Abstract. The coastal alkalinity cycle controls the global burial of carbonate which modulates the ability of the ocean to trap anthropogenic CO₂. Twelve high vertical resolution profiles from the temperate Chesapeake Bay estuary during two summers allow precise description of carbonate dynamics over the salinity and redox gradient along with the measurement of the speciation of most redox sensitive elements. In the presence of oxygen, carbonate dissolution, primary production and aerobic respiration are able to explain the evolution of total alkalinity (TA) versus dissolved inorganic carbon (DIC), once corrected for fresh and oceanic water mixing. A significant flooding event in 2018 prevented the trapping of atmospheric CO₂ in the estuary and favoured carbonate dissolution to balance DIC consumption from photosynthesis. In oxygen depleted waters, a particularly high ratio of alkalinity versus DIC occurred ($\Delta TA_{ex}/\Delta DIC_{ex} = 2.4$), that has not been previously reported in the literature, and that seemed invariant over the two years. The stoichiometric analysis agrees with Mn measurements to explain this carbonate signature by the critical role of MnO₂ reduction followed by Mn carbonate precipitation. Our results underline that Fe and Mn are critical elements of the alkalinity cycle, especially due to their ability to limit the H₂S oxidation into SO₄²⁻ and by favouring sulphur burial.

1 Introduction

25 About a third of anthropogenic CO₂ emission is rapidly trapped by dissolution in the ocean as dissolved inorganic carbon (DIC) which is dominated by bicarbonate ions (HCO₃⁻, Friedlingstein et al., 2019). At the century time scale, atmosphere-ocean exchanges result in oceanic HCO₃⁻ enrichment not associated with a Ca²⁺ enrichment, in contrast to the HCO₃⁻ released from continental erosion (preponderant at thousands to a million year scale, Urey, 1952). This disequilibrium corresponds to an excess of proton release compared to carbonate ions during CO₂ dissolution that is only balanced in the deep ocean by
30 increasing Ca²⁺ production from carbonate dissolution, a process named the chemical carbonate compensation (Boudreau et al., 2018). However, in most shallow water, where carbonate precipitation largely predominates over dissolution and accounts for 2/3 of buried carbonate (Smith and Mackenzie, 2016), other, localised processes may constrain the carbonate dynamic (Borges et al., 2006; Lohrenz et al., 2010). For example, some calcifying species may slow down their carbonate precipitation in case of pH decrease (so called biological carbonate compensation; Boudreau et al., 2018). As another example, in estuaries,
35 the seasonality of river flow, temperature and continental erosion modulate CaCO₃ dissolution (e.g. Su et al., 2020b), atmospheric CO₂ exchanges (e.g. Borges et al., 2018) or respiratory activity (Abril et al., 2003). As recently highlighted (Middelburg et al., 2020), the transfer of carbonate particles over estuaries is poorly estimated due to a sparse dataset (Meybeck, 1987).

To better constrain the carbonate cycle in temperate microtidal estuaries and the associated HCO₃⁻ dynamics, we sampled
40 a stratified water column in the Chesapeake Bay a dozen times over two campaigns with a high vertical resolution (down to 10 cm). This protocol allows a precise description of carbonate dynamics over a redox gradient along with the measurement of the speciation of most redox sensitive elements. Such sampling can thus illustrate carbonate chemistry on transitioning from oxygenated waters to waters devoid of oxygen as usually only encountered in sediments or in anoxic lakes or seas (e.g. Black Sea). The original observed changes of alkalinity versus DIC changes are interpreted based on anoxic reactions occurring
45 along the redox gradient.

2 Materials and methods

2.1 Sampling

During two sampling campaign from August 3rd to 9th, 2017 and July 28th to August 3rd 2018 eleven profile casts were conducted in a 25 m water depth in the Chesapeake Bay (Station 858, 38°58.54'N; 076°22.22'W). The Susquehanna River is
50 the main tributary of the bay representing on average 2/3 of the fresh water input (Zhang et al., 2015). Despite similar season, the two campaigns occurred at very different river flow with about 850 m³ s⁻¹ in 2017 versus 8500 m³ s⁻¹ in 2018 due to release of flood waters from the Conowingo Dam and which corresponds to flooding which occurs on average every 3.5 years (return period of 3.5 years, USGS survey).

Each CTD cast was performed during low or high tide slack periods. An oxygen sensor (Clark electrode, SBE Inc.;
55 detection limit of 1 μM) and fluorescence sensor (Eco-FL Fluorometer, WETLabs) were part of the CTD Rosette to take
measurements during sampling. Also, a submersible all plastic pump profiler was attached with the pump near the sensor
orifices allowing measurement and sampling at a resolution of a few centimetres over 25 m water depth. Water was pumped
to the deck within 1 minute and water passed through a flow through voltammetry system measuring continuously O_2 , Mn(II) ,
 Fe(II) , organically complexed Fe(III) , FeS clusters, H_2S and polysulfides (Hudson et al., 2019). When redox interfaces were
60 identified, samples were filtered through an acetate cartridge filter (pore size 0.45 μm) for pH and inorganic carbon parameters,
which were processed onboard within a few hours after sampling in order to conserve chemical speciation. The pump profiler
system was cleaned with DI water onboard the deck of the ship after deployment. No coating effects were observed with the
pump system.

2.2 Discrete Measurements

65 For each sample, all redox species were determined in the through flow voltammetry system using cyclic voltammetry with
a 100 μm Au/ Hg amalgam PEEK microelectrode prepared according to Luther et al. (2008) connected to a DLK-60
electrochemical analyser from Analytical Instrument Systems Inc. The detection limit of this method is 0.2 μM for sulfide and
polysulfides. Discrete samples for the determination of NO_2^- , Fe and Mn species were filtered through nylon luer-lock syringe
filters (Millipore, 0.20 μm) filters. Iron was measured based on the ferrozine method (Stookey, 1970): after HCl acidification
70 and an optional reduction step with hydroxylamine hydrochloric (final concentration 0.7 M) for 1 hour, ammonium acetate
(final concentration 0.5 M) and ferrozine (final concentration 1 mM) were added and absorbance at 562 nm was read with a
diode array spectrophotometer (Hewlett Packard 8452B). Limit of detection is 100 nM for Fe(II) . Shipboard nitrite
determination was performed using the method of Grasshoff (1983). To 25 ml of sample, 0.5 ml of 58mM sulfanilamide in
10% v/v HCl and 0.5 ml of a 4mM N(1-naphthyl)ethylene diamine hydrochloride solution were added. Samples with added
75 reagents were shaken and left to sit for 15 min, followed by UV–Vis analysis at 540 nm using a 10-cm cell to increase detection
limits. Calibration curves were constructed using sodium nitrite. Limit of detection is 10 nM for NO_2^- .

Dissolved manganese was determined by displacement of a Cd(II)-porphyrin complex with Mn(II) to form the Mn(II)-
porphyrin complex (Ishii et al., 1982). Mn(III) species were identified based on slower reactivity with the Cd complex
(Madison et al., 2011) as modified in Thibault de Chanvalon and Luther (2019). Alternatively, Mn(III) species were identified
80 after HCl treatment (down to pH=1.5) follow by filtration in order to flocculate and eliminate the dissolved manganese bound
to humic material by filtration (Oldham et al., 2017b). Limit of detection is 50 nM for Mn(II). MnOx was measured on 20 mL
samples of suspended material retained on 0.2 μm filters by the Leucoberbelin blue (LBB) method (Jones et al., 2019). Four
millilitres of a reagent solution ($[\text{LBB}] = 78 \mu\text{M}$, $[\text{acetic acid}] = 14\text{mM}$) react with the filter and the absorbance is read at 624
nm. KMnO_4 was used to calibrate the LBB method which allows the calculation the electron equivalents obtained from
85 particulate MnOx. Results are given in as MnO_2 equivalent with a limit of detection of 0.1 μM and an uncertainty below 5%.

The DIC samples were preserved in 250-mL borosilicate glass bottle with 50 μL saturated HgCl_2 solution. The TA samples were not poisoned to prevent HgS precipitation and H^+ release in anoxic and low salinity waters (Cai et al. 2017). The DIC samples were measured by a nondispersive infrared analyzer (AS-C3, Apollo Scitech) within a week (Huang et al. 2012). The total alkalinity (TA) was analyzed by Gran titration in an open-cell setting (AS-ALK2, Apollo Scitech) inboard within 24 h of collection (Cai et al. 2010a). The precision for DIC and TA was about 0.1%. Both DIC and TA measurements were calibrated against certified reference materials. The pH samples were measured onboard at 25 °C within 1 h of collection using an Orion Ross glass electrode, and calibrated with NIST standard buffers. The pCO_2 , calcite saturation were calculated from measured DIC and TA via an excel sheet implemented with values from (Millero, 1995) and further validated using CO2sys program. The measured TA was found highly correlated to TA calculated with CO2sys using pH and DIC as input value ($r^2 = 0.998$, slope = 1.03) suggesting low effect of organic alkalinity (Cotovicz Jr. et al., 2016).

2.3 Models of biogeochemical process on TA and DIC

2.3.1 Observed changes induced by biogeochemical process

To distinguish TA and DIC changes produced by biogeochemical processes from the river/ocean mixing, the excess of TA and DIC, noted TA_{ex} and DIC_{ex} have to be calculated. This excess corresponds to the cumulative effects from all unknown biogeochemical processes observed. As total concentrations, TA and DIC are conservative during mixing and can be easily calculated as the deviation from the river-ocean mixing line after identification of riverine and oceanic endmembers. In contrast, pH and the concentrations of individual C species are not conservative. The oceanic endmember selected in this study was the one proposed by Su et al. (2020a) for both DIC and TA. However, the upstream estuary endmember from Su et al. (2020a) corresponded to the Chesapeake Bay in 2016 with a river flow of only 226 $\text{m}^3 \text{s}^{-1}$. The two campaigns described here are characterised by much higher river flow. Since large variations exist in the upstream estuary endmember mainly due to changes of weathering intensity and riverine discharge (Meybeck, 2003; Joesoef et al., 2017), we slightly modify the TA endmember of Su et al. (2020a) to improve the fit with in situ measurements with the lowest measured salinity (Fig. A1). Such changes were not necessary for DIC_{ex} calculation. This endmember is not a river endmember (Su et al., 2020a) but correspond to a salinity above 1.5 preventing any interpretation for biological activity in the fresh water part of the estuary (Meybeck et al., 1988). Compared to Su et al. (2020a), the slope change associated is mostly insignificant ($\text{TA}_{\text{ex}}/\text{DIC}_{\text{ex}}$ differs by less than 0.2) and represents the uncertainty of our description. The TA_{ex} and DIC_{ex} correspond to an excess from a sum of reactions spread all over the estuary and can therefore decomposed into several components induced by multiple localised geochemical reactions, $\Delta\text{TA}_{\text{ex}}$ and $\Delta\text{DIC}_{\text{ex}}$.

2.3.2 TA changes indicated by reactions' stoichiometry

The simplest way to calculate the TA changes induced by individual, localised, geochemical reactions ($\Delta\text{TA}_{\text{ex}}$) is to do a direct look to reaction stoichiometry. Indeed, it is possible to mathematically separate acid active and acid inactive species.

Active species are defined as species forming acid-base couples whose one form is able to exchange protons during the titration of a sample down to pH 4.5 either as electron donor or as acceptor, such as NH_3 or HCO_3^- while inactive species include Cl^- , SO_4^{2-} and Ca^{2+} among others. Writing z , the charge held by a species, the electroneutrality of water can be written as Eq. (1),

$$0 = \sum z_{inactive} + \sum z_{active} \quad (1)$$

120 The total alkalinity (TA) corresponds to the quantity of acid added to titrate a solution down to pH 4.5 (Dickson, 1981), according to Eq. (2), with the example of HCl as acid and B^- any titrated base.

Assuming a complete reaction, the quantity of acid added is equal to the negative charges consumed from the active species pool (Cl^- is inactive). Indeed, the titration transfers the charges from the acid active pool to the acid inactive pool. Thus, the total alkalinity corresponds to the loss of negative charges (or gain of positive charges) for active species produced by the pH
125 change from the initial $\text{pH} = \text{pH}_{ini}$ to $\text{pH} = 4.5$ (Eq. (3)):

$$\text{TA} = \sum z_{active}^{\text{pH}=4.5} - \sum z_{active}^{\text{pH}_{ini}} \quad (3)$$

Equation (1) can be reorganized and combined with Eq. (3) leading to Eq. (4) :

$$\begin{aligned} \sum z_{inactive} &= - \sum z_{active}^{\text{pH}_{ini}} + \sum z_{active}^{\text{pH}=4.5} - \sum z_{active}^{\text{pH}=4.5} \\ \text{TA} &= \sum z_{inactive} + \sum z_{active}^{\text{pH}=4.5} \end{aligned} \quad (4)$$

From Eq. (4), one can easily deduce the changes of alkalinity. Most of the time, the only charged active species at $\text{pH} = 4.5$, are H_2PO_4^- and NH_4^+ . In that respect, whatever the initial pH and the acid-base equilibrium of species in the sample, the sum of phosphate species will count negatively and the sum of ammonium species will count positively. Strictly speaking, at
130 $\text{pH}=4.5$, acid species with pK_a between 2.5 and 6.5, such as F^- and NO_2^- , would be only partially titrated and the charge equals their concentration multiplied by a correction factor of $(1+10^{\text{pK}_a-4.5})^{-1}$, but this correction can be neglected to a first approximation. The Eq. (4) corresponds to those published in Soetaert et al. (2007) or Wolf-Gladrow et al. (2007) whose equation 32 can be find back replacing the two term in Eq. (4) by:

$$\begin{aligned} \sum z_{inactive} &= [\text{Na}^+] + 2 [\text{Mg}^{2+}] + 2 [\text{Ca}^{2+}] + [\text{K}^+] + 2[\text{Sr}^{2+}] + \dots - [\text{Cl}^-] - [\text{Br}^-] \\ &\quad - [\text{NO}_3^-] - 2\text{T}\text{SO}_4 - \text{T}\text{H}\text{F} - \text{T}\text{H}\text{NO}_2 - \dots \\ \sum z_{active}^{\text{pH}=4.5} &= -\text{T}\text{P}\text{O}_4 + \text{T}\text{N}\text{H}_3 \end{aligned}$$

where $TPO_4 = [H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [PO_4^{3-}]$, $TNH_3 = [NH_3] + [NH_4^+]$, $TSO_4 = [SO_4^{2-}] + [HSO_4^-]$, $THF = [F^-] + [HF]$, and $THNO_2 = [NO_2^-] + [HNO_2]$. However, the Eq. (4) is more synthetic and more general. For example, in suboxic water, specific species such as polysulfides (as HS_8^{2-} , Rickard and Luther, 2007) and in highly productive environment, carboxylic group from DOC can be easily added as soon as the bearing charges at $pH = 4.5$ are known. Finally, note that the definition of active species used differs from the weak acid-base couple definition, since our definition classifies the weak acid-based couples with pK_a between -1.75 and 4.5 as inactive species, but the reasoning would be similar if the term active/inactive species is changed by weak/strong acid-base couple.

2.3.3 Linear combinations of reactions

To estimate the participation of each reaction to the observed changes of TA_{ex} , DIC_{ex} and AOU or H_2S , a linear combination of pre-selected reactions is calculated. This combination has to fit 3 equations (one for each parameter) which allows a maximum of 3 variables to be used to solve the system. Each reaction being one variable, a limited number of reactions is selected as candidates based on the discussion (see section 3.3.2). Then, the system is solved with the minimum possible reactions.

3 Results and Discussion

3.1 Water column stratification

High-resolution (< 1 m) profiles of carbonate and redox chemistry are plotted against salinity in Fig. 1. These data result from the 11 CTD casts performed over 1 week during each campaign and correspond to depths ranging from 2 to 25 meters. While direct plots against depth generate noisy profiles that are less informative, plots against salinity provide consistent information about the processes. Despite the overall much lower salinity due to a near 7-fold flow increase in 2018 than 2017 ($5800 \text{ m}^3 \text{ s}^{-1}$ in 2018 versus $850 \text{ m}^3 \text{ s}^{-1}$ in 2017), similar zonation of the water column occurred. A surface layer (named primary production zone or PP in Fig. 1) is characterized by high amount of O_2 (about or above 100% saturation), high pH (above 7.5), high day to day temperature variation (above 1°C between different days) and low pCO_2 (below atmospheric CO_2 of $400 \mu\text{atm}$). This signature corresponds to important atmospheric exchange and primary production (PP). Fluorescence (not shown) correlates with pH as expected for primary production ($pH = \text{Fluo (mV)} \times 13 + 7.14$, $r^2=0.8$ in 2017 and $r^2=0.9$ in 2018). Below, with increasing depth, an important increase of pCO_2 accompanying the decrease of O_2 , pH and temperature is visible. A relatively invariable low O_2 zone (called ILO in Fig. 1) is here defined by the depth invariance of O_2 concentrations, and corresponds to a concentration of about $30 \mu\text{M}$ in 2017 and $110 \mu\text{M}$ in 2018. Other species are also relatively stable for this depth such as pCO_2 , at about $2500 \mu\text{atm}$ in 2017 and $1800 \mu\text{atm}$ in 2018, and pH , about 7.3 in 2017 and 7.4 in 2018. Deeper, where the oxygen is not detectable ($< \sim 1 \mu\text{M}$), the so-called suboxic zone corresponds to a pH minimum at 7.2 that generates a pCO_2 maximum. The deepest layer is a sulfidic layer in which the pH seems quite stable at 7.4 and 7.3 in 2017 and 2018 respectively. The main changes between the two campaigns correspond to a greater oxygen penetration in 2018, preventing

165 nitrite accumulation, and to the appearance of a surface layer (with salinity below 3) that stands above the primary production zone in 2018.

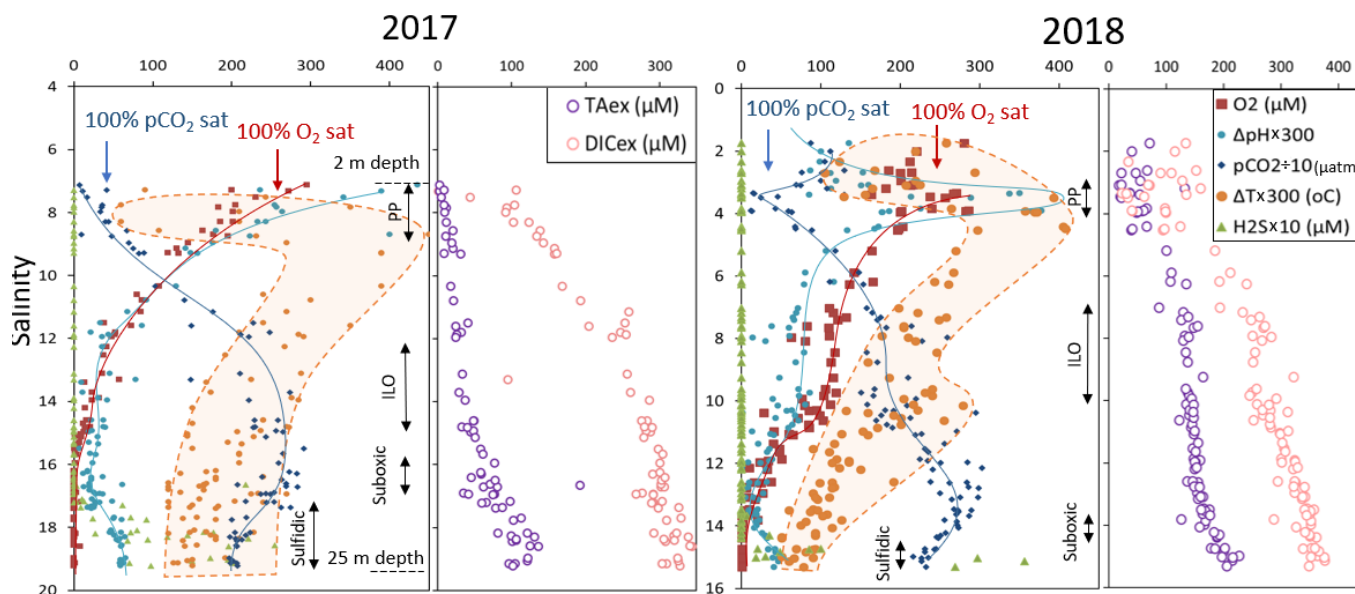

Figure 1: Superimposed carbonate and redox chemistry profiles over 11 casts. Simple mathematic transformation allows to plot all variable on the same scale, lines are only here to guide eyes. Base line for temperature is 25 °C and base line for pH 7.175. For example, pH maximum value of 400 correspond to a $\text{pH} = 400/300 + 7.175 = 8.5$, a reading at 100 for $\text{pCO}_2 \div 10$ indicates a value of $\text{pCO}_2 = 1000 \mu\text{atm}$.

The development of the suboxic zone during summer (Su et al., 2021) and the regularity of this development over the years (Sholkovitz et al., 1992; Trouwborst et al., 2006; Lewis et al., 2007; Cai et al., 2017; Oldham et al., 2017a), requires the presence of species able to rapidly oxidise the H_2S mixing upward and to reduce the O_2 mixing downward. The three main redox couples known to play this role, $\text{NO}_3^- / \text{NO}_2^-$, $\text{MnO}_x / \text{Mn}^{2+}$ and $\text{Fe}^{3+} / \text{Fe}^{2+}$ are described in the Fig. 2 by the superimposition of all cast results against salinity. Four representative casts are plotted in the Fig. A2. NO_2^- reaches a maximum in the ILO zone, at low but measurable oxygen concentrations. Because of the presence of oxygen, the NO_2^- production would be more likely associated with nitrification of the NH_4^+ diffusing upward rather than denitrification despite the possibility of reducing conditions occurrence in micro niches. Just below oxygen depletion, in the suboxic zone, MnO_x reaches a maximum probably produced by the Mn^{2+} diffusing upward that is biologically oxidized by very low, undetected, O_2 concentration (Clement et al., 2009). Additionally, Mn^{2+} could be oxidized by the nitrite diffusing downward (thermodynamically favourable (Luther, 2010)), it is also possible that the Mn oxidation is produced by chemodenitrification *i.e.* by reduction of (not measured) nitrate into nitrite. The MnO_x decrease fits perfectly to the Mn^{2+} increases in sulfidic conditions (Fig. 2) according to the reduction of settling MnO_x by H_2S . The increase of total manganese concentration with depth may result from sedimentary efflux or dissolved manganese trapping in more stagnant bottom water. No Mn(III) was detected with the porphyrin kinetics method (Thibault de Chanvalon and Luther, 2019) but about 30% of the total dissolved manganese flocculated after

acidification down to pH 1.5 when analysed in 2017. Although similar recycling is expected for iron, fresh precipitates are harder to catch due to higher particles content, and, in our study, lower dissolved total Fe concentration. Some features are discernible for a single cast (Fig. A2), but overall the only merging picture is an increase with proximity to the sediment interface for dissolved Fe(III) and Fe(II) and solid Fe(III) and Fe(II) (Fig. 2).
185

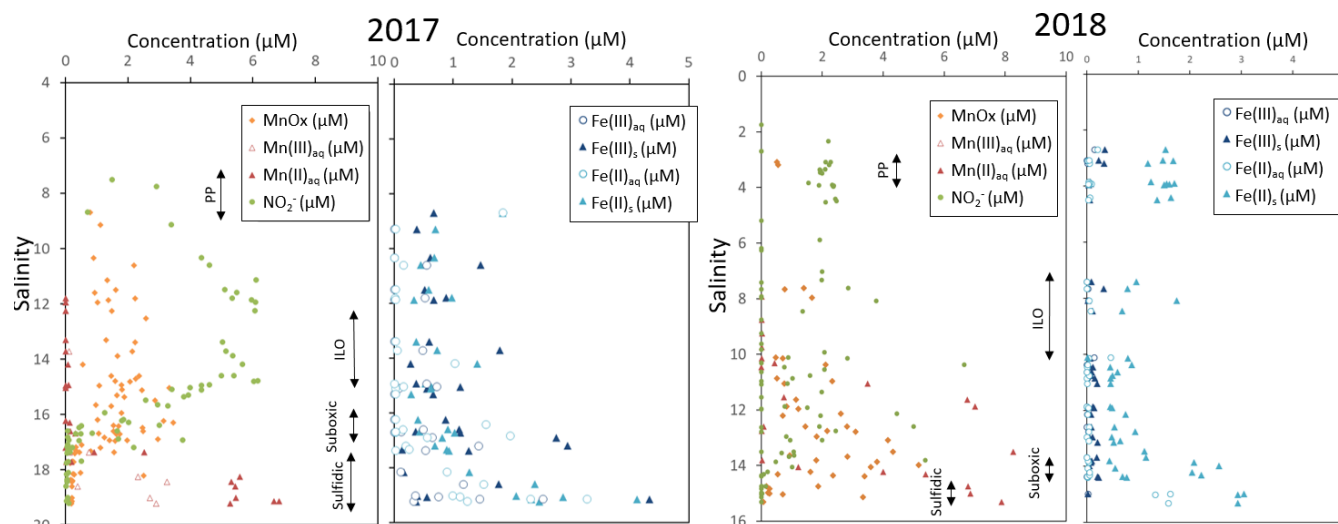

Figure 2: Mn, Fe and nitrate profiles build by superimposition of 11 casts for each campaign.

3.2 River flow control

In rivers, the carbonate system equilibria depend on processes as varied as weathering intensity, draining bedrock and *in situ* biological activities. The inspection of dissolved inorganic carbon (DIC) changes versus total alkalinity (TA) changes is a frequent and efficient method to unravel the origin of these changes whereas other related parameters such as pCO₂ or pH are non-conservative during mixing and harder to interpret (*e.g.* Cai et al. 2017). However, due to river mixing with ocean waters, both TA and DIC change with salinity (S) as observed in the Chesapeake Bay during our campaigns ($r^2 > 0.95$, Fig. A1). The calculation of the excess of TA and DIC, named TAex and DICex (see section 2.3.1), is required to interpret further biogeochemical processes (Su et al., 2020b).
190

DICex increases progressively with depth up to about 330 μM and 350 μM at 25 m depth in 2017 and 2018 respectively (Fig. 1). The plot of TAex versus DICex (Fig. 3a) shows at the lowest observed salinity (7.1 in 2017 and 1.7 in 2018), an intercept for TAex = 0 corresponding to DICex ~ 40 μM. This offset is within the uncertainty of the endmember calculation even if slight DICex background enrichment has been modelled (Shen et al., 2019) resulting from faster atmospheric equilibration of O₂ than CO₂ after respiration reactions. Interestingly, the relative changes of DICex and TAex, further named ΔTAex and ΔDICex, does not depend on the endmember calculation and their ratio presents much lower uncertainties (about
195

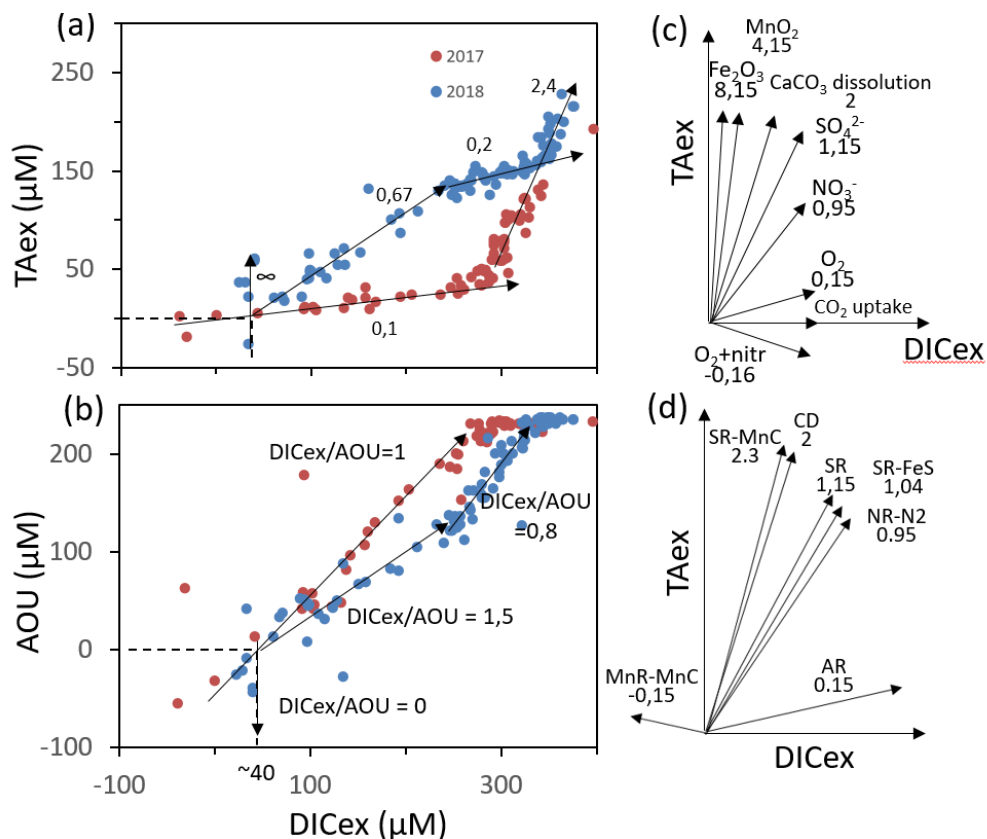

Figure 3: Description of the Taex/DICex/AOU system. (a) and (b) panels show samples measured along with interpretative slope discussed in the main text. Panels (c) and (d) show theoretical slope of Taex/DICex, (c) from seven primary redox reaction in seawater (pH=8,2) described in Soetaert et al. (2007). (d) from combination of reaction discussed in the main text.

200 0.1) facilitating their interpretation. In 2017, TAex stayed almost constant up to the oxic zone (Fig. 3a) with a $\Delta TAex/\Delta DICex$ ratio of 0.1 ± 0.1 which indicates a net aerobic respiration (AR) (theoretical slope of $\Delta TAex/\Delta DICex = 0.15$ see Table 1 and Fig. 3c). The AOU increase (Fig. 3b) confirms this possibility with a $\Delta DICex/\Delta AOU$ signal similar to the expected theoretical slope of 1 for AR (Table 1). Note that this $\Delta TAex/\Delta DICex/\Delta AOU$ signature stands for absent or negligible nitrification following respiration. In case of nitrification, the theoretical slopes should be $\Delta TAex/\Delta DICex = -0.165$ and $\Delta DICex/\Delta AOU = 0.76$ as proposed by Zeebe and Wolf-Gladrow (2001). The absence of noticeable nitrification can be explain by slow kinetics of NH_4^+ oxidation, with a half-life time estimated between a few days in estuaries (Horrrigan et al., 1990) to multiple years in coastal environments (Heiss and Fulweiler, 2016). As a comparison, other NH_4^+ fates, such as adsorption leads to ammonium half life time of about a few minutes (Alshameri et al., 2018) to a few hours (Raaphorst and Malschaert, 1996) depending on the concentration of fine particles. Additionally, algae are known to use NH_4^+ as a N source (Raven et al., 1992) and NH_4^+ can be directly assimilated by heterotrophic organisms. Finally, for 2017, despite pCO_2 being below atmospheric saturation at

205

210

about 2 m depth (Fig. 1), the possible CO₂ invasion does not significantly modify the observed ΔDIC_{ex}/ΔAOU signal at the shallowest depth sampled.

In 2018, this surface water history did not repeat as fresh and light water masses brought by the exceptional flood drastically modified the carbonate system equilibrium. First, a low salinity layer with pCO₂ at 1000 μatm overlays the primary production layer (Fig. 1), preventing the uptake of atmospheric CO₂ by primary production as was observed for other years (Chen et al., 2020). Just below the air-sea interface, the lock down of atmospheric exchanges by the low salinity layer produces supersaturation of trapped O₂ (Fig. 1, for S between 3 and 4). In Fig. 3a and 3b, this process translates into a vertical distribution at DIC_{ex} = 40 μM associated with negative AOU and slightly positive TA_{ex}. This original signature can be modelled by the combination of simultaneous carbonate dissolution (CD) and PP fuelled by NH₄⁺, in equal proportion and would result in no

Table 1: Summary of the main net reactions occurring among the different zones of a redox gradient with reactants starting in equilibrium with the atmosphere, adapted from Soetaert et al. (2007). The calculations assume Redfield ratio of the organic matter, i. e. $\gamma^N = 0.156$ and $\gamma^P = 0.0094$ (Soetaert et al., 2007). Redox zones describe the different conditions required for completing the reaction.

Name	Redox zones	Net Formula	ΔTA	ΔDIC
AR	Oxic	$(\text{CH}_2\text{O})(\text{NH}_3)_{\gamma^N}(\text{H}_3\text{PO}_4)_{\gamma^P} + \text{O}_2 \rightarrow \gamma^N \text{NH}_3 + \gamma^P \text{H}_3\text{PO}_4 + \text{CO}_2 + \text{H}_2\text{O}$	0.15	+1
CD	Any	$\text{CaCO}_3 + \text{CO}_2 \rightarrow \text{Ca}^{2+} + 2 \text{HCO}_3^-$	2	+1
NR-N2	Suboxic	$(\text{CH}_2\text{O})(\text{NH}_3)_{\gamma^N}(\text{H}_3\text{PO}_4)_{\gamma^P} + 0.8 \text{HNO}_3 \rightarrow \gamma^N \text{NH}_3 + \gamma^P \text{H}_3\text{PO}_4 + \text{CO}_2 + 0.4 \text{N}_2 + 1.4 \text{H}_2\text{O}$	0.95	1
MnR-MnC	Suboxic	$(\text{CH}_2\text{O})(\text{NH}_3)_{\gamma^N}(\text{H}_3\text{PO}_4)_{\gamma^P} + 2 \text{MnO}_2 + \text{CO}_2 \rightarrow \gamma^N \text{NH}_3 + \gamma^P \text{H}_3\text{PO}_4 + 2 \text{MnCO}_3 + \text{H}_2\text{O}$	0.15	-1

DIC_{ex}, only TA_{ex} production (see Table 2); the carbonate dissolution buffers the DIC consumption produced by PP. The Ca²⁺ concentrations observed by Su et al. (2021) and during the 2018 cruise (data not shown) vary linearly with salinity i. e. [Ca²⁺]

= 0.282 S + 0.4 in mmol L⁻¹. Assuming similar behaviour in 2017, calculations show that the whole water column is undersaturated with respect to calcite and validates the possibility for CD.

225 In 2018, below the PP zone down to DIC_{ex} = 240 μM, the beginning of the ILO zone, the TA_{ex} increases significantly with a ΔTA_{ex}/ΔDIC_{ex} signature incompatible with AR (ΔTA_{ex}/ΔDIC_{ex} = 0.67 ± 0.1, Fig. 3A) and a ΔDIC_{ex}/ΔAOU close to 1.5. Although there are other available candidates, a contribution of CD superimposed on AR seems most likely (theoretical ΔTA_{ex}/ΔDIC_{ex} slope of 2 for CD, Table 1). A linear combination fitting leads to TA contribution of 13% from AR and 87% from CD (Table 2) and results in ΔTA_{ex}/ΔDIC_{ex} = 0.77 and ΔDIC_{ex}/ΔAOU = 1.5. An explanation of its occurrence solely
230 in 2018 could be particularly carbonate rich suspended material at high flow conditions. Deeper, in the ILO zone, the relations of ΔTA_{ex}/ΔDIC_{ex}/ΔAOU (Fig. 3) result from aerobic respiration with almost indiscernible carbonate precipitation (ΔTA_{ex}/ΔDIC_{ex} = 0.2, ΔDIC_{ex}/ΔAOU = 0.8). Overall, our results show that the higher river flow of 2018 increases carbonate

Table 2: Linear combination of reactions from Table 1 that fit the observations (see text for details, H₂O molecules are omitted).

dissolution for the top 5-10 m depth (at salinity below 8) that superimpose on primary production (for salinity below 4) or aerobic respiration (for salinity between 4 and 8).3.3. Sediment control

235 3.3.1 Identification of preponderant reactions

In the absence of oxygen, in the suboxic and sulfidic zone, both campaigns show a similar evolution of the TA_{ex} and DIC_{ex} with very high $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ of 2.4 (Fig. 3a). This exceptionally high ratio, never reported in the literature, cannot be explained by most typical chemical reactions such carbonate dissolution (CD), aerobic respiration (AR), CO₂ uptake or primary production (PP = -AR). A scenario combining sulfate reduction (SR) is particularly attractive since SR represents the main carbon remineralisation pathway in absence of oxygen. However, a combination of SR with CD would result in a $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ between 1.15 and 2 (see Table 1 or Fig. 3c) and fails to reach the $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ of 2.4. Moreover, SR alone underestimates the importance of the H₂S oxidation pathway. H₂S oxidation is critical in the Chesapeake Bay since no H₂S is measurable in the suboxic zone while the gradient at the sediment/water interface indicates high H₂S sedimentary efflux (Fig. 1) and that oxidation can consume all the alkalinity produced during SR, as with oxygenated oxidation (see reaction SR-O in Table 1).

Generalizing these observations, recent efforts to build an alkalinity budget on the global scale (Hu and Cai, 2011; Middelburg et al., 2020) highlight that the alkalinity produced by anaerobic respiration corresponds to the uncharged species produced, mostly in solid or gaseous phases. Indeed, the alkalinity changes produced during a natural reaction equal the “charges transfer” from species having some charge at pH = 4.5, such as NO₃⁻ and SO₄²⁻, to “acid active species” that would lose its charges at pH = 4.5, mainly HCO₃⁻, that does not count in the alkalinity calculation (see Eq. (4)). Although correct, this approach tends to neglect the roles of Fe and Mn oxides (Middelburg et al., 2020) since their transformation from (oxyhydr)oxides into sulphur or carbonate species does not involve any charge transfer. When looking in detail at these processes, the metal oxides are critical since they are the main H₂S oxidation pathway that does not regenerate H₂SO₄ but rather produces S⁰ instead (Findlay et al., 2014; Avetisyan et al., 2021) which limits alkalinity consumption. The plot of selected redox sensitive species against TA_{ex} (Fig. 4) reveals a particular behaviour of MnOx in the suboxic water with a maximum concentration at the disappearance of O₂ followed by a decrease down to zero in presence of H₂S. Manganese changes from MnOx to Mn²⁺, and ultimately to MnCO₃, consuming DIC and transforming H₂S to a non-charged species. This TA source is generally overlooked but may be important in the Chesapeake Bay. Fig. 2 and 4 also depict recycling of NO₂⁻ whose concentrations increase simultaneously to O₂. However, the small vertical shift between NO₂⁻ and O₂ minimum (Fig. 4) and the lack of overlap between NO₂⁻ and H₂S indicates that NO₂⁻ does not directly oxidize H₂S. Since, NH₄⁺ and NO₃⁻ concentration were not measured, we limit our reasoning to the layer depleted in NO₂⁻, that signals the negligible role of N cycling at these depths.

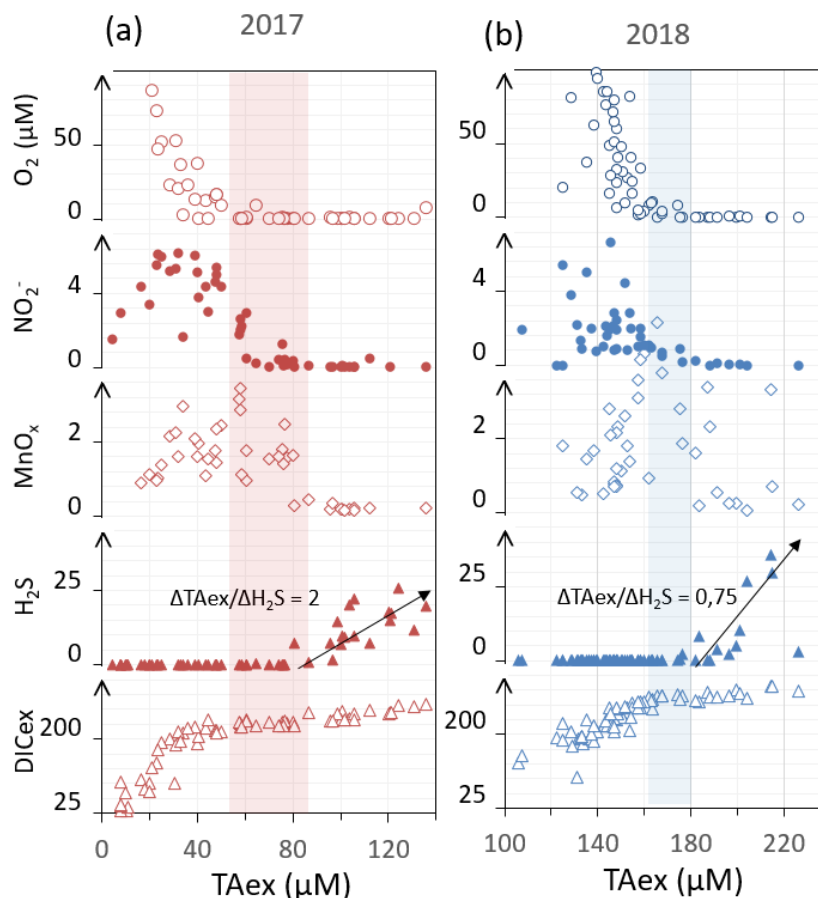

Figure 4: Evolution of selected species versus TAex for the 2017 (a) and 2018 (b) campaigns with the suboxic zone colored.

In the anoxic layer, most of the dissolved species are at too low concentration (*e.g.* Mn^{2+}_{aq} , Fe^{2+}_{aq}) to be a net reagent to affect the carbon cycle on a monthly time scale. These species are usually recycled rapidly and hold a role of catalyser or electron shuttle between other redox species. Therefore, to explain the 100 μM TAex increase in absence of oxygen (Fig. 3a), only aqueous species with “important” stock concentrations at a monthly timescale (with concentrations that frequently exceed 1 mM in anoxic porewater) are taken into account, *i. e.*, SO_4^{2-} , Ca^{2+} , H_2S , NH_4^+ together with gaseous (N_2 , CO_2) and main solid phases (FeS , S^0 , $MnCO_3$, $FeOOH$, MnO_2). Based on these species, we detailed the most likely preponderant reactions for each redox zone (Table 1), although, for the sake of simplicity, many mineral and associated reactions are neglected (*e.g.*, iron phosphate, ferrous or manganous oxide, sulphur clusters, adsorption processes, reverse weathering). For the suboxic zone, the nitrite reduction associated with N_2 production or denitrification (NR- N_2 , Table 1) and the manganese oxides reduction associated with manganese carbonates precipitation (MnR-MnC, Table 1) represent the main expected respiration processes. The reduction of HNO_3 down to NH_3 is not detailed but would result in almost similar alkalinity changes: 1.15 for NH_3 production (DNRA) versus 0.95 for N_2 production. The only solid form of Mn(II) is $MnCO_3$, since MnS is negligible despite

275 thermodynamic possibilities. FeCO_3 production would produce a very similar reaction as MnCO_3 production; the latter, more
common, is favoured in this simple description. Accordingly, the only solid product from iron reactions is FeS and requires a
coupling between iron oxide respiration and the minimum required amount of sulfate reduction (equation SR- FeS). However,
 FeS_2 is implicitly taken into account since it corresponds to FeS plus S_0 and a specific coupling of iron oxide respiration with
sulfate reduction to produce FeS_2 would result in $\Delta\text{TA}_{\text{ex}}=1.21 \text{ molC}^{-1}$ instead of $\Delta\text{TA}_{\text{ex}}=1.04 \text{ molC}^{-1}$ when FeS is the final
280 product (Table 1). After sulfate reduction, H_2S can also accumulate in the water (SR reaction) or be oxidized back to SO_4^{2-}
(SR-O is detailed as an example). Finally, SR-MnC describes H_2S oxidation by MnO_2 into S_0 . Table 1 illustrates the importance
of metal oxide to generate amount of high alkalinity in the case of sulfate reduction. In particular, it highlights that the higher
 $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ obtained ratio is 2.3 which corresponds to a combination of sulfate reduction follow by Mn (or Fe) oxide
reduction follow by Mn (or Fe) carbonate precipitation, and is here illustrated by the SR-MnC reaction from Table 1.

285 3.3.2 Quantification of reactions importance

In the absence of H_2S , the simplest combination leading to the observed $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ of 2.4 ± 0.1 is to consider sulfide
oxidation by MnO_x and formation of MnCO_3 leading to the SR-MnC reaction (theoretical ratio of $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}} = 2.3$, see
Table 1). More complex combinations to better fit the $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ can be found graphically in Fig. 3d. Note here the
arrows demonstrate that the slope of 2.4 can be obtained for any reaction in combination with MnR-MnC. Combinations
290 without MnR-MnC, however, leads to a negative SR and are not considered despite a possible small participation of
anoxygenic phototrophic (purple) bacteria (Findlay et al., 2015, 2017). Therefore, in the absence of nitrate, oxygen and H_2S ,
only a combination of MnR-MnC with SR-MnC (producing S^0 , Table 2), SR- FeS (producing FeS , Table 2) or CD (releasing
 Ca^{2+} , Table 2) gives the particularly high $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ of 2.4. S_0 was not measured during our campaign, but it has been
reported at this site (Findlay et al., 2014); thus, S_0 produced by SR-MnC can react with FeS to form FeS_2 . The three identified
295 combinations require a critical role of MnO_2 in agreement with the observed remobilization in the hypoxic zone (Fig. 4).
However, since the Ca^{2+} survey (Su et al. 2021) did not reveal a significant production in the Chesapeake Bay, and since the
available data on iron speciation (Fig. 2) do not indicate any clear reaction, the combination of MnR-MnC with SR-MnC is
most likely.

In the presence of H_2S , a closer look at the relation between $\Delta\text{H}_2\text{S}$ versus $\Delta\text{TA}_{\text{ex}}$ (Fig. 4) reveals an interannual variation
300 of the $\Delta\text{TA}_{\text{ex}}/\Delta\text{H}_2\text{S}$ ratio changing from 2 in 2017 to 0.75 in 2018 whereas the theoretical ratio of SR is $\Delta\text{TA}_{\text{ex}}/\Delta\text{H}_2\text{S} = 2.3$
when no H_2S is oxidized. These observed ratios indicates either TA_{ex} consumption without H_2S oxidation or H_2S formation
without TA_{ex} production. The retained combination should implicate at least SR, to produce the H_2S , and MnR-MnC, to
increase the $\Delta\text{TA}_{\text{ex}}/\Delta\text{DIC}_{\text{ex}}$ slope, but it also requires another reaction to decrease the $\Delta\text{TA}_{\text{ex}}/\Delta\text{H}_2\text{S}$ ratio. Since carbonate
under saturation prevents carbonate precipitation, and no primary production is expected, the most likely source of H_2S is from
305 S_0 , although FeS_2 is also possible, as depicted in Table 2. From this equation, the main TA source is the absence of SO_4^{2-}
regeneration after sulfate reduction whereas the second source is the nutrient release that accounts for 19% and 29% of the TA

produced in 2017 and 2018, respectively. The alternative possibility of NH_4^+ oxidation by MnO_2 into N_2 (Mn-anammox, (Luther et al., 1997; Thamdrup, 2012)) could also reduce the alkalinity without additional H_2S oxidation.

310 Based on the stoichiometry proposed, about $88 \mu\text{M}$ to $155 \mu\text{M}$ of MnO_2 are required to produce the $100 \mu\text{M}$ TAex increase observed (Fig. 3a), one order of magnitude higher than the observed MnOx concentration (Fig. 4). Based on an average concentration of $20 \mu\text{mol g}^{-1}$ of Mn in suspended particles, the $88 \mu\text{M}$ of MnO_2 would require a suspended material concentration of about 4.4 g L^{-1} , which is again one or two orders of magnitude higher than the $0.01 - 0.1 \text{ g L}^{-1}$ usually found in the Chesapeake Bay. However, previous studies at this station (*e.g.*, Sholkovitz et al., 1992) explained the seasonality of anoxia with an upward move of the redox front from the sediments to bottom waters during the start of summer. Accordingly, 315 it is likely that the observed dissolved species, notably TAex and DICex, have not been produced in the water column but rather in the sediment during the year and then transported simultaneously with other reduced elements as the summer begin. Therefore, the $100 \mu\text{M}$ TA increase does not fit with the ambient Mn^{2+} or MnO_2 in the water column but rather with the MnCO_3 deposited in the sediment. The sedimentary solid Mn stock is about 10 mM (assuming a porosity of 0.8, a solid density of 2.6 and a Mn content of $20 \mu\text{mol g}^{-1}$), which largely exceeds the $88 \mu\text{M}$ required to produce the $100 \mu\text{M}$ TAex increase.

320 At a global scale, beside its role on alkalinity, MnO_2 can also be a trap for CO_2 as proposed in this Urey-Ebelman (Urey, 1952, Eq. 5) like reaction (Eq.6):

Assuming all the Mn is in the form of MnO_2 , a weathering intensity similar to iron (Poulton and Raiswell, 2002) and based on the upper continental crust composition (Rudnick and Gao, 2003), the continental MnO_2 input to the ocean can be estimated at $0.4 \times 10^{12} \text{ mol y}^{-1}$. Assuming a steady state ocean toward Mn and MnCO_3 as the unique sedimentary phase, this estimation 325 represent 1.4 % of the total carbonate burial (Middelburg et al., 2020). Although negligible at the global scale, this carbonate burial may be significant in MnO_2 rich semi-enclosed basins.

Conclusion

The summer anoxia observed in the Chesapeake Bay is characterized by exceptional high $\Delta TA_{ex}/\Delta DIC_{ex}$ of 2.4 which
330 has never been reported in anoxic water columns or sediment pore waters. By comparison, pore water $\Delta TA_{ex}/\Delta DIC_{ex}$ was
measured at 1.15 in the Gulf of Mexico (Hu et al., 2010) with $\Delta TA_{ex} / \Delta H_2S \sim 2.2$ as expected when sulfate reduction is
associated with H_2S accumulation (theoretical $\Delta TA_{ex} / \Delta H_2S$ ratio from SR being 2.3, Table 1). In the Baltic Sea, a
 $\Delta TA_{ex}/\Delta DIC_{ex}$ ratio of 1.3 was reported (Lukawska-Matuszewska, 2016) with $\Delta TA_{ex} / \Delta H_2S > 17.5$, signs of important H_2S
consumption by Fe oxides. In oxygenated coastal sediment, where dissolved reduced compounds are oxidised before release
335 in the water columns, fluxes of TA over fluxes of DIC ranged from 0.4 to 1 (Rassmann et al., 2020 and references therein). In
the Chesapeake Bay, $\Delta TA_{ex} / \Delta H_2S$ is below 2.3, a sign of another preponderant reaction. The stoichiometry analysis agrees
with direct measurements to underline the critical role of MnO_2 reduction followed by Mn carbonate precipitation. This
scenario could be confirmed by a careful analysis of Mn oxides concentration in the bottom sediment during the entire year,
since semi-enclosed basins are known to concentrate manganese oxides into the deeper area during oxygenated conditions
340 (Thamdrup and Dalsgaard, 2000; Madison et al., 2013; Lenstra et al., 2020). Despite the fact that $MnCO_3$ production from
 MnO_2 involves no charge transfer (Hu and Cai, 2011), our study demonstrates that it can have strong impact on local alkalinity
(Middelburg et al., 2020). The lack of charge transfer visible from the stoichiometry implies that Mn has no bearing on the
alkalinity it produces, but it is a critical element to limit the H_2S oxidation to its S_0 intermediate form and finally to favour its
burial.
