return period of 3.5 years, USGS survey).

Each CTD cast was performed during low or high tide slack periods. An oxygen sensor (Clark electrode, SBE Inc.; detection limit of 1 µM) and fluorescence sensor (Eco-FL Fluorometer, WETLabs) were part of the CTD Rosette to take measurements during sampling. Also, a submersible all plastic pump profiler was attached with the pump near the sensor orifices allowing measurement and sampling at a resolution of a few centimetres over 25 m water depth. Water was pumped  
65 to the deck within 1 minute and water passed through a flow through voltammetry system measuring continuously O<sub>2</sub>, Mn(II), Fe(II), organically complexed Fe(III), FeS clusters, H<sub>2</sub>S and polysulfides (Hudson et al., 2019). When redox interfaces were identified, samples were filtered through an acetate cartridge filter (pore size 0.45 µm) for pH and inorganic carbon parameters, which were processed onboard within a few hours after sampling in order to conserve chemical speciation. The pump profiler system was cleaned with deionised water (18 MΩ) onboard the deck of the ship after deployment. No coating effects were  
70 observed with the pump system.

### 2.2 Discrete Measurements

For each sample, all redox species were determined in the through flow voltammetry system using cyclic voltammetry with a 100 µm diameter Au/ Hg amalgam PEEK microelectrode prepared according to Luther et al. (2008) connected to a DLK-60 electrochemical analyser from Analytical Instrument Systems Inc. The detection limit of this method is 0.2 µM for sulfide and  
75 polysulfides. Discrete samples for the determination of NO<sub>2</sub><sup>-</sup>, Fe and Mn species were filtered through nylon luer-lock syringe filters (Millipore, 0.20 µm). Iron was measured based on the ferrozine method (Stookey, 1970): after HCl acidification and an optional reduction step with hydroxylamine hydrochloric (final concentration 0.7 M) for 1 hour, ammonium acetate (final concentration 0.5 M) and ferrozine (final concentration 1 mM) were added and absorbance at 562 nm was read with a diode array spectrophotometer (Hewlett Packard 8452B). Limit of detection is 100 nM for Fe(II). Shipboard nitrite determination  
80 was performed using the method of Grasshoff (1983). To 25 ml of sample, 0.5 ml of 58 mM sulfanilamide in 10% v/v HCl and 0.5 ml of a 4 mM N(1-naphthyl)ethylene diamine hydrochloride solution were added. Samples with added reagents were shaken and left to sit for 15 min, followed by UV–Vis analysis at 540 nm using a 10-cm cell to increase detection limits. Calibration curves were constructed using sodium nitrite. Limit of detection is 10 nM for NO<sub>2</sub><sup>-</sup>.

Dissolved manganese was determined by displacement of a Cd(II)-porphyrin complex with Mn(II) to form the Mn(II)-  
 85 porphyrin complex (Ishii et al., 1982). Mn(III) species were identified based on slower reactivity with the Cd complex  
 (Madison et al., 2011) as modified in Thibault de Chanvalon and Luther (2019). Alternatively, Mn(III) species were identified  
 after HCl treatment (down to pH=1.5) followed by filtration in order to flocculate and eliminate the dissolved manganese  
 bound to humic material by filtration (Oldham et al., 2017b). Limit of detection is 50 nM for Mn(II). MnOx was measured on  
 20 mL samples of suspended material retained on 0.2 µm filters by the Leucoberbelin blue (LBB) method (Jones et al., 2019).  
 90 Four millilitres of a reagent solution ([LBB]= 78 µM, [acetic acid]=14mM) react with the filter and the absorbance is read at  
 624 nm. KMnO<sub>4</sub> was used to calibrate the LBB method which allows the calculation of the electron equivalents obtained from  
 particulate MnOx. Results are given in as MnO<sub>2</sub> equivalent with a limit of detection of 0.1 µM and an uncertainty below 5%.

The DIC samples were preserved in 250-mL borosilicate glass bottle with 50 µL saturated HgCl<sub>2</sub> solution. The total  
 alkalinity (TA) samples were not poisoned to prevent HgS precipitation and H<sup>+</sup> release in anoxic and low salinity waters (Cai  
 95 et al. 2017). Then TA was analysed by Gran titration in an open-cell setting (AS-ALK2, Apollo Scitech) within 24 h of  
 collection (Cai et al. 2010a). The DIC samples were measured by a nondispersive infrared analyzer (AS-C3, Apollo Scitech)  
 within a week (Huang et al., 2012). The precision for DIC and TA was about 0.1%. Both DIC and TA measurements were  
 calibrated against certified reference materials (CRMs Batch 163 and Batch 173 provided by Andrew Dickson of the Scripps  
 Institution of Oceanography). The pH samples were measured onboard at 25 °C within 1 h of collection using an Orion Ross  
 100 glass electrode, and calibrated with NIST standard buffers. The *p*CO<sub>2</sub>, calcite saturation and TA were calculated from measured  
 DIC and pH via CO<sub>2</sub>sys program using Cai and Wang (1998) constants. The measured TA was found highly correlated to the  
 calculated TA (*r*<sup>2</sup> = 0.995 and 0.998, slope = 0.995 and 1.017 for 2017 and 2018 campaign respectively) and their difference  
 was always below 30 µM with an average of 7.5 µM for 2017 and of 22.2 µM in 2018. These results suggest low contribution  
 of non-carbonate species (e.g. nitrite, ammonium or organic matter (Cotovicz Jr. et al., 2016)) and measured TA was used for  
 105 the interpretation.

## 2.3 Models of biogeochemical process on TA and DIC

### 2.3.1 Identification of biogeochemical processes from scatter plots: the hammer, the bow and the spear

As total concentrations, TA and DIC are conservative during mixing which means that they obey to the law:

$$C = C_A \chi + C_B (1 - \chi) \quad (1)$$

With *C<sub>A</sub>* and *C<sub>B</sub>* the concentration at the two endmember locations A and B; *C* is the concentration of the mixture and *χ* is  
 110 the contribution of endmember A relatively to the contribution of endmember B. In case of two water masses at the locations  
 A and B, respectively, any pairs of elements conservative by mixing whose concentrations *C* and *D* can be defined by the  
 endmember *C<sub>A</sub>*, *D<sub>A</sub>* at the location A and *C<sub>B</sub>*, *D<sub>B</sub>* at the location B obeys the equation 2:

$$C = C_B - D_B \frac{C_A - C_B}{D_A - D_B} + D \frac{C_A - C_B}{D_A - D_B} \quad (2)$$

Equation (2) demonstrates that mixing of two conservative elements between two endmembers results in a straight line passing through the points of coordinates ( $C_A; D_A$ ) and ( $C_B; D_B$ ). This “endmember driven” interpretation is illustrated in Fig. 1a and stands on the implicit assumption that the endmembers are stable over time– they should be hammer-fixed nails. In an environment where at least one of the endmembers changes too fast, equation 2 is not as valuable. Endmember changes can occur due to processes external to the system studied, such as a river endmember varying according to weathering inputs and biogeochemical reactions in rivers and drainage basins (Officer, 1979; Boyle et al., 1974).

**Figure 1: Theoretical scatter plot of two species (dashed and dotted line) conservative by mixing. A) two possible “endmember driven” interpretations. B) two “reaction driven” interpretations. A segment, as represented by the dashed line, can be interpreted as a conservative mixing between two endmembers as described in A), the hammer-fixed nails interpretation, or as the result of a geochemical signature as indicated by the arrow in B), the spear interpretation. A curve, as represented by the dotted line, can be interpreted as an excess (from biogeochemical process or additional source) superimposed to a mixing as described by the arrow in A), the bow interpretation, or as a succession of multiple geochemical reaction as described by the arrows in B), the spears interpretation.**

In the case of an estuary with stable endmembers and without significant lateral effluents, any deviation from the mixing line signals the occurrence of one or more biogeochemical processes easily identified in a scatter plot; the bow interpretation (the arrow between the dashed and the dotted line in Figure 1A). Due to the different rate of mixing and rate of reaction and because these variables are not separated in the differential equation describing this behaviour, mathematics alone does not help further in the interpretation. However, the difference between the observation and the mixing prediction is indicative of the non-conservation production or removal of the element(s) being studied. In our case, this deviation is measured using the observed TA and DIC vs those predicted from their conservative behaviour based on salinity as described by equations 1 and 2. These deviations are usually called the excess of TA (or TA<sub>ex</sub>) and the excess of DIC (or DIC<sub>ex</sub>). In our case, the oceanic endmember was the one proposed by Su et al. (2020a) for both August campaigns. The oceanic endmember varies mainly with season (Cai et al., 2020) and a change of 50 μM results in 5% uncertainty on the slope of the mixing line. Large variations exist in the upstream estuary endmember mainly due to changes of weathering intensity and riverine discharge (Meybeck, 2003; Joesoef et al., 2017) and a one-off endmember has to be determined by fit with the in situ measurements at the lowest

measured salinity (Fig. A1). The upstream endmember is not a river endmember (Su et al., 2020a) but corresponds to a salinity above 1.5 preventing any interpretation for biological activity in the fresh water part of the estuary (Meybeck et al., 1988). However, it corresponds to a larger water mass pool, less sensitive to short term changes and thus more likely to satisfy the condition of stability of the endmember.

135 In case of a water mass isolated from any exchange, including air-water exchanges, but submitted to a given reaction with C and D being the reactants, E and F the reaction products, and  $\alpha_i$  being the stoichiometry of species (equation 3), the variation of the species C and D obeys equation 4, with  $v$  the rate of the reaction, which can be determined in equation 5.

$$\alpha_C C + \alpha_D D = \alpha_E E + \alpha_F F \quad (3)$$

$$\frac{dC}{dt} = -\alpha_C v \text{ and } \frac{dD}{dt} = -\alpha_D v \quad (4)$$

$$\frac{dC}{dD} = \frac{\alpha_C}{\alpha_D} \quad (5)$$

Equation 5 indicates that the ratio of small variations over time of two species is equal to the ratio of the stoichiometry of the reactions governing their transformations, whatever the exact rate of the reaction is. In our case, in a plot representing  
140 TAex versus DICex, the local slope  $\Delta TAex/\Delta DICex$  over time would be equal to the stoichiometry of the occurring reactions, which corresponds to the “reaction driven” interpretation or the spear interpretation as illustrated in Fig. 1B. The uncertainty of  $\Delta TAex/\Delta DICex$  is equal to the sum of the relative uncertainty of  $\Delta TAex$  and  $\Delta DICex$ . Posing  $\Delta TA$  the change of TA measured,  $\Delta S$  the change of salinity and sml\_TA, the slope of the mixing line for TA, we have  $\Delta TAex = \Delta TA - \text{sml\_TA} \times \Delta S$ . Uncertainty on  $\Delta TA$  and  $\Delta S$  are negligible to the relative uncertainty of slope\_ml and posing  $\delta(x)$  the uncertainty on x, we  
145 get:

$$\frac{\delta(\Delta TAex/\Delta DICex)}{\Delta TAex/\Delta DICex} = \frac{\delta(\Delta TAex)}{\Delta TAex} + \frac{\delta(\Delta DICex)}{\Delta DICex} = \frac{\delta(\text{sml\_TA})}{\text{sml\_TA}} + \frac{\delta(\text{sml\_DIC})}{\text{sml\_DIC}} = 0.1 \quad (6)$$

However, if the temporal evolution of water masses is visible in space, it requires that some mixing occur which puts into question the validity of equation 5 defined for time variations alone. By the way, equation 6 describes the behaviour of a solute, conservative by mixing, in case of turbulent diffusion mixing (sometimes called eddy diffusion or diffusive like mixing) superimposed on a chemical reaction as described in equation 3, with  $D_s$  the effective diffusion coefficient:

$$\frac{dC}{dt} = -D_s \frac{d^2 C}{dx^2} + \alpha_C v \quad (7)$$

150 Assuming steady state, *i.e.*  $dC/dt=0$ , applying equation 7 to two different species sharing the same reactions at rate  $v$ , we can express the rate of the reaction as

$$-\frac{v}{D_s} = \frac{1}{\alpha_C} \frac{d^2 C}{dx^2} = \frac{1}{\alpha_D} \frac{d^2 D}{dx^2}$$

By integration with respect to x, it becomes equation 8:

$$\frac{dC}{dx} = \frac{\alpha_C}{\alpha_D} \frac{dD}{dx} + G \quad (8)$$

This is valuable at any position, with G being the constant rising from the integration. If, at the initial location, mixing is negligible then equation (5) is valuable, so G=0 and equation (8) is equivalent to equation (5), but particularly valuable in the case of turbulent diffusion mixing at steady state.

Therefore, away from atmospheric exchanges, in case of turbulent diffusion mixing and steady-state, TAex and DICex correspond to a sum of biogeochemical reactions spread all over the water column that can be decomposed into several reaction zones. In each zone, the local  $\Delta\text{TAex}/\Delta\text{DICex}$  ratio will equal the apparent stoichiometry of a combination of the biogeochemical reactions occurring in this zone. In case of multiple simultaneous reactions in the same zone, by posing  $\alpha_C^i$  the stoichiometry of the  $i^{\text{th}}$  reaction concerning the reagent C and  $v^i$  the reaction rate of the  $i^{\text{th}}$  reaction, we obtain:

$$\alpha_C v = \sum_i \alpha_C^i v^i$$

To maintain a global reaction rate independent to the species we have

$$v = \sum_i v^i$$

so

$$\alpha_C = \frac{1}{v} \sum_i \alpha_C^i v^i \quad (9)$$

Equation 9 indicates that the apparent stoichiometry in a given zone corresponds to the sum of the stoichiometric coefficients of each reaction weighted by the relative rate of each reaction. Therefore, to estimate the relative rate of each reaction to the observed local changes of TAex, DICex and AOU or  $\text{H}_2\text{S}$ , a linear combination of reactions is calculated. This combination has to fit 3 equations (one for each parameter) which allows a maximum of 3 reactions to be used to solve the system. A limited number of reactions is selected as candidates based on the discussion (see Table 1 and sections 4.2 and 4.3). Then, the system is solved with the minimum possible reactions and the weighted coefficients,  $v^i/v$ , are calculated.

### 2.3.2 TA changes indicated by reactions' stoichiometry

The simplest way to calculate the TA changes induced by an individual reaction is to do a direct look to reaction stoichiometry. Indeed, the total alkalinity (TA) corresponds to the quantity of acid added to titrate a solution down to pH 4.5 (Dickson, 1981). It can be described by the equation (10), with the example of HCl as acid and  $\text{B}^-$  any titrated base.

Assuming a complete reaction, the quantity of acid added is equal to the negative charges initially present in the sample consumed plus the positive charges added to the species initially present in the sample. Thus, the total alkalinity corresponds to the loss of negative charges (or gain of positive charges) for species initially present in the sample produced by the pH change from the initial pH = pH<sub>ini</sub> to pH = 4.5. Writing  $z_i^{pH}$ , the charges held by any specie  $i$ , initially present in the sample at a given pH, we get equation (11):

$$TA = \sum_i z_i^{pH=4.5} - \sum_i z_i^{pH_{ini}} \quad (11)$$

However, the electroneutrality of water induces:

$$\sum_i z_i^{pH_{ini}} = 0$$

so

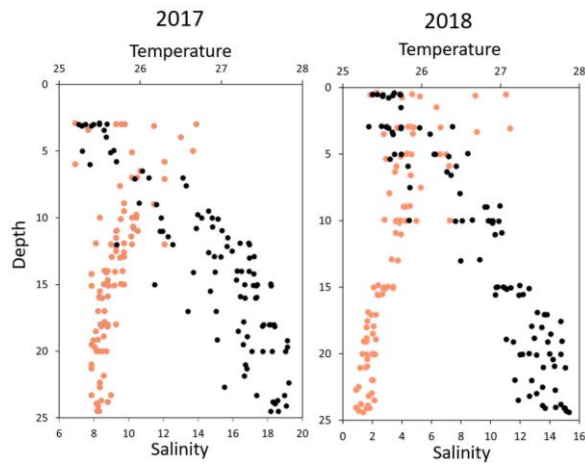

$$TA = \sum_i z_i^{pH=4.5} \quad (12)$$

Equation (12) demonstrates that the total alkalinity is simply the sum of charges that each species present in the sample would have at pH 4.5. From Eq. (12), one can easily deduce the changes of alkalinity from any reaction stoichiometry as soon as the bearing charges at pH = 4.5 are known. For example, for a 0.0020 M NaOH solution, its TA is simply 0.0020 M as at pH=4.5,  $TA = ([Na^+] + [H^+] - [OH^-]) = 0.002 + 10^{-4.5} - 10^{-14+4.5} = 0.0020$  M. For natural waters, most of the time, the only charged active species at pH = 4.5, are  $H_2PO_4^-$  and  $NH_4^+$ . In that respect, whatever the initial pH and the acid-base equilibrium of species in the sample, the sum of phosphate species will count negatively and the sum of ammonium species will count positively. Strictly speaking, at pH=4.5, acid species with pK<sub>a</sub> between 2.5 and 6.5, such as  $F^-$  and  $NO_2^-$ , would be only partially titrated and the charge equals their concentration multiplied by a correction factor of  $(1+10^{pK_a-4.5})^{-1}$ , but this correction can be neglected to a first approximation. The Eq. (12) are equivalent to those published in Soetaert et al. (2007) or Wolf-Gladrow et al. (2007). However, the Eq. (12) are more synthetic and more general. For example, in suboxic water, specific species such as polysulfides (as  $HS_8^{2-}$ , Rickard and Luther, 2007) and in highly productive environments, carboxylic groups from DOC can be easily added as soon as the bearing charges at pH = 4.5 are known.

**3.1 Water column stratification**

High-resolution profiles of salinity and temperature plotted in Fig. 2 shows the stratified water column at station 858. Carbonate and redox chemistry are plotted against salinity in Fig. 3. These data result from the 11 CTD casts performed over 1 week during each campaign and correspond to depths ranging from 0.7 to 25 meters depth. Plots against depth generate noisier  
195 profiles are shown in Appendix 2 while plots against salinity follow the water masses. Despite the overall lower salinity due to a near 7-fold river flow increase in 2018 than 2017 ( $5800 \text{ m}^3 \text{ s}^{-1}$  in 2018 versus  $850 \text{ m}^3 \text{ s}^{-1}$  in 2017), similar zonation of the water column occurred.

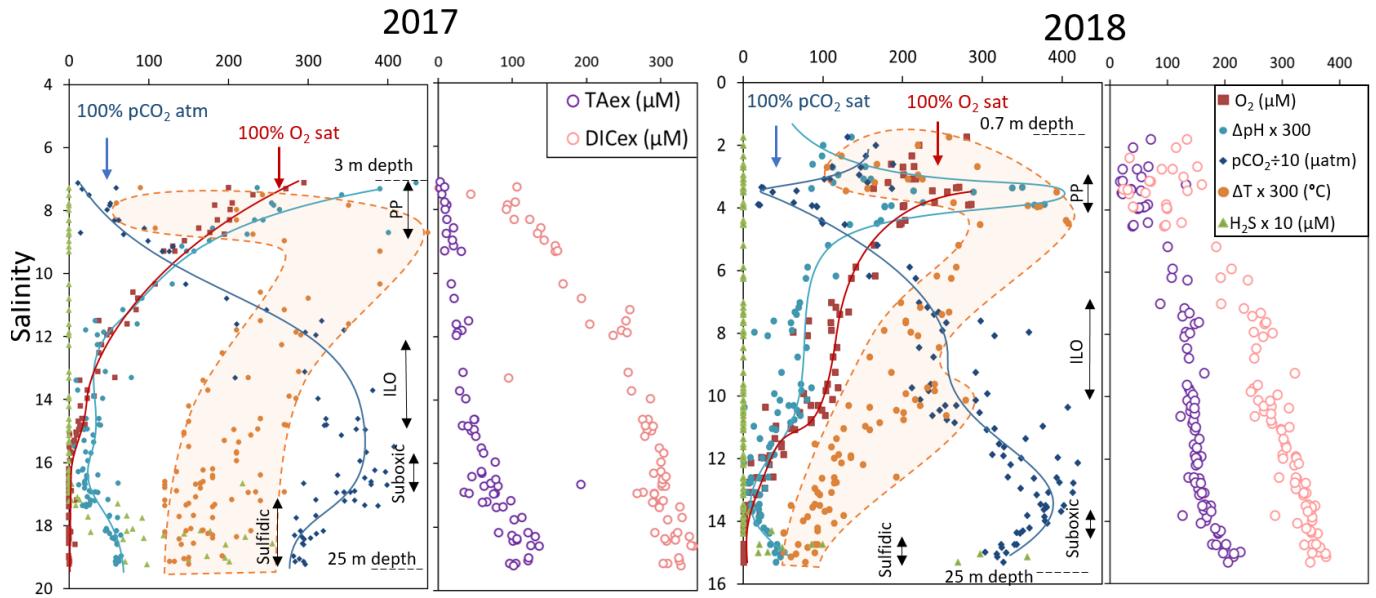

**Figure 2: Superimposed salinity (in black) and temperature (in orange) profiles over the 11 casts for each campaign.**

A surface layer sampled only in 2018 is visible in the top 3 meter depth. It presents highly variable temperature and oxygen concentration and oversaturation of  $\text{pCO}_2$  indicating export to the atmosphere. Below, at 3 meter depth, a subsurface layer  
200 (named primary production zone or PP in Fig. 3) is characterized by a high amount of  $\text{O}_2$  (about or above 100% saturation), high pH (about 8;  $8.11 \pm 0.07$ ,  $n=13$  in 2017 and  $7.94 \pm 0.08$ ,  $n=14$  in 2018), high day to day temperature variation (above  $1^\circ\text{C}$  between different days) and low  $\text{pCO}_2$  (below atmospheric  $\text{CO}_2$  of  $407 \mu\text{atm}$  (Chen et al., 2020);  $505 \pm 75 \mu\text{atm}$ ,  $n=13$  in 2017 and  $770 \pm 130 \mu\text{atm}$ ,  $n=14$  in 2018 with minimal value at  $110 \mu\text{atm}$  in 2017 and  $205 \mu\text{atm}$  in 2018). This signature corresponds to important primary production (PP). Fluorescence (not shown) correlates with pH as expected for primary  
205 production ( $\text{pH} = \text{Fluo} (\text{mV}) \times 13 + 7.14$ ,  $r^2=0.8$  in 2017 and  $r^2=0.9$  in 2018).  $\text{DIC}_{\text{ex}}$  and  $\text{TA}_{\text{ex}}$  reach their minimal value in this surface layer. While  $\text{DIC}_{\text{ex}}$  minimum is similar between the two campaigns ( $78 \pm 17 \mu\text{M}$ ,  $n=13$  in 2017 and  $76 \pm 10 \mu\text{M}$ ,  $n=14$  in 2018);  $\text{TA}_{\text{ex}}$  minimum is much lower in 2017 ( $7 \pm 3 \mu\text{M}$ ,  $n=12$ ) than in 2018 ( $48 \pm 7 \mu\text{M}$ ,  $n=14$ ).

Below, with increasing salinity, an important increase of  $\text{pCO}_2$  accompanying the decrease of  $\text{O}_2$ , pH and temperature is visible. A relatively invariable low oxygen zone (called ILO in Fig. 3) is here defined by the salinity invariance of  $\text{O}_2$  concentrations  
210 at about  $24 \pm 3 \mu\text{M}$ ,  $n=15$  in 2017 and  $105 \pm 5$ ,  $n=16 \mu\text{M}$  in 2018. Other species are also relatively stable for this depth such

as  $p\text{CO}_2$ , at about  $3250 \pm 150 \mu\text{atm}$ ,  $n=10$  in 2017 and  $2590 \pm 100 \mu\text{atm}$ ,  $n = 16$  in 2018, and pH, about  $7.28 \pm 0.01$ ,  $n=13$  in 2017 and  $7.37 \pm 0.02$ ,  $n=16$  in 2018. Deeper, where the oxygen is not detectable ( $< \sim 1 \mu\text{M}$ ), the so-called suboxic zone corresponds to a pH minimum at  $7.24 \pm 0.01$ ,  $n=40$ , similar in 2017 and 2018 that generates a  $p\text{CO}_2$  maximum. The deepest layer is a sulfidic layer ( $[\text{H}_2\text{S}] = 11.2 \pm 2.8 \mu\text{M}$ ,  $n=36$ ) in which the pH seems quite stable at  $7.33 \pm 0.01$ ,  $n=29$  and  $7.32 \pm 0.01$ ,  $n=9$  in 2017 and 2018 respectively.

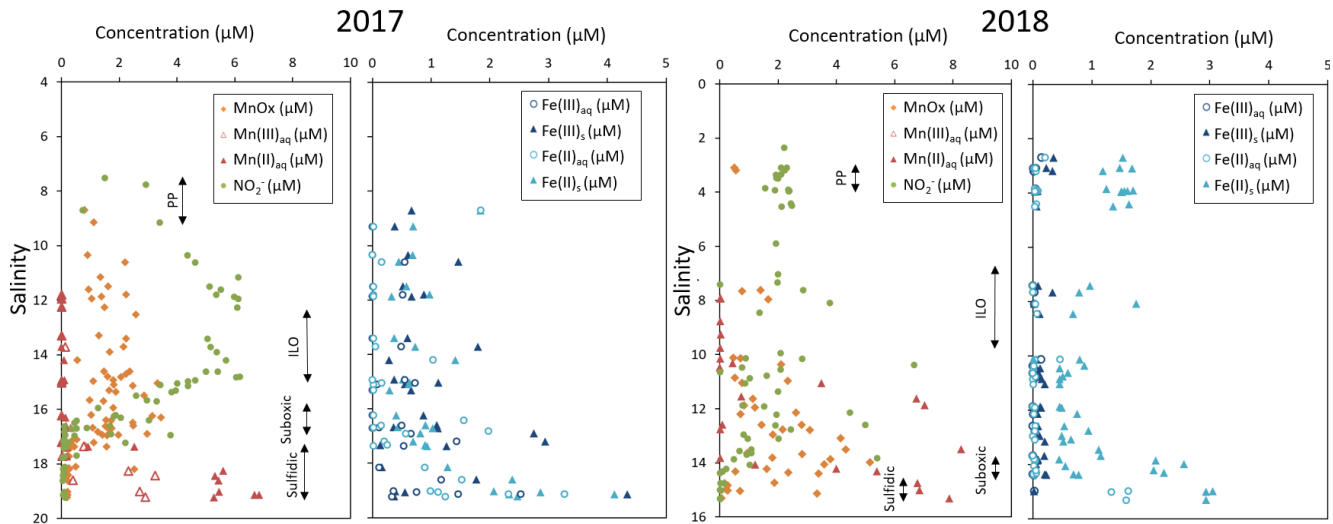

The  $\text{Ca}^{2+}$  concentrations observed by Su et al. (2021) and during the 2018 cruise (data not shown) vary linearly with salinity (calcium excess stay below  $200 \mu\text{M}$  or 10% of total Ca). Assuming similar behaviour in 2017, calculations show that the whole water column (except 4 samples from the PP zone) is under saturated ( $0.36 < \Omega_{\text{cal}} < 1$ ; mean=0.68) with respect to calcite in 2018, while undersaturation is only valid below  $S=10$  in 2017. The main changes between the two campaigns correspond to a greater oxygen penetration in 2018, especially visible in the ILO zone. Additionally, a surface layer (with salinity below 3) is visible above the primary production zone in 2018 but is related to the more superficial sampling in 2018.

**Figure 3: Superimposed carbonate and redox chemistry profiles of 11 casts done in August 2017 (left) and 11 casts done in August 2018 (right). Linear mathematic transformation allows to plot all variable on the same scale, lines are only here to guide eyes. In particular  $T = 25 + \Delta T/300$  and  $\text{pH} = 7.175 + \Delta \text{pH}/300$ . For example, pH maximum value of 400 correspond to a  $\text{pH} = 400/300 + 7.175 = 8.5$ , a reading at 100 for  $p\text{CO}_2+10$  indicates a value of  $p\text{CO}_2 = 1000 \mu\text{atm}$ .**

### 3.2 Intermediate redox species

The development of the suboxic zone during summer (Su et al., 2021) and the regularity of this development over the years (Sholkovitz et al., 1992; Trouwborst et al., 2006; Lewis et al., 2007; Cai et al., 2017; Oldham et al., 2017a), requires the presence of species able to rapidly oxidise the  $\text{H}_2\text{S}$  mixing upward and to reduce the  $\text{O}_2$  mixing downward. The three main redox couples known to play this role,  $\text{NO}_3^- / \text{NO}_2^-$ ,  $\text{MnO}_x / \text{Mn}^{2+}$  and  $\text{Fe}^{3+} / \text{Fe}^{2+}$  are described in the Fig. 4 by the superimposition of all cast results against salinity. Four representative casts are plotted in the Fig. A3. The primary production zone is depleted in dissolved Mn(II) and Mn(III), and shows an average value for solid MnOx ( $0.7 \pm 0.1 \mu\text{M}$ ,  $n=4$ ) and  $\text{NO}_2^-$  ( $2.1 \pm 0.1 \mu\text{M}$ ,  $n=18$ ). In 2018, iron speciation was investigated in the primary production zone showing an important iron pool ( $1.6 \pm 0.1 \mu\text{M}$ ,  $n=9$ ) dominated by solid Fe(II) ( $95 \pm 2\%$ ). Below, in the ILO zone,  $\text{NO}_2^-$  reaches a maximum plateau at  $5.3 \pm 0.2 \mu\text{M}$ ,  $n=11$  in 2017 that is not visible in 2018, MnOx dominates the Mn pool in the ILO zone with concentration of  $1.8 \pm 0.1 \mu\text{M}$ ,  $n=14$  in 2017 and  $1.3 \pm 0.2 \mu\text{M}$ ,  $n=3$  in 2018). Fe(II) represents only  $49\% \pm 13$ ,  $n=4$  of the iron pool (for a total iron concentration of  $2.0 \pm 0.4 \mu\text{M}$ ,  $n=4$ ) in 2017 while it represents  $87 \pm 5\%$ ,  $n=4$  of the iron pool in 2018 (for a total concentration of  $1.2 \mu\text{M} \pm 0.2$ ,  $n=4$ ). Just below oxygen depletion, in the suboxic zone, MnOx reaches a maximum ( $2.0 \pm 0.1 \mu\text{M}$ ,  $n=25$  in 2017 and  $2.9 \pm 0.4 \mu\text{M}$ ,  $n=12$  in 2018). During both campaigns, the sulfidic layer is characterised by the absence of  $\text{NO}_2^-$  and

**Figure 4: Mn, Fe and nitrite profiles build by superimposition of 11 casts for each campaign.**

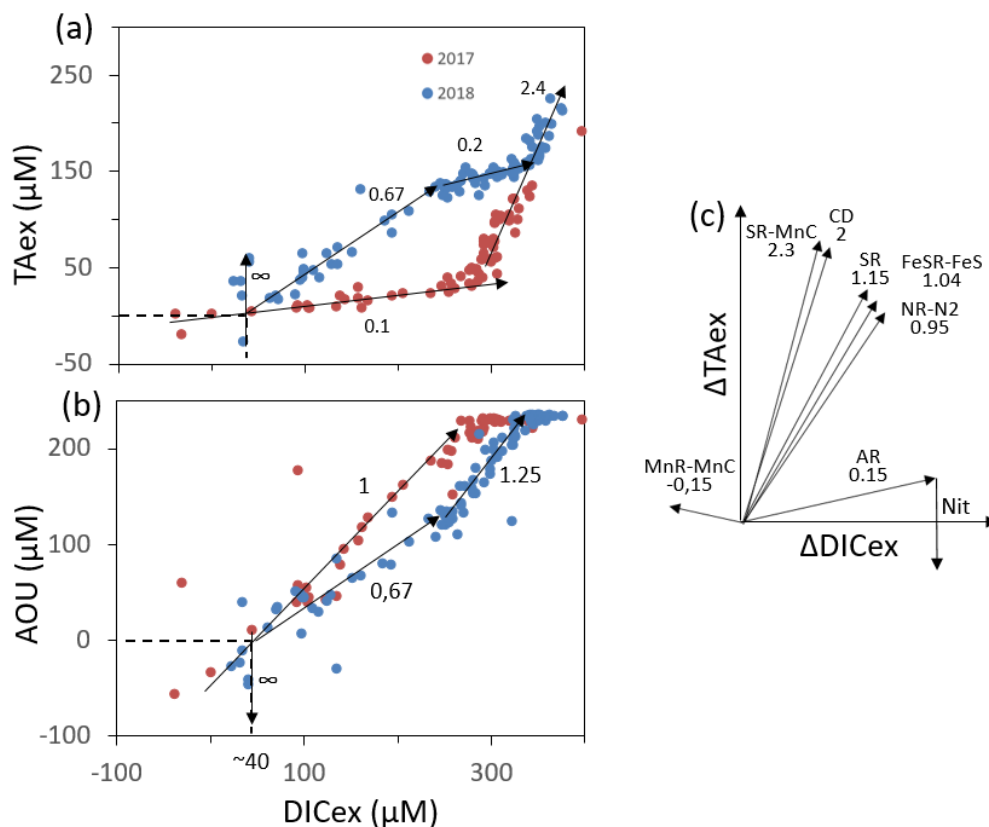

MnOx while dissolved manganese concentration increases up to  $7.7 \pm 0.8 \mu\text{M}$ ,  $n=15$  and the iron pool increases to  $5.0 \pm 0.7 \mu\text{M}$ ,  $n=13$ . No Mn(III) was detected with the porphyrin kinetics method (Thibault de Chanvalon and Luther, 2019) but about 30% of the total dissolved manganese flocculated after acidification down to pH 1.5 when analysed in 2017 indicating the existence of Mn(III).

The station 858 of the Chesapeake Bay shows very similar water column stratification between summer 2017 and summer 2018 despite a 10-fold differences in freshwater discharge rates (Fig. 3 and Fig. 4). Major features are: first, a surface layer characterized by intense atmospheric exchanges only sampled in 2018. Below, at about 3 meter depth, a subsurface layer associated with high primary production (PP zone) with high pH about 8, oversaturation of dioxygen and low CO<sub>2</sub> partial pressure (down to 110  $\mu$ atm). Below, a low oxygen layer with invariant concentration of most species surveyed (the invariant low oxygen (ILO) zone) is characterized by significant nitrite accumulation in 2017 (Fig. 4) probably due to oxidation of NH<sub>4</sub><sup>+</sup> diffusing upward and/or produced by *in situ* remineralisation. This feature is not visible in 2018 probably because the higher O<sub>2</sub> concentration in 2018 accelerates nitrite oxidation into nitrate and prevents any significant accumulation. Below, the suboxic zone, with neither O<sub>2</sub> nor H<sub>2</sub>S detectable, is characterized by an increase of MnOx concentration and a pH minimum. This MnOx maximum can be explained by the upward diffusing Mn<sup>2+</sup> that is biologically oxidized by the downward diffusing O<sub>2</sub>, even at low, undetectable, concentration (Clement et al., 2009). Additionally, Mn<sup>2+</sup> could be oxidized by the nitrite or the nitrate (not measured) diffusing downward (thermodynamically favourable (Luther, 2010)). Compared to the ILO zone, the suboxic MnOx maximum corresponds to an increase of 0.2  $\mu$ M in 2017, while it is much more marked in 2018 with an increase of 1.6  $\mu$ M (Fig. 4). This difference could come from a faster Mn<sup>2+</sup> oxidation produced by the steeper oxygen gradient above the suboxic zone and by the thinness of the suboxic layer in 2018. Finally, in the deeper and sulfidic layer, the MnOx disappearance corresponds to the Mn<sup>2+</sup> increases (Fig. 4) according to the reduction of settling MnOx by H<sub>2</sub>S. The concentration increase of the manganese pool and of the iron pool with depth in the suboxic and sulfidic layers probably results from important sedimentary efflux.

#### 4.1 Validity of the “reaction driven” interpretation in the context of station 858

The simultaneous and high-resolution sampling of multiple carbonate parameters and redox species gives us the rare opportunity to investigate in detail the interaction between carbonate species and redox sensitive elements. In the Chesapeake Bay, main changes of DIC and TA can be explained by mixing between upstream and oceanic endmembers (Appendix, Fig. A1). This “endmember driven” interpretation (see section 2.3.1), leads to the calculation of an excess of DIC and TA, DIC<sub>ex</sub> and TA<sub>ex</sub>, relative to the mixing line and shown in Fig. 5a. As detailed in section 2.3.1, these excesses can be explained either by the occurring processes leading to a “reaction driven” (or spear) interpretation (Fig. 1b), or by mixing with an additional, third, endmember leading to an “endmember driven” (or hammer and bow) interpretation (Fig. 1a). In station 858, the steep gradient observed, for example the pH and pCO<sub>2</sub> gradient in the PP zone, the O<sub>2</sub> and NO<sub>2</sub><sup>-</sup> gradient above the suboxic zone and the Mn, Fe and H<sub>2</sub>S gradient at depth suggest that *ongoing in situ* processes control the changes of concentrations rather than the time-dependent endmember variability or the existence of an unknown third endmember. Additionally, the TA<sub>ex</sub> versus DIC<sub>ex</sub> plot (Fig. 5a) shows steep changes of direction while a preponderance of mixing would produce more progressive

changes. Finally, at depth, Fig. 5a shows a similar slope for both years studied ( $\Delta\text{TAex}/\Delta\text{DICex} = 2.4$ ) rather than a similar TAex and DICex concentration, which reinforces the validity of the “reaction driven” interpretation.

**Figure 5: Description of the TAex/DICex/AOU system. (a) and (b) panels show samples measured along with interpretative slope discussed in the main text. Panel (c) shows the theoretical slope of TAex/DICex from combination of reactions presented in Table 1.**

Assuming 1) that mixing is efficiently described by turbulent diffusion mixing, 2) that the measured concentrations correspond to a steady state – no gradient change over the 1 week sampling, 3) that the concentration at the starting point does not vary with time – as observed during one week sampling and 4) that the samples are isolated from atmospheric exchanges – sampling focus below 3 meters depth; the “reaction driven” interpretation (section 2.3.1) permits interpretation of the concentration changes as a linear combination of the stoichiometry of several chemical reactions (equation 5). The weighted coefficients of each reaction are equal to the rate of each reaction relative to the sum of the rate of all occurring reactions,  $v^i/v$  (equation 9). This interpretative framework describes the vertical stratification of the water column as the journey of a water mass slowly mixed deeper and deeper and whose DIC and TA are progressively enriched by all chemical reactions they undergo. Accordingly, this interpretation does not identify reactions with minor impact on the carbonate cycle or reactions cancelled later during the journey, for example, PP is frequently cancelled by similar amount or excess of AR. The starting

point corresponds to the upstream (S=1.5) endmember at DIC<sub>ex</sub>=0; TA<sub>ex</sub>=0. Figure 5a shows a slight DIC<sub>ex</sub> enrichment at  
 285 TA<sub>ex</sub>=0 which reflects a bias from the endmember calculation.

#### 4.2 Identification of major reactions in oxygenated water column using $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU}$ signature.

In oxygenated water, the  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  analysis can be improved by looking also to the  $\Delta\text{AOU}/\Delta\text{DIC}_{\text{ex}}$  ratio (Fig 5b) and establishing a  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU}$  signature for each water layer. Then, a linear combination of up to 3 reactions can be fit to the observed  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU}$  signature. The main candidate reactions to be combined are: aerobic respiration  
 290 (AR), primary production (-AR), carbonate dissolution (CD) and nitrification of ammonium (Nit) as presented in the Table 1 and in Fig. 5c. In 2017, the whole oxygenated zone, including the PP zone and the ILO zone, is characterised by a  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU} = 0.1/1/1$  (Fig. 5a and 5b) which corresponds to the occurrence of only net aerobic respiration (AR)

**Table 1: Summary of the main net reactions occurring among the different zones of a redox gradient with reactants starting in equilibrium with the atmosphere. The calculations assume Redfield ratio of the organic matter, i. e.  $\gamma_{\text{N}} = 0.156$  and  $\gamma_{\text{P}} = 0.0094$  (Soetaert et al., 2007).**

Name	Redox zones	Net Formula	$\Delta\text{TA}$	$\Delta\text{DIC}$

(theoretical value are 0.15/1/1 see Table 1 and Fig. 5c). Note that this  $\Delta\text{TAex}/\Delta\text{DICex}/\Delta\text{AOU}$  signature stands for absent or negligible nitrification following respiration. In case of full nitrification, the theoretical slopes should be

295  $\Delta\text{TAex}/\Delta\text{DICex}/\Delta\text{AOU} = -0.167/1/1.31$  as proposed by Zeebe and Wolf-Gladrow (2001). The absence of noticeable nitrification can be explained by slow kinetics of  $\text{NH}_4^+$  oxidation, with a half-life time estimated between a few days in estuaries (Horrigan et al., 1990) to multiple years in coastal environments (Heiss and Fulweiler, 2016). As a comparison, other  $\text{NH}_4^+$  fates, such as adsorption leads to ammonium half life time of about a few minutes (Alshameri et al., 2018) to a few hours (Raaphorst and Malschaert, 1996) depending on the concentration of fine particles. Additionally, algae are known to use  $\text{NH}_4^+$

300 as a N source (Raven et al., 1992) and  $\text{NH}_4^+$  can be directly assimilated by heterotrophic organisms.

In 2018, fresh water masses brought by the exceptional flood modified the carbonate system equilibrium. First, a low salinity layer with  $\text{pCO}_2$  at 1540  $\mu\text{atm}$  overlays the primary production layer (Fig. 3), preventing the uptake of atmospheric

CO<sub>2</sub> by primary production as was observed in 2016 (Chen et al., 2020). Just below the surface layer, in the PP zone, the lock down of atmospheric exchanges by the low salinity layer produces supersaturation of trapped O<sub>2</sub> (Fig. 3). In Fig. 5a and 5b, this process translates into a vertical distribution at DIC<sub>Cex</sub> = 40 μM associated with negative AOU and slightly positive TA<sub>ex</sub>, *i.e.* a  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU} = \infty/0/-\infty$ . This original signature can be modelled by the combination of simultaneous carbonate dissolution (CD), the water column being undersaturated, and PP fuelled by NH<sub>4</sub><sup>+</sup>, in equal proportion (2<sup>nd</sup> line in Table 2); the carbonate dissolution buffers the DIC consumption produced by PP.

In 2018, below the PP zone down to DIC<sub>Cex</sub> = 240 μM, the beginning of the ILO zone, the TA<sub>ex</sub> increases significantly with a  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU} = 0.67/1/0.67$  (Fig. 5a and 5b), incompatible with AR. To explain this signature a contribution of CD superimposed on AR seems most likely. A linear combination fitting leads 0.5 CD for 1 AR (3<sup>rd</sup> line in Table 2) and results in  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU} = 0.77/1/0.67$ . An explanation of its occurrence solely in 2018 could be the increase in carbonate rich suspended material at high flow conditions (Su et al., 2021). Excess of Ca<sup>2+</sup> compared to the mixing line with oceanic end member (not shown) indicate that up to 200 μM of Ca<sup>2+</sup> is produced in the oxygenated layer. Deeper, in the ILO zone,  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU} = 0.2/1/1.25$  (Fig. 5a and 5b) results mainly from AR (0.15/1/1) with possible addition of CD and Nit, the exact signature being fitted for 0.54 CD and 0.46 Nit for 1 AR (4<sup>th</sup> line in Table 2), in close continuity of AR and CD relative rates from the overlaying layer. This important nitrification is also in good agreement with the lack of nitrite build up in the ILO zone and the relatively high oxygen concentration (at 105 μM) in the ILO zone in 2018 which is able to sustain nitrification. Overall, our results show that the higher river flow of 2018 increases carbonate dissolution for the top 5-10 m water depth that is superimposed on primary production or aerobic respiration. Additionally, in 2017 the  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU}$  system was indiscernible from the AR signature without nitrification, while in 2018 some nitrification in the ILO zone is suggested by the “reaction driven” interpretation.

#### 4.3 Identification of major reactions in the anoxic water column using $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{H}_2\text{S}$ signature.

In the absence of oxygen, the  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{H}_2\text{S}$  will be used for rates calculation. In the suboxic zone, the signature is similar in summer 2017 and 2018 at  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{H}_2\text{S} = 2.4/1/0$ . The “reaction driven” interpretation of this signature is more difficult than in oxidized water because more reactions are known to occur simultaneously in absence of oxygen. However, it is not necessary to describe each reaction step but only the overall changes concerning the journey of a water mass over different redox conditions resulting in combined reaction. This approach has recently been proposed for FeS burial by Hiscock and Millero (2006), Rassmann et al. (2020) or Su et al. (2020b). A scenario combining sulfate reduction (SR) is particularly attractive since SR represents the main carbon remineralisation pathway in absence of oxygen. However, a combination of SR with CD would result in a  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  between 1.15 and 2 (see Table 1 or Fig. 5c) and fails to reach the  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  of 2.4. Moreover, SR alone underestimates the importance of the H<sub>2</sub>S oxidation pathway that can consume all the alkalinity produced during SR. For example, SR follow by oxygenated oxidation results in  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{AOU}$  signature equal to AR only. In the Chesapeake Bay, H<sub>2</sub>S oxidation is critical since no H<sub>2</sub>S is measurable in the suboxic zone while the gradient at the sediment/water interface indicates high H<sub>2</sub>S sedimentary efflux (Fig. 3).

Generalizing these observations, recent efforts to build an alkalinity budget on the global scale (Hu and Cai, 2011; Middelburg et al., 2020) highlight that the alkalinity produced by anaerobic respiration corresponds to the uncharged species produced, mostly in solid or gaseous phases. Indeed, the alkalinity changes produced during a natural reaction equal the “charge transfer” from species having some charge at pH = 4.5, such as  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ , to species that would lose its charges at pH = 4.5, mainly  $\text{HCO}_3^-$ , that is not counted in the alkalinity calculation (see Eq. (12)). Although correct, this approach tends to neglect the roles of Fe and Mn oxides (Middelburg et al., 2020) since their transformation from (oxyhydr)oxides into sulphur or carbonate species does not involve any charge transfer. When looking in detail at these processes, the metal oxides are critical since they are the main  $\text{H}_2\text{S}$  oxidation pathway that does not regenerate  $\text{H}_2\text{SO}_4$  but rather produces  $\text{S}^0$ ,  $\text{S}_n^{2-}$  or  $\text{FeS}$  (Findlay et al., 2014; Avetisyan et al., 2021) which limits alkalinity consumption.

To build a pool of candidate reactions for the fitting, first, dissolved species at too low concentration (*e.g.*  $\text{Mn}^{2+}_{\text{aq}}$ ,  $\text{Fe}^{2+}_{\text{aq}}$ ) to be a net reagent to affect the carbon cycle at steady state are not taken into account. These species are usually recycled rapidly and hold a role of catalyser or electron shuttle between other redox species. Second, many minerals are expected to be at low concentration or thermodynamically not favoured, and their associated reactions are neglected (*e.g.*, iron phosphate, ferrous or manganous oxide, sulphur clusters,  $\text{MnS}$ ,  $\text{FeCO}_3$ , adsorption processes, reverse weathering). Therefore, only aqueous species with important stock concentrations (that can exceed 0.1 mM in anoxic water) are taken into account, *i. e.*,  $\text{SO}_4^{2-}$ ,  $\text{Ca}^{2+}$ ,  $\text{H}_2\text{S}$ ,  $\text{NH}_4^+$  together with gaseous ( $\text{N}_2$ ,  $\text{CO}_2$ ) and main solid phases ( $\text{FeS}_2$ ,  $\text{FeS}$ ,  $\text{S}^0$ ,  $\text{MnCO}_3$ ,  $\text{FeOOH}$ ,  $\text{MnO}_2$ ). Third, many combinations of the carbon remineralisation reaction with a re-oxidation reaction are equal to another remineralisation reaction. As an example, SR followed by  $\text{H}_2\text{S}$  oxidation with oxygen is equal to aerobic respiration.

Table 1 lists the resulting combined reactions and the calculated  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  slopes are represented in Fig. 5c. For the suboxic zone, the nitrate respiration can be associated with  $\text{N}_2$  production (NR- $\text{N}_2$ ) or with  $\text{NH}_3$  production (NR- $\text{NH}_3$ ) and the manganese oxides respiration produces carbonates precipitation (MnR-MnC). For the sulfidic zone, SR can occur alone producing a build-up of  $\text{H}_2\text{S}$ . However, at a certain point,  $\text{H}_2\text{S}$  gets significantly oxidised either by  $\text{MnO}_2$  which produces  $\text{MnCO}_3$  and  $\text{S}_0$  (SR-MnC) or by  $\text{FeOOH}$ , producing  $\text{FeS}$  and  $\text{S}_0$  (SR-SFeS) and ultimately  $\text{FeS}_2$  (SR- $\text{FeS}_2$ ). Direct respiration of  $\text{FeOOH}$  is also taken into account, but as the only Fe product is  $\text{FeS}$  or  $\text{FeS}_2$  it has to be accompanied by some SR (FeSR- $\text{FeS}$ ). This exercise highlights that the higher  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  obtained ratio is 2.3 which corresponds to a combination of sulfate reduction followed by Mn oxide reduction and Mn carbonate precipitation (SR-SMnC) which fits extremely well with the signature  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}/\Delta\text{H}_2\text{S} = 2.4/1/0$  reported in the Chesapeake Bay.

However, other linear combination of reactions listed in Table 1 result in the 2.4/1/0 signature. Figure 5c demonstrates that the slope of 2.4 can be obtained for any reaction in combination with MnR-MnC. Combinations without MnR-MnC, however, lead to a negative SR and are not considered despite a possible small participation of anoxygenic phototrophic (purple) bacteria (Findlay et al., 2015, 2017). Therefore, in the absence of nitrate, oxygen and  $\text{H}_2\text{S}$ , only a combination of MnR-MnC with SR-MnC (producing  $\text{S}^0$ , 5<sup>th</sup> line in Table 2), SR- $\text{FeS}$  (producing  $\text{FeS}$ , 6<sup>th</sup> line in Table 2) or CD (releasing  $\text{Ca}^{2+}$ , 7<sup>th</sup> line in Table 2) gives the particularly high  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  of 2.4.  $\text{S}_0$  was not measured during our campaign, but it has been previously reported at this site (Findlay et al., 2014), and the  $\text{S}_0$  produced by SR-MnC can react with  $\text{FeS}$  to form  $\text{FeS}_2$ . All the three

370 identified combinations require a critical role of MnO<sub>2</sub>. Since Figure 4 does not indicate any clear reaction for iron while the steep gradient of MnOx in proximity to the H<sub>2</sub>S rich layer suggests reaction between MnOx and H<sub>2</sub>S; the combination with SR-MnC is the most likely (5<sup>th</sup> line in Table 2). Deeper, in the presence of sulphide, the  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S$  signature is 2.4/1/1.2 in 2017 and 2.4/1/3.2 in 2018 and can be explained by the same combination of reactions without oxidized SR to take into account the build-up of H<sub>2</sub>S (Table 2).

375 **4.4 Comparison with other studies**

The high observed ratio of  $\Delta TA_{ex}/\Delta DIC_{ex} = 2.4$  seems very specific to the Chesapeake Bay. Moreover, the “reaction driven” interpretation can be applied to other published datasets for which the  $\Delta TA/\Delta DIC/\Delta H_2S$  system can be calculated (Table 3). In the water column, most of the available datasets are not suitable for the “reaction driven” interpretation since either they focus on surface water where DIC and TA are strongly impacted by atmospheric exchanges or the water masses change too fast to consider that reactions dominate over water mixing. However, porewater measured in the Gulf of Mexico has  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S = 1.15/1/0.53$  (Hu et al., 2010) as expected when sulfate reduction is associated with H<sub>2</sub>S accumulation (SR reaction;  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S = 1.15/1/0.5$ ; Table 1). Similarly, Hiscock and Millero (2006) report  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S = 1.3/1/0.5$  in the Western Black Sea close to the SR signature. In the Baltic Sea sediment,  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S = 1.3/1/0.07$  was reported (Lukawska-Matuszewska, 2016), which is close to the expected signature in case of important H<sub>2</sub>S consumption by Fe oxides and precipitation as pyrite (SR-FeS<sub>2</sub> reaction;  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S = 1.2/1/0$ ). In Rhone river prodelta sediments, the reported  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S$  is 1/1/0 that can be related to the 1/1/0 signature of FeSR-FeS (Table 1) that is expected in iron rich sediment with high sedimentation rate preventing FeS<sub>2</sub> formation in the pore water (Rassmann et al., 2020). In permeable, carbonate rich sediments, the reported signature of  $\Delta TA_{ex}/\Delta DIC_{ex}/\Delta H_2S$  in Hawaii sands is 0.86/1/ND (Drupp et al., 2016). The lack of salinity and oxygen datasets prevents

**Table 3: Overview of the  $\Delta TA/\Delta DIC/\Delta H_2S$  signature observed in different environments**

Publication	Sample type	$\Delta TA/\Delta DIC/ \Delta H_2S$ or $\Delta TA/\Delta DIC/ \Delta AOU$	$\Delta TA$	Reaction driven interpretation
Hu et al., 2010	Gulf of Mexico sediment (slope)	1.15/1/0.53	+ 17 mM	SR
Lukawska-Matuszewska, 2016	Baltic Sea sediment	1.3/1/0.07	+ 15 mM	SR-FeS <sub>2</sub>
Rassmann et al., 2020	Rhone prodelta sediment	1/1/0	+ 56 mM	FeSR-FeS
Cai et al. 1998	Satilla estuary	2/1/ND	+ 0.2 mM	CD
Drupp et al. 2016	Oxygenated Hawai carbonate reef sands	0.86-0.91/1/ND	+ 1.5 mM	Not applicable*
Su et al. 2021	Chesapeake Bay water column	2/1/1.5 AOU	+0.4 mM	Not applicable**
		0.2/1/1 AOU	+0.05 mM	AR
		0.8/1/ND	+0.1 mM	NR-N2 or CD+Nit
Hiscock and Millero 2006	Western Black Sea water column	1.3/1/0.5	+1.2 mM	SR+?CD

\*Lack of data on oxygen concentration prevent any interpretation. \*\* Important air-water exchange prevent any “reaction driven” interpretation.

390 further model fits, but the  $\Delta\text{TAex}/\Delta\text{DICex}$  is below 2.4. For oxygen depleted data from the whole Chesapeake Bay described in Su et al. (2020), the signatures are  $\Delta\text{TAex}/\Delta\text{DICex}/\Delta\text{AOU} = 0.2/1/1$  in presence of oxygen (typical signature of AR) and  $0.8/1/\text{ND}$  in absence of oxygen that could correspond to NR-N<sub>2</sub> or a combination of CD+Nit. Overall, this bibliographic survey highlights the effectiveness of the reaction driven approach to identify preponderant reactions controlling the carbon cycle and puts in perspective the originality of the  $\Delta\text{TAex}/\Delta\text{DICex}/\Delta\text{AOU}$  signature of 2.4/1/0 observed in the Chesapeake Bay.

#### 395      **4.5 Local and global budget**

While the “reaction driven” interpretation indicates a dominant role of the SR-MnC reaction; this possibility needs to be validated looking at the saturation state of rhodocrosite (main MnCO<sub>3</sub> mineral) and looking at the mass budget between MnOx consumed and TAex produced. The rhodocrosite saturation (Luo and Millero, 2003) is always below 0.3 which stands against the occurrence of *in situ* SR-MnC reaction. When inspecting the mass budget, the 88 μM to 155 μM of MnO<sub>2</sub> required to produce the 100 μM TAex increase observed (Fig. 5a) is one order of magnitude higher than the observed MnOx or Mn<sup>2+</sup> concentration (Fig. 4). This mass budget discrepancy cannot be solved invoking suspended material since the 88 μM of MnO<sub>2</sub> would require a suspended material concentration of about 4.4 g L<sup>-1</sup> (assuming an average concentration of 20 μmol g<sup>-1</sup> of Mn), which is again one or two orders of magnitude higher than the 0.01 – 0.1 g L<sup>-1</sup> usually found in the Chesapeake Bay (Cercio et al., 2013). Therefore the SR-MnC reaction does not happen in the water column of the Chesapeake Bay. However, it is likely that the TAex and DICex have rather been produced in the sediment during the previous year and then diffused simultaneously with other reduced elements as the summer begins. Indeed, previous studies at station 858 (*e.g.*, Sholkovitz et al., 1992) explained the seasonality of anoxia with an upward move of the redox front from the sediments to bottom waters during the start of summer. Important sedimentary efflux of H<sub>2</sub>S, Fe<sub>aq</sub> and Mn<sub>aq</sub> were still visible during both August campaigns. Therefore, the 100 μM TA increase does not fit with the ambient Mn<sup>2+</sup> or MnO<sub>2</sub> in the water column but rather with the MnCO<sub>3</sub> deposited in the sediment. The sedimentary solid Mn stock of the Chesapeake Bay is particularly important, up to 70 μmol g<sup>-1</sup> at station 858 (Sinex and Helz, 1981) compared to an average value of 15 μmol g<sup>-1</sup> for the upper continental crust (Rudnick and Gao, 2003). Indeed semi-enclosed basins are known to concentrate manganese at the deeper sediment (Thamdrup and Dalsgaard, 2000; Lenstra et al., 2020). Recent investigations at a close station (ET 5.1; 38°48.36'N; 75°54.66'W) in the Chesapeake Bay (Lenstra et al., 2021) report that about 60% of the surface sedimentary Mn pool is MnOx (acid ascorbic extractable) and 25 % is Mn carbonate (1M HCl extraction). Assuming a porosity of 0.8, a bulk solid density of 2.6, the sedimentary pool corresponds to 35 mM of manganese which largely exceeds the 88 μM required to produce the 100 μM TAex increase. Therefore, the Chesapeake Bay sediment is particularly rich in manganese and could host important SR-MnC reactions in the superficial pore water whose soluble products diffuse up to the water column during summer and could bear with them the high  $\Delta\text{TAex}/\Delta\text{DICex}$  signature observed.

420      At a global scale, beside its role on alkalinity, MnO<sub>2</sub> can also be a trap for CO<sub>2</sub> as proposed in this Urey-Ebelman (Urey, 1952, Eq. 13) like reaction (Eq.14):

Assuming all the Mn is in the form of  $\text{MnO}_2$ , a weathering intensity similar to iron (Poulton and Raiswell, 2002) and based on the upper continental crust composition (Rudnick and Gao, 2003), the continental  $\text{MnO}_2$  input to the ocean can be estimated at  $0.4 \times 10^{12} \text{ mol y}^{-1}$ . Assuming a steady state ocean toward Mn and  $\text{MnCO}_3$  as the unique sedimentary phase, this estimation  
 425 represents 1.4 % of the total carbonate burial (Middelburg et al., 2020). Although negligible at the global scale, this carbonate burial may be significant in  $\text{MnO}_2$  rich semi-enclosed basins.

## Conclusion

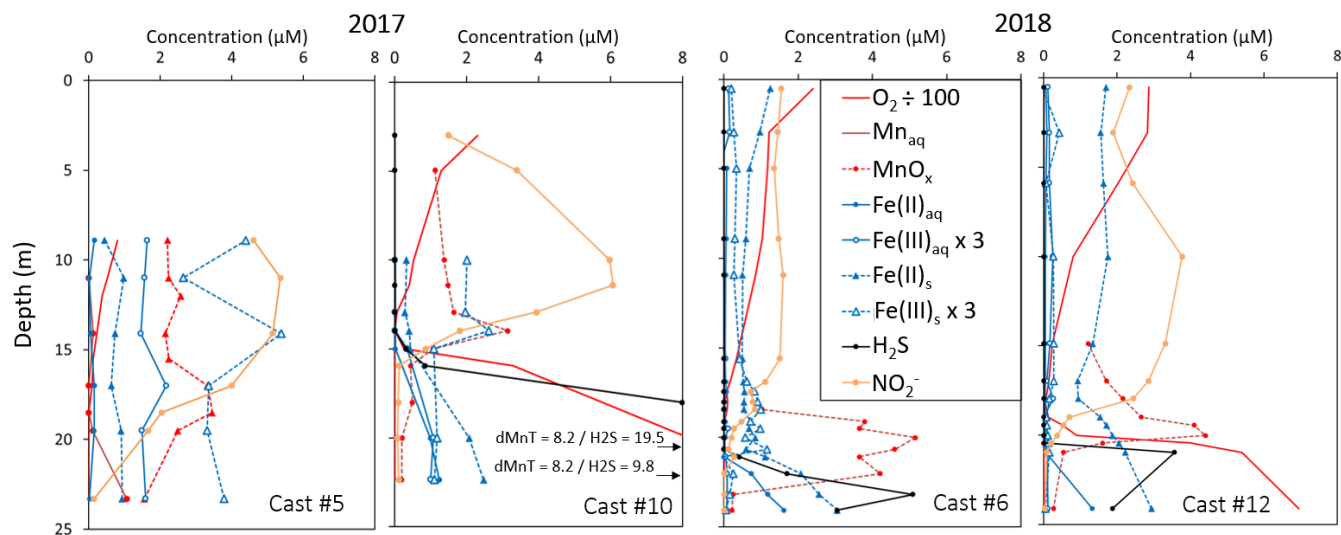

The “reaction driven” interpretation identifies the major reactions controlling the carbonate cycle. In the Chesapeake Bay, similar redox stratification can support varying intensity of carbonate dissolution, absent in 2017 or important as in 2018. The summer anoxia observed in the Chesapeake Bay is characterized by an exceptionally high  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  of 2.4 which has never been reported in anoxic water columns or sediment pore waters. The “reaction driven” interpretation suggests it comes from sulphate reduction followed by almost complete hydrogen sulphide oxidation by  $\text{MnOx}$  followed by  $\text{MnCO}_3$  precipitation. This interpretation is supported by the important manganese dynamics observed. However, the rhodocrosite saturation index is below 1, and the weak pool of manganese measured indicates that most of the reactions would have occurred in the upper pore water from which the  $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$  of 2.4 would have diffused into the bottom water with the redox front during summer water column anoxia set up. Although  $\text{MnCO}_3$  production from  $\text{MnO}_2$  involves no charge transfer (Hu and Cai, 2011), our study demonstrates that it can have strong impact on local alkalinity (Middelburg et al., 2020). The lack of charge transfer visible from the stoichiometry implies that Mn does not bear the alkalinity it produces, but it is a critical element to limit the  $\text{H}_2\text{S}$  oxidation to its  $\text{S}_0$  intermediate forms and finally to favour its burial.
