Abstract. Wind-waves and swell are a main driver of coastal environment changes. Wave setup contribute to coastal hazards such as coastal flooding during extreme water level events. Wave characteristics used to estimate wave setup are sensitive to changes in water depth in shallow and intermediate waters. However, wave models used for historical simulations and
15 projections typically do not account for water level changes whether from tides, storm surges, or long-term sea level rise. In this study, the sensitivity of projected changes in wave characteristics to the non-linear interactions between waves and water level changes is investigated along the Atlantic European coastline. For this purpose, a global wave model is dynamically downscaled over the northeastern Atlantic for the 1950-2100 period and for two climate change scenarios (SSP1-2.6 and SSP5-8.5). Twin experiments are performed by accounting (or not) for hourly variations of water level from regional ocean
20 simulations in the regional wave model. The largest impacts of wave-water level interactions are found in the Bay of Mont-Saint-Michel in France, due to a large tidal range of 10 m. At this location and during an historical extreme event, significant wave height was found to be up to 1 m higher (or +25 %) when considering water level variations. At the end of the 21st century under SSP5-8.5 scenario, the wave simulation including water level variations exhibits an increase in extreme significant wave heights and wave setup values by up to +20 % and +10 % respectively. These results are found for many
25 coastal points of the large continental shelf where shallow and intermediate water dynamics prevail, and especially so in macro-tidal areas. However, as the wave setup is computed with a parameterization based on offshore characteristics, the depth-induced wave breaking is not activated in the model. The estimates provided in this study therefore only partially represent the processes responsible for the wave-water level non-linear interactions.

1 Introduction

30 Coastal zones are among the most densely populated and urbanized areas in the world (McMichael et al., 2020; Neumann et al., 2015; Wolff et al., 2020). Wind-waves and swell are a major driver of coastal environment changes (Ranasinghe, 2016) and can drive coastal marine hazards such as coastal flooding (Melet et al., 2020b). Coastal marine flooding is most severe during extreme water level events. Extreme water levels actually cause most of the sea level-related damages and are on the rise due to mean sea level rise (e.g. Fox-Kemper et al. 2021, Le Cozannet et al. 2022).

35 Wind-waves and swell contribute to extreme water level events at the coast via wave setup and runup, combined with astronomical tides, storm surges (due to low atmospheric surface pressure and wind setup) and mean sea level changes. In this study, wave contribution assessment will be limited to wave setup. Wave setup corresponds to the time-mean (over several wave groups) elevation of the water level in the shallow surf zone due to breaking waves (Dodet et al., 2019; Longuet-Higgins and Stewart, 1964). At a large spatial scale, wave setup usually scales with offshore wave characteristics such as the wave
40 height and wavelength (Holman, 1986; Stockdon et al., 2006; Dodet et al., 2019). As a rule of thumb, wave setup reaches 10 % to 20 % of the significant wave height (Holman, 1986; Guza and Thornton, 1981).

To build knowledge on future changes in wave climate, a growing number of global and regional wave projections have been developed and intercompared (Hemer et al., 2013; Hemer and Wand 2017; Morim et al., 2018, 2021; Lobeto et al., 2021; Meucci et al., 2020). Projections are commonly based on dynamical wave models forced by projected surface winds from
45 general circulation models, notably from climate models contributing to the Coupled Model Intercomparison Project (CMIP), with potential downscaling of atmospheric forcing. Regional dynamic downscaling can be used to provide wave projections at higher resolution. A multi-model analysis is required to assess uncertainties and robustness of projected wave climate changes. Morim et al., 2018, 2019 provided a review of wave projections. Over the northeastern Atlantic and Mediterranean Sea bordering the coasts of western Europe, models project a robust decrease in annual and seasonal mean significant wave
50 height, together with a decrease in the mean wave period. Regarding mean wave direction, a robust clockwise change is projected for the Atlantic Iberian coast. Extreme significant wave heights are also consistently projected to decrease over the northeastern Atlantic and Mediterranean Sea (Morim et al., 2018, 2021; Aarnes et al., 2017).

Wave characteristics used to estimate wave setup are sensitive to water level changes in shallow and intermediate waters, where waves start to interact with the ocean bottom. This occurs through a variety of processes. Very close to the coast, in shallow waters, depth-induced wave breaking is the fundamental mechanism, but it is a very small-scale process compared to the resolution of global and regional models used for climate projections. In intermediate waters, at a greater distance from the coast, other larger scale processes are involved and can also be affected by water level variations for instance through bottom friction effects or non-linear interactions between the different waves of the spectrum. However, wave models used for historical simulations and projections typically do not account for water level changes, whether from tides, storm surges, or long-term sea level rise. Yet, wave statistics have been shown to be sensitive to sea level rise (Chini et al., 2010; Wandres et al., 2017; Arns et al., 2017) and to tide-surges during extreme events (Alari, 2013; Viitak et al., 2016; Fortunato et al., 2017; Lewis et al., 2019; Staneva et al., 2021; Calvino et al., 2022). A review of tide and sea level rise effects on waves and wave setup is provided in Idier et al., 2019. Tides-wave setup interactions can induce changes in total water level at the coast of a few centimeters to tens of centimeters in some cases (Idier et al., 2019). These studies have mainly been conducted at fine scales including very coastal processes. But on a larger scale and in the context of climate change and sea level rise, projections of wave setup could also differ substantially when non-linear interactions between water level and waves are accounted for, due to other larger scale processes.

The present study aims at investigating the sensitivity of wave mean and extreme characteristics to non-linear interactions between waves and water level changes. In particular, wave setup is presented as an indicator for coastal hazard related to coastal flooding. To that aim, regional hindcasts and projections of waves are produced over the 1950-2100 period considering two climate change scenarios corresponding to low-emissions, high-mitigation (SSP1-2.6) and high-emissions, low-mitigation (SSP5-8.5) pathways (O'Neill et al., 2016). The simulations are produced over the northeastern Atlantic region, called the IBI domain (Iberian-Biscay-Ireland). The wave model is intended to represent the open ocean wave characteristics therefore the depth-induced wave breaking is not activated. Given that the model resolution is not fine enough to calculate properly the wave setup, it is estimated using a generic parameterization based on offshore characteristics. To assess the sensitivity of wave projections to the wave-water level non-linear interactions, the regional wave model is adapted to consider hourly variations of water level from a regional ocean model described in Chaigneau et al., 2022 for the same IBI domain.

The paper is organized as follows. Global and regional wave model configurations and simulations are presented in Sect. 2 together with the calculation of the wave setup contribution. Regional simulations for the northeastern Atlantic domain are compared to observations over the historical period and to previously published 21st century projections in Sect. 3, in terms of mean and extreme conditions. Sect. 4 provides an assessment of the impact of including hourly water level changes on wave characteristics and wave setup along the European Atlantic coastlines. Finally, results are discussed in Sect. 5 and conclusions are drawn in Sect. 6.

2 Methods: models and simulations

The aim of the present study is to investigate the sensitivity of historical and projected sea states to the wave-water level non-linear interactions for the IBI coastlines. To this end, a regional dynamical downscaling of a global wave model (CNRM-HR-WAV, Sect. 2.3.1) forced by a global climate model (CNRM-CM6-1-HR) was implemented over the northeast Atlantic region. Regional wave simulations (IBI-CCS-WAV, Sect. 2.2) are forced by hourly surface currents from a regionally downscaled ocean model (IBI-CCS, Sect. 2.3.3), using the same CNRM-CM6-1-HR parent climate model. In addition, a twin regional wave configuration was set up to investigate wave-water level interactions by considering hourly water level outputs from IBI-CCS in the wave model (IBI-CCS-WAV_ssh, Sect. 2.4). Figure 1 describes the downscaling strategy and the links between the different models used in this study. All the wave simulations described in the following sections are performed over the historical period (1950-2014) and the 21st century (2015-2100) under the SSP1-2.6 and SSP5-8.5 climate change scenarios.

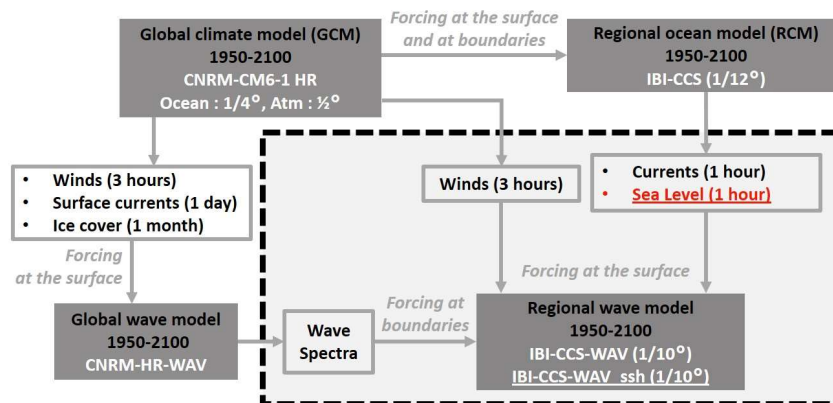

Figure 1: Sketch of the downscaling strategy explaining the links between the different models used in this study.

2.1 The numerical wave model: MFWAM

The MFWAM wave model is a spectral sea-state prediction model (wind-wave and swell). It is a modified version of IFS ECWAM-CY41R2 cycle (ECMWF, 2014) developed at Météo-France for their operational applications (Aouf and Lefèvre, 2015). The variables used to force such a model are surface winds, ocean currents and sea ice cover (if relevant for the ocean domain for the latter).

MFWAM primarily aims at describing the open ocean sea states. As such, the coastal depth-induced breaking is not activated in the model and overall, the model is not able to resolve very coastal processes such as the shoaling effect even if included. Large-scale processes included in the model are the terms of wave growth by wind, non-linear interactions between waves, dissipation by breaking in deep water referred to as whitecapping, dissipation by friction between long and short waves, bottom friction. These processes, which occur from the deep ocean to intermediate waters, are likely to be affected by the water level variations.

Additions from Météo-France concern (i) the use and adjustment of the Ardhuin et al., 2010 source term for wave breaking and swell damping dissipation (ST4 physics, Ardhuin et al., 2010), (ii) the use of a Phillips spectrum tail to better constrain the surface roughness for high-frequency waves. The wind input source term is based on Bidlot et al., 2007 and has been improved by considering wave damping by surface friction and sheltering effects for short waves. The non-linear source term uses the discrete interaction approximation (DIA) approach developed by Hasselmann et al., 1985. A better wave propagation around islands, mostly in the Pacific Ocean, is obtained thanks to an island obstructions scheme.

Supported by the assimilation of satellite observations, MFWAM is successfully operated within the Copernicus Marine Service (<https://marine.copernicus.eu/>) to provide near-real time (analyses/forecasts) and multi-year (reanalysis/hindcasts) wave products over both the global ocean and the northeastern Atlantic corresponding to the region of interest in this study.

2.2 Regional wave model: IBI-CCS-WAV

Regional wave simulations IBI-CCS-WAV (IBI Climate Change Scenarios Wave) are produced over the 1950-2100 period using MFWAM (Sect. 2.1) at a $1/10^\circ$ resolution. The configuration was designed over the IBI domain based on a Copernicus Marine Service (CMEMS) configuration (<https://doi.org/10.48670/moi-00030>). The regional domain covered by IBI-CCS-WAV extends from 27° to 61° N and 17° W to 8° E (Fig. 2), leading to a horizontal resolution ranging from 5.5 to 10 km. IBI-CCS-WAV is used to dynamically downscale the CNRM-HR-WAV global simulations described in Sect. 2.3.1. The dynamical downscaling method allows the resolution of regional processes at a finer scale. The method consists in forcing the regional wave model at its lateral boundaries by wave spectra from the CNRM-HR-WAV larger scale model and at the surface by winds, surface currents and possibly water level variations from simulations performed with other suitable models. The models and simulations that provide these forcings are described in the following sections 2.3 et 2.4. In the regional wave model, the bathymetry used is a smoothed ETOPO1 ocean bathymetry (<https://sos.noaa.gov/datasets/etopo1-topography-and-bathymetry/>). In our simulations, the wave spectrum is discretized in 24 directions and 30 frequencies starting from 0.035 up to 0.58 Hz. The time step of IBI-CCS-WAV is set to 240 s. Classical integrated wave parameters are generated hourly for IBI-CCS-WAV.

The IBI zone is interesting for wave modeling as it contains a variety of physical processes. First, the domain contains strong variations of bathymetry, with a wide continental shelf in the northern part of the domain (North Sea, English Channel) and a tight continental shelf in the southern part (Spain, Portugal, Morocco, Mediterranean Sea) (Fig. 2). There are also contrasting wave regimes: the Atlantic coasts are subject to very energetic events in terms of significant wave heights, wave periods and energy flows (Masselink et al., 2016; Bruciaferri et al., 2021) whereas the Mediterranean Sea and North Sea are more sheltered areas dominated by wind waves (Chen et al., 2002; Bergsma et al., 2022). In addition, the zone also contains very different

tidal regimes with both macro and micro tidal regimes respectively in the English Channel/Celtic Sea (Valiente et al., 2019; Stokes et al., 2021) and in the Mediterranean Sea.

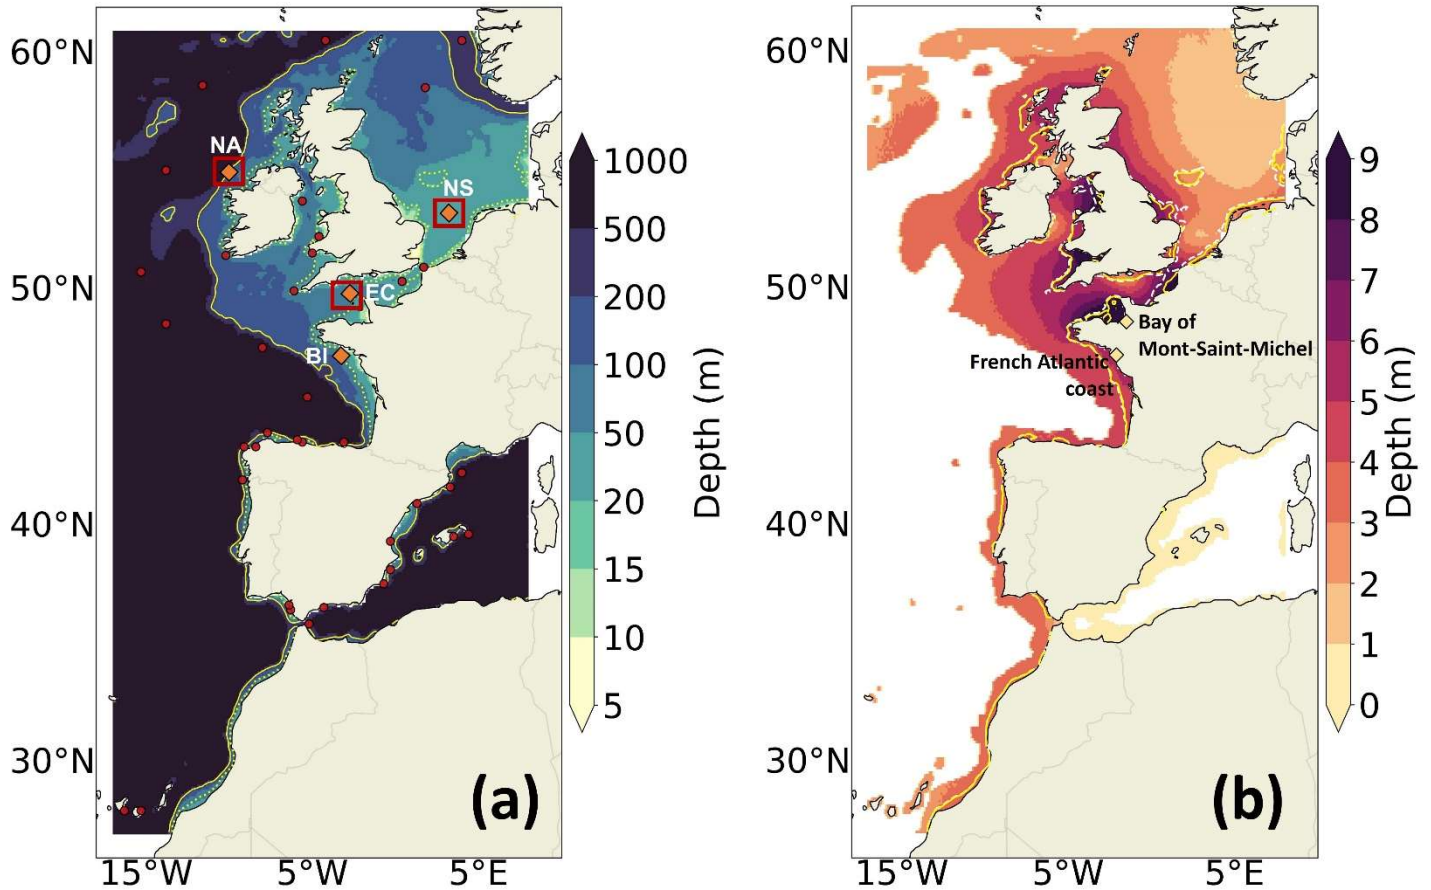

Figure 2: (a) Bathymetry (m) of the IBI domain in the regional wave model. The shelf break (defined by the 200 m isobath) is indicated by the solid yellow line. The yellow dotted lines indicate the areas where the waves start to interact with the bathymetry in IBI-CCS-WAV (intermediate waters that cannot be considered as purely deep water), identified when $h < L/2$ with h the bathymetry and L the mean wavelength over the 1993-2014 period. The red dots represent the locations of the wave buoys from the Copernicus Marine Service (Wehde et al., 2021) used for the validation in Sect. 3.1. The three red boxes are used in Sect. 2.3.2 to validate extreme winds in CNRM-CM6-1-HR. Orange diamonds indicate the wave buoys used for the wave roses calculation of Sect. 3.1.2 and 3.2.2 (North Atlantic (NA) buoy 6200093 and Belle-Ile (BI) buoy 6200074); used for the extreme wind validation of Sect. 4 (North Atlantic (NA) buoy 6200093, English Channel (EC) buoy 6200103 and North Sea (NS) buoy 6200145). (b) Bathymetric adjustment (Sect. 2.4) corresponding here to the M2 tidal range from IBI-CCS (1993-2014). The lines indicate the areas where the waves start to interact with the bathymetry at low tide (dashed white lines) and at high tide (solid yellow lines). The yellow diamonds indicate the zones where the impact of including hourly water level outputs in the wave model is assessed in Sect. 4.

2.3 External forcings

2.3.1 Wave forcing from CNRM-HR-WAV global wave model

The regional wave model described in Sect. 2.2 is forced at its lateral boundaries by 3-hourly wave spectra information from CNRM-HR-WAV global wave model (Fig. 1). CNRM-HR-WAV simulations are produced over the 1950-2100 period using MFWAM (Sect. 2.1) at a 1° resolution. These simulations are forced by 3-hourly surface winds ($1/2^\circ$), monthly sea-ice cover ($1/4^\circ$) and daily ocean surface currents ($1/4^\circ$) taken from the CMIP6 CNRM-CM6-1-HR global climate simulations (Voldoire et al., 2019; Saint-Martin et al., 2021). The historical simulation of CNRM-CM6-1-HR is used over the 1950-2014 period. Then, over the 2015-2100 period, the SSP1-2.6 and SSP5-8.5 climate change scenarios simulations are used (O'Neill et al., 2016).

CNRM-HR-WAV simulations use 2-min gridded global topography data from ETOPO2/NOAA (National Geophysical Data Center 2006). The model grid has a constant spacing in longitude but is compressed in latitude to maintain a constant resolution (Bidlot, 2012). A wave growth calibration was performed to adjust the mean significant wave height of CNRM-HR-WAV to the Copernicus Marine Service Waverys wave reanalysis (Law-Chune et al., 2021) over the IBI domain. As for the regional simulations, the wave spectrum is discretized in 24 directions and 30 frequencies starting from 0.035 up to 0.58 Hz. The time step is fixed at 720 s. Classical integrated wave parameters such as significant wave height (H_s) or average wave period (T_m) are generated three-hourly for CNRM-HR-WAV.

2.3.2 Atmospheric forcing from CNRM-CM6-1-HR global climate model

Regional wave projections are driven by the same 3-hourly surface winds as CNRM-HR-WAV (Sect. 2.3.1) produced by the CNRM-CM6-1-HR global climate model (Voldoire et al., 2019; Saint-Martin et al., 2021), which is part of the CMIP6 database. The use of a global climate model with a higher spatial resolution compared to the typical coarse resolutions of CMIP5 and 6 models was interesting for the atmosphere ($1/2^\circ$) for the intensity of the winds notably.

By driving our simulations with only one global climate model simulation, the aim of the study is not to characterize the uncertainties of wave projected changes over the IBI domain, but rather to discuss the impact of the water level changes on the downscaled projections. However, before using the winds to force the global and regional wave models, we verified that CNRM-CM6-1-HR was consistent with other CMIP6 global climate models in particular in terms of extreme winds and their projections. A comparison of extreme winds (99th percentile) between CNRM-CM6-1-HR, some other CMIP6 global climate models, the atmospheric reanalysis ERA5 (Hersbach et al., 2020) and wind observations from wave buoys (Wehde et al., 2021) is performed at different locations in the IBI region (Fig. 3a). The three different locations considered (shown in Fig. 2) are chosen along storm trajectories in the northeastern Atlantic and North Sea (Lozano et al., 2004). Figure 3a shows that CNRM-CM6-1-HR is representative of an ensemble of 21 CMIP6 models over the historical period. In general, CNRM-CM6-1-HR is also in good agreement with ERA5 which is the reference here. However, wave buoys observations seem to be significantly different from both the global climate models and ERA5, except in the North Sea. Figure 3b shows the projected changes for the extreme wind speed at the three locations. Projected changes in extreme wind speed are quite small in all models and rather uncertain (large interquartile range). Projected changes are of the same sign for 7, 9 and 10 models out of twelve for the three boxes respectively. In the English Channel and North Sea, CNRM-CM6-1-HR shows an increase in extreme wind speed which is representative of the other CMIP6 models. In the North Atlantic, CNRM-CM6-1-HR exhibits a large decrease in extreme wind speed which is in the high range (in absolute value) of CMIP6 models but still of the same sign as most models.

Figure 3: (a) Extreme winds (99th percentile) for CNRM-CM6-1-HR (dark red dot), 21 different CMIP6 global climate models (black box), the atmospheric reanalysis ERA5 (dark red cross) and wind observations from wave buoys (yellow cross) at the three locations in the IBI region marked on Fig. 2a for the 1993-2014 period. The 2011-2022 period was chosen for the wave buoy in the North Sea as it was the only period available. (b) Projected changes in extreme wind speed for CNRM-CM6-1-HR and 12 different CMIP6 climate models at the three locations marked on Fig. 2a under the SSP5-8.5 scenario (2081-2100 vs 1986-2005). The selected CMIP6 climate models are those with three-hourly atmospheric outputs. In (a) and (b), the purple line represents the median, the black box represents the interquartile range and the whiskers represent the last model under or above 1.5 times the interquartile range. The black circles represent the outlier models i.e. models outside 1.5 times the interquartile range. Units are in $m s^{-1}$.

2.3.3 Ocean forcing from IBI-CCS regional ocean model

Regional wave projections are also forced by the hourly surface current (and hourly water level variations in the dedicated simulation IBI-CCS-WAV_ssh) of IBI-CCS, a regional ocean model at a $1/12^\circ$ horizontal resolution, itself forced by CNRM-CM6-1-HR global climate model. IBI-CCS was implemented in Chaigneau et al., 2022 to refine sea level projections of CNRM-CM6-1-HR over the northeastern Atlantic region through a dynamical downscaling. For a more complete representation of processes driving coastal water level changes, tides and atmospheric surface pressure forcing are explicitly resolved in IBI-CCS in addition to the ocean general circulation (dynamic sea level).

2.4 Inclusion of water level variations in the regional wave model: IBI-CCS-WAV_ssh

The water levels over which the waves propagate control the intermediate and shallow water wave dynamics and the refraction by bathymetric gradients, as well as bottom friction induced wave breaking. To measure the impact of wave-water level non-

linear interactions in the IBI region, a twin configuration to IBI-CCS-WAV (Sect. 2.2) was set up to consider water level variations as an additional forcing: IBI-CCS-WAV_ssh. For this purpose, MFWAM (Sect. 2.1) has been modified to include an hourly water level forcing (coming from IBI-CCS simulations, Sect. 2.3.3) which adjusts bathymetric depth (Fig. 2b) to hydrodynamic effects such as tides, storm surges, dynamic sea level associated with ocean circulations but also to the long-term mean sea level rise over the next century. In practice, water elevation is read at the same time as ocean surface currents (Fig. 1) and added to the topographic depth at each forcing time step. These depth variations associated with water level variations affect the source terms (Sect. 2.1) and wave propagation from intermediate to shallow waters. Wave propagation parameters such as group velocities and wave numbers are tabulated at the beginning of the simulation according to a fixed list of depths and frequencies in the form of look up tables. The depth discretization for the propagative aspects was adapted with a first level at 3 meters and a vertical resolution of the order of 15 centimeters near the surface.

A minimum time-mean water depth of 6 meters was chosen to be consistent with that applied in the ocean simulation from IBI-CCS (Chaigneau et al., 2022). This value avoids the occurrence of uncovered banks in macro-tidal areas, especially around Mont-Saint-Michel in France and in the Bristol Channel. These settings are applied for all regional wave simulations, whether they are forced by time-varying water levels (IBI-CCS-WAV_ssh) or not (IBI-CCS-WAV).

2.5 Wave setup calculation based on a parametrization

The present study aims at investigating the sensitivity of projected changes in mean and extreme wave conditions to wave-water level non-linear interactions. In particular, the focus is given on the wave setup which drives coastal sea level hazards such as coastal flooding. Wave setup and runup can be resolved directly from wave-resolving coastal models such as Xbeach (Roelvink et al., 2009), SWASH (Zijlema et al., 2011) or BOSZ (Pinault et al., 2022). Such models require a high resolution of several meters and nearshore profiles as inputs. They cannot yet simulate nearshore morphological changes over long time periods and at large spatial scales due to their limitations to represent cross-shore sediment exchanges (Elsayed and Oumeraci, 2017). For models such as MFWAM that do not directly resolve the wave setup and runup, they can be estimated, at first order, via empirical formulations that relate them to a set of simple deep water environmental parameters (e.g. Dodet et al., 2019). In our study, the wave contribution to sea level is limited to wave setup. As the aim is to provide a first order estimate of wave setup projected changes, our wave setup estimates η are based on an empirical formulation (Stockdon et al., 2006), applicable for sandy beaches :

$$\eta = 0.35\beta\sqrt{H_s L_p} \quad (1) \quad (\text{Stockdon et al., 2006})$$

where β is the foreshore beach slope (i.e. the slope in the swash zone), H_s is the deep water significant wave height, L_p is the deep water peak wave wavelength related to the deep water peak wave period T_p through the deep water linear dispersion relationship: $L_p = \frac{g}{2\pi} T_p^2$, g is the acceleration of gravity.

As the wave setup estimation largely depends on the beach slope parameter, in this study, for the wave setup changes of Sect. 3.2 and 4, we provided a wave setup scaling $\sqrt{H_s L_p}$ rather than using the formulation of equation (1) to allow our results to be scaled with different beach slopes or empirical formulae (Dodet et al., 2019). To provide a range of wave setup changes estimates, formulation (1) was used with time and space constant beach slope values of 0.04 (4 %) and 0.07 (7 %), which correspond to the low and high spatial-mean values found in previous broad-scale studies (Melet et al., 2020a, Vos et al., 2020). The limitations of such an approach based on parametrizations are discussed in Section 5.

3 Validation and projections of IBI-CCS-WAV, without waves-sea level interactions

3.1 Validation of IBI-CCS-WAV over the 1993-2014 period

IBI-CCS-WAV is validated over the 1993-2014 period against Copernicus Marine Service products: a regional wave reanalysis which will be referred to as IBI-WAV thereafter (García San Martín et al., 2021; Toledano et al., 2021) and observations from wave buoys (Wehde et al., 2021). The IBI-WAV reanalysis covers the whole 1993-2020 period and has a horizontal resolution of 5 km. IBI-WAV uses the currents from the IBIRYS regional ocean reanalysis (Levier et al., 2020). In the present study, we considered the IBI-WAV reanalysis as the reference for the domain as Toledano et al., 2021 have shown that its performance was good compared to satellite and buoy observations over the 1993-2019 period. The selected wave buoys have a temporal data coverage of at least 60% over the validation period. The 1993-2014 period was chosen for the validation period because it corresponds to the intersection between the period covered by the IBI-WAV regional reanalysis (starting in 1993) and the historical period of IBI-CCS-WAV (ending in 2014).

The ability of IBI-CCS-WAV and IBI-CCS-WAV_ssh to reproduce observed distributions is assessed for the mean state and the 99th percentile of the significant wave height and peak period since these variables are then used to compute the wave setup scaling (Sect. 3.2, 4).

3.1.1 Significant wave height and mean wave period

Mean state validation

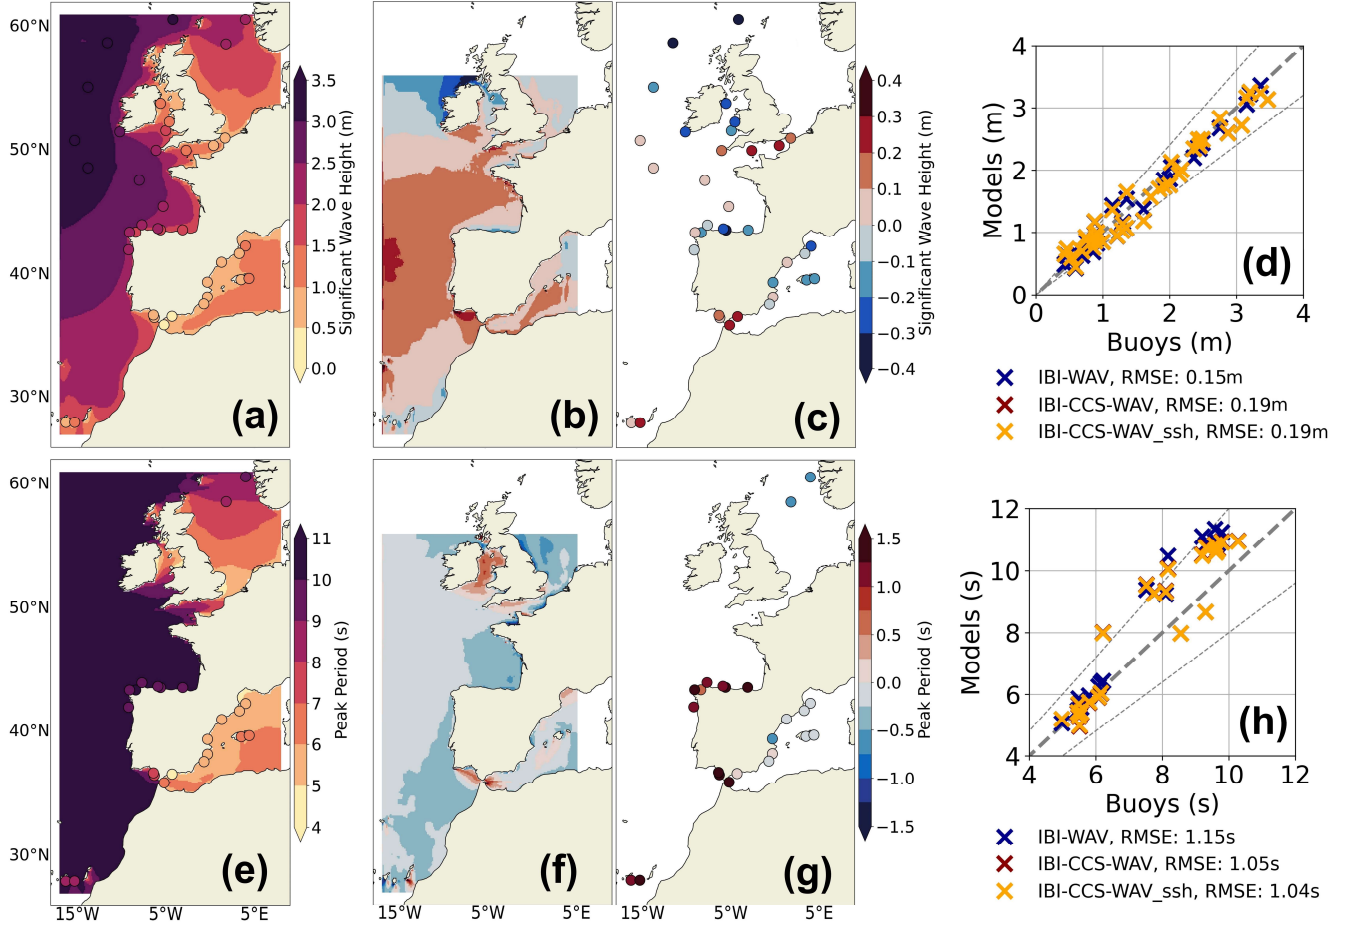

Figure 4: (a), (b), (c) and (d) show the mean significant wave height (H_s , in m) over the 1993-2014 period for: (a) IBI-CCS-WAV. (b) Differences between IBI-CCS-WAV and the reanalysis IBI-WAV. (c) Bias between IBI-CCS-WAV and CMEMS wave buoys. (d) Scatter plot at each wave buoy location of simulations IBI-CCS-WAV (red marks), IBI-CCS-WAV_ssh (yellow marks) and IBI-WAV reanalysis (blue marks) vs observations. (e), (f), (g) and (h) are the corresponding figures for peak period (T_p , in s). Note the different color bars in (a) and (b), (c), and in (e) and (f), (g). For (b) and (f) the domain is limited to the domain distributed by the Copernicus Marine Service, with a cut in the northern part. In (d) and (h), the thin dashed lines indicate the 20 % error margin. The RMSE is calculated as the root mean squared deviations from the line $y=x$ (spatial RMSE).

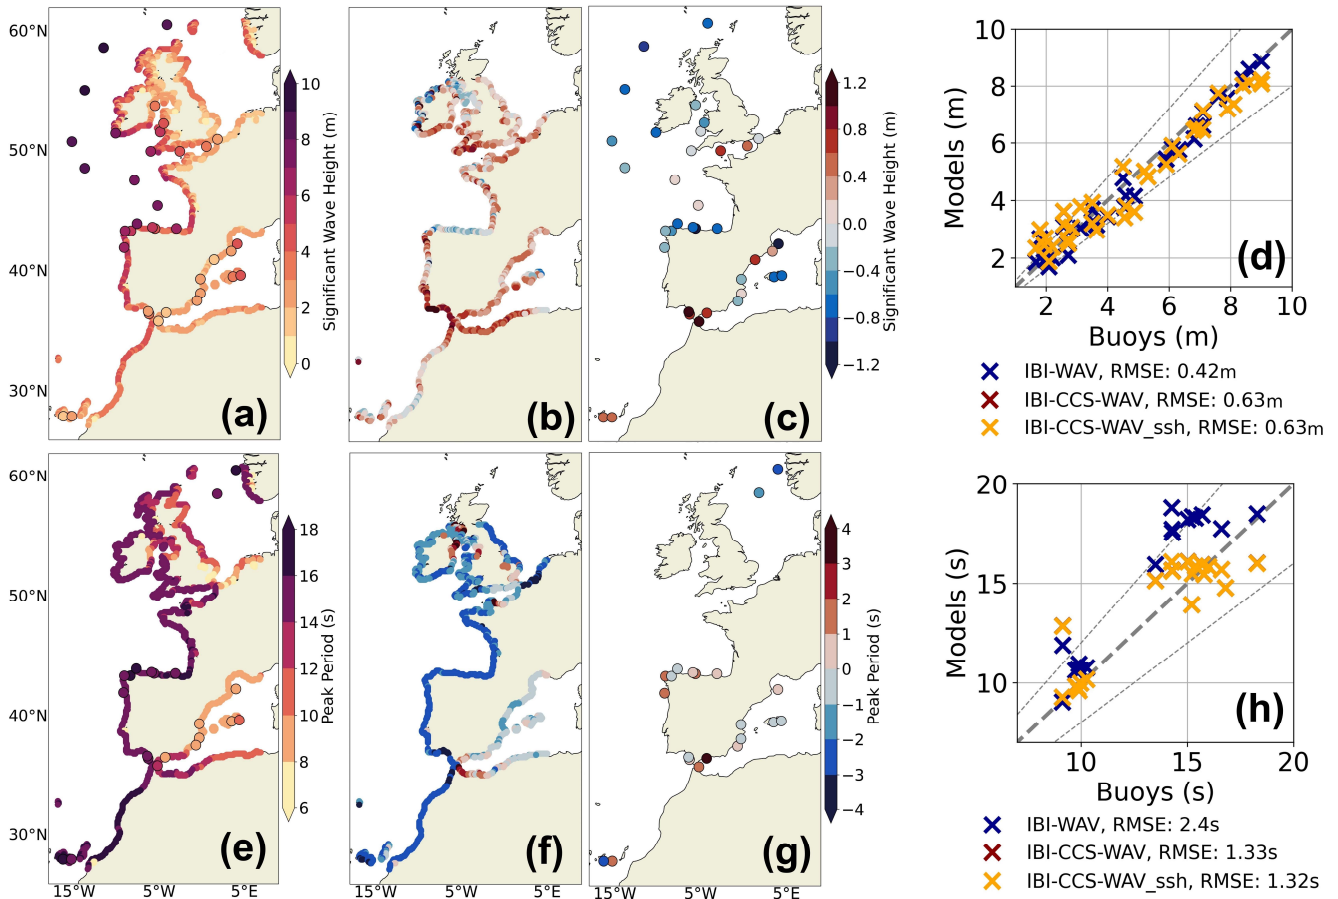

Figure 4 illustrates the mean state validation of the IBI-CCS-WAV simulation against the IBI-WAV reanalysis and observations from wave buoys. In general, the mean significant wave height and mean peak period of IBI-CCS-WAV seem to be in reasonable agreement with both the reanalysis IBI-WAV and the wave buoys over the 1993-2014 period. Around 40 °N in the deep ocean, IBI-CCS-WAV nevertheless exhibits a positive bias for the significant wave height inherited from the global wave model forcing through the boundaries (Fig. 4b). This feature is due to the wind forcing taken from the CNRM-CM6-1-HR (Sect. 2.3.1). In CNRM-CM6-1-HR, the westerlies are slightly shifted southward. As a result, significant wave heights are slightly overestimated in the IBI-CCS-WAV southern domain and underestimated in the northern part of the domain, around Ireland, leading to an overall relative error of 10 %. In the deep ocean, the peak period of the IBI-CCS-WAV seems to be in good agreement with the reanalysis IBI-WAV (Fig. 4f). However, the significant wave height and peak period differences between IBI-CCS-WAV and IBI-WAV are often larger in coastal zones and can reach a relative error of 20 % in the Gulf of Cadiz (Fig. 4a,b,e and f). Differences in coastal zones mainly arise from the different surface currents forcings, coming from IBI-CCS for IBI-CCS-WAV and from IBIRYS (Levier et al., 2020) for IBI-WAV. The currents are particularly different around the Strait of Gibraltar. At this location, the incoming transport and the currents from IBIRYS are more intense than those of IBI-CCS. Indeed, IBI-CCS has been corrected in Chaigneau et al. 2022 to obtain a more accurate transport through the Strait of Gibraltar.

Figure 4c displays the mean significant wave height biases between IBI-CCS-WAV and wave buoys over the 1993-2014 period. The spatial pattern of the biases is generally in agreement with Figure 4b showing a negative bias in the northern part of the domain and a positive bias around the Strait of Gibraltar (Fig. 4b and c). Around the Iberian Peninsula, the biases found for the peak period between IBI-CCS-WAV and the reanalysis IBI-WAV seem to be in contradiction with those found between IBI-CCS-WAV and the wave buoys (Fig. 4f and g). Toledano et al., 2021 also reported large errors in northern Spain between IBI-WAV and the wave buoys for the mean wave period. The uncertainty seems to be large in this region and IBI-CCS-WAV

is within the range of uncertainties. The scatter plots of Figure 4d and h show that the performances of both IBI-CCS-WAV and IBI-WAV are quite similar on average over the domain with a root mean square error (RMSE) of the same order of magnitude: about 20 cm for the significant wave height and 1 s for the peak period. Figure 4h must be interpreted with caution as the observations of peak period are scarce and located close to the coast. Most likely coastal buoys are subject to very local effects that are poorly represented at the $1/10^\circ$ model resolution (Fig 4g,h).

The comparison of IBI-CCS-WAV_ssh with the reanalysis is not relevant since the latter does not consider the forcing with hourly sea level variations. The IBI-CCS-WAV_ssh simulation is compared to the buoy data in Figure 4d,h and Figure 5,d,h. However, it is difficult to get useful information from these comparisons with buoys since they are not located at the coast. Actually, they are in areas where there is no impact of the wave-water level non-linear interactions (Sect. 4) so the performances of IBI-CCS-WAV_ssh are similar to those of IBI-CCS-WAV.

Extreme validation: 99th percentile

between IBI-CCS-WAV and IBI-WAV along the Atlantic coasts (Fig. 5f). However, this feature seems to be related to an overestimation of the extreme peak periods in the reanalysis IBI-WAV as the differences do not appear when IBI-CCS-WAV is directly compared to wave buoys (Fig. 5g). The scatter plot of Figure 5h also shows a smaller RMSE with IBI-CCS-WAV than with IBI-WAV when compared to wave buoys. This overestimation is also reported in Toledano et al., 2021 in which the reanalysis IBI-WAV is validated.

3.1.2 Wave roses

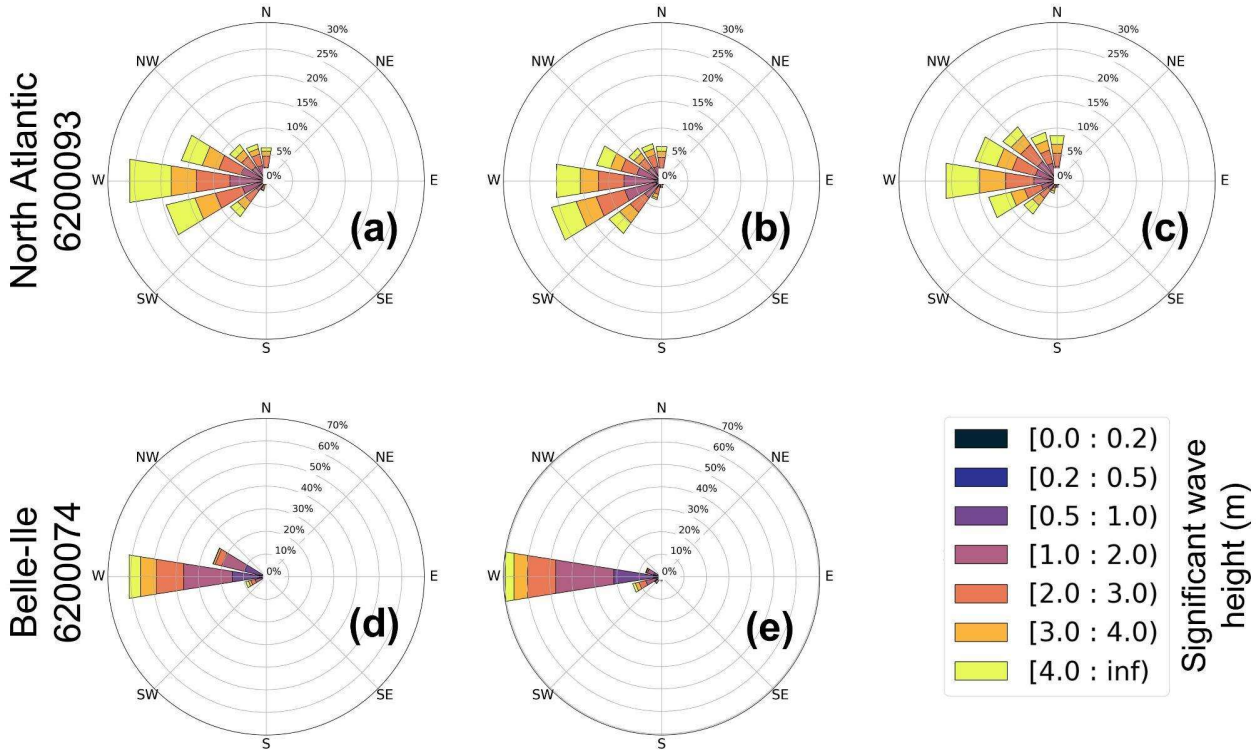

Figure 6: Directional distributions of significant wave height at star locations of Fig. 2a: North Atlantic buoy 6200093 (first row), Belle-Ile buoy 6200074 (French Atlantic coast, second row). First column (a,d) are the wave roses based on wave buoy data over the 2003-2022 period for (a) and 2005-2022 for (d). Second column (b,e) are the roses for IBI-CCS-WAV over the 1993-2014 period and (c) for the IBI-WAV reanalysis over the 1993-2014 period. Different periods are chosen for the wave buoys because of the lack of data for the wave direction over the 1993-2014 period. Wave roses at North Atlantic buoy 6200093 location were computed using mean wave direction. Wave roses at Belle-Ile buoy 6200074 location were computed using the wave direction at spectral peak as it was the data provided by the wave buoy. However, this variable was not an output of the IBI-WAV reanalysis. Colors indicate the wave height distribution in each direction bin.

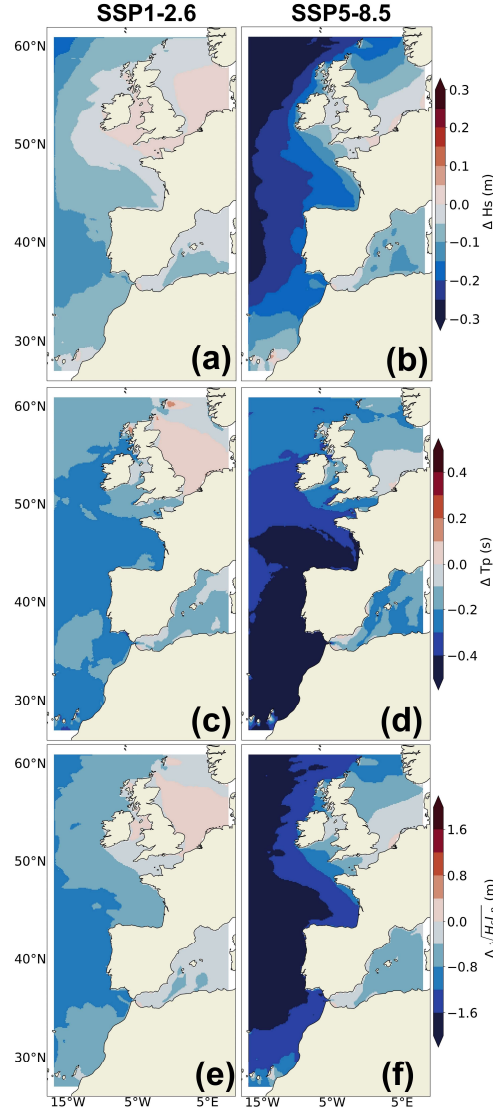

Directional distributions are shown on wave roses at two locations in the Atlantic Ocean (Fig. 2a). In Figure 6, the focus is only on the IBI-CCS-WAV simulation as we found that the impact of the water level variations on the mean wave direction was negligible over the 1993-2014 period. As both locations are found in the westerlies-exposed Atlantic Ocean, the wave roses indicate dominant waves in the west, west-northwest and west-southwest directions. For North Atlantic buoy 6200093, IBI-WAV shows the same main west direction as the buoy data (Fig. 6a and c). However, the observed west distribution is slightly underestimated (by 5 %) by IBI-CCS-WAV and IBI-WAV, especially for the highest waves, superior to 4 m. In IBI-WAV, this could be associated with a larger directional spread of the biggest waves coming from the north (Fig. 6c). In IBI-CCS-WAV, waves tend to have a slight southward direction bias, as the dominant wave direction is west-southwest (Fig. 6b). For Belle-Ile buoy 6200074, the west direction represents 70 % of occurrence in IBI-CCS-WAV against 60 % for the wave buoy (Fig. 6d and e). Half of the 70 % are related to waves with a significant wave height of less than 2 m whereas for the buoy it represents only 25 %. This difference of 25 % is found in the west-northwest direction bin for the wave buoy data.

Overall, the IBI-CCS-WAV regional wave model has shown good performances compared to the IBI-WAV reanalysis and wave buoys, although observations are scarce. For the future period, as in the present study we use a single global climate model forcing, we assess the regional projections compared to previous published studies.

3.2 Regional wave projections of IBI-CCS-WAV under two climate change scenarios: SSP5-8.5 and SSP1-2.6

Regional projections over 2015-2100 are now presented for the SSP5-8.5 and SSP1-2.6 scenarios for the significant wave height and peak period validated in Sect. 3.1 and for wave setup scaling $\sqrt{H_s L_p}$ (Sect. 2.5.3).

Mean state projections

355 **Figure 7: Projected changes in incoming waves conditions for the 2081-2100 period (relative to 1986-2005) under the SSP1-2.6 (first column) and SSP5-8.5 (second column) scenarios for (a,b) significant wave height (ΔH_s , in m), (c,d) peak period (ΔT_p , in s) and (e,f) scaling for wave setup ($\Delta \sqrt{H_s L_p}$, in m).**

Projected changes in the significant wave height, peak period and wave setup scaling are illustrated in Figure 7 for the end of the century under two climate change scenarios. Projected changes under the SSP5-8.5 scenario are consistent with other studies (Lobeto et al., 2021; Melet et al., 2020a; Morim et al., 2019; Aarnes et al., 2017; Casas-Prat et al., 2018) with a large decrease in the significant wave height, peak period and thus in the wave setup scaling in the Atlantic Ocean and Mediterranean Sea (Fig. 7b,d,e). For the SSP5-8.5 scenario, in the south of the domain, projected changes in the peak period can reach -0.5 s which represents a decrease of 6 % in comparison to the historical period of Figure 4e. For the significant wave height, projected changes can reach -30 cm or -10 %. Changes in the wave height and peak period result from changes in the wave spectrum composed by different wave regimes (e.g. swells and wind-waves). The large decrease in the significant wave height under the SSP5-8.5 scenario (Fig. 7b) is due to a general decline in the wind speed forcing from CNRM-CM6-1-HR over the domain and in the North Atlantic Ocean, inducing changes in both wind-waves and swells in the domain (not shown). The decrease in the wind speed under the SSP5-8.5 scenario is consistent with other CMIP6 models projections (Carvalho et al., 2021). In terms of wave setup scaling, projected changes can reach a decrease of 2 m or 6 % under SSP5-8.5 scenario along the north Iberian coasts (Fig. 7f). In terms of sea level equivalent, using parameterization (1) with a beach slope of 4 % and 7 % (Sect. 2.3), the decrease in the wave setup in the deep ocean can reach between -2.8 cm and -4.9 cm. These changes are thus rather small (but not negligible) compared to the projected sea level rise of about +80 cm over the northeastern Atlantic domain (Chaigneau et al., 2022) but are of opposite sign. These changes in wave setup are mainly related to moderate changes in the peak period which is squared in formulation (1): 63 % of the wave setup changes are due to those in peak period and 37 % are due to changes in significant wave height. Except in the North Sea, the spatial patterns of the wave projected changes under the SSP1-2.6 scenario (Fig. 7a,c,e) are broadly the same as under the SSP5-8.5 scenario, but with an overall smaller magnitude.

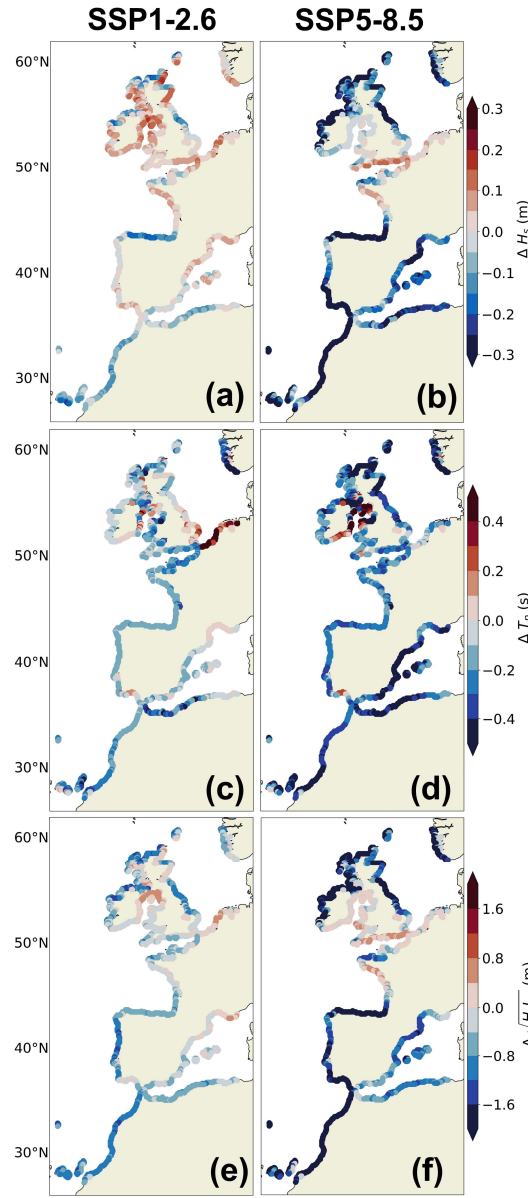

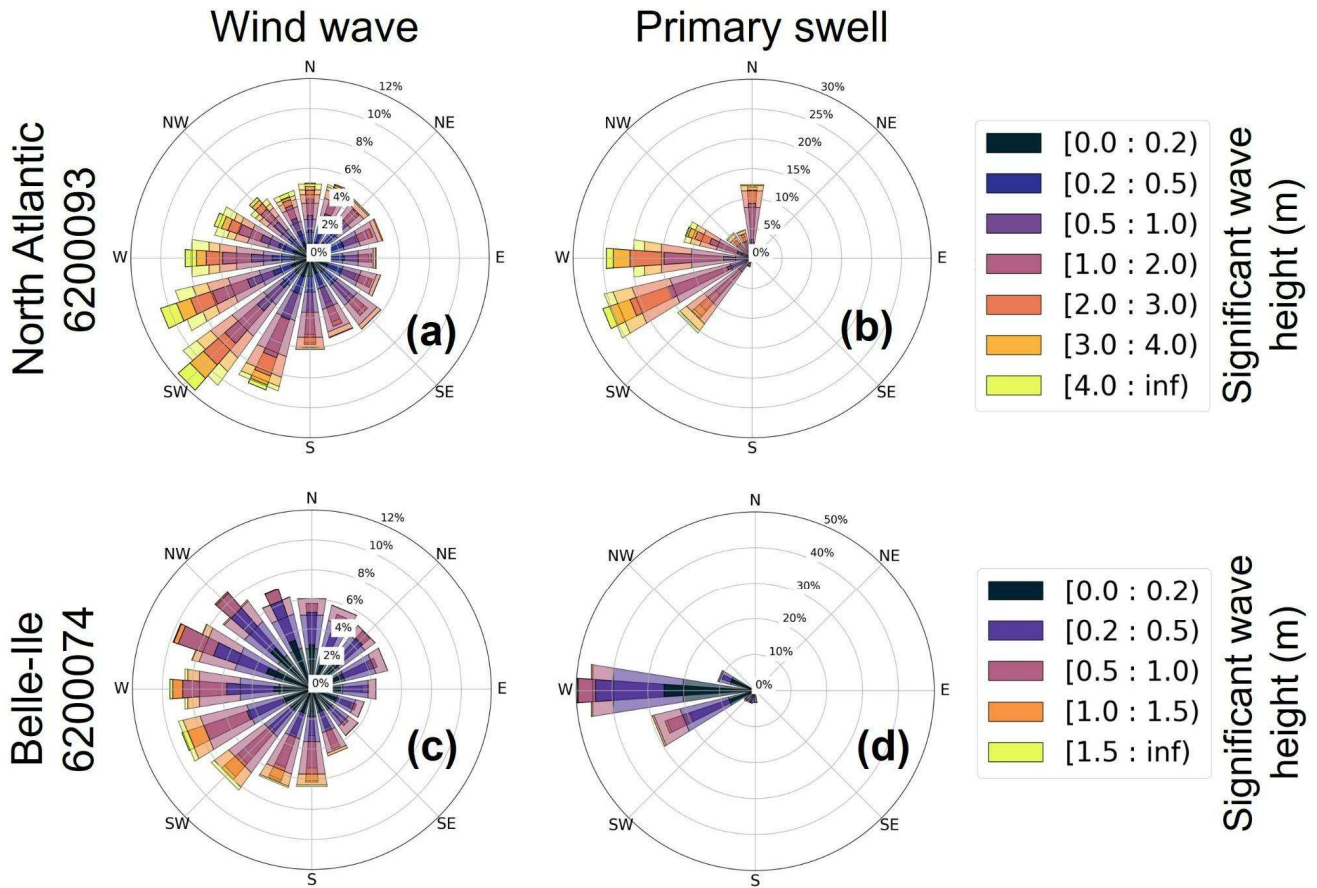

Figure 8: Projected changes in incoming extreme (99th percentile) waves conditions for the 2081-2100 period (relative to 1986-2005) under the SSP1-2.6 (first column) and SSP5-8.5 (second column) scenarios in IBI-CCS-WAV for (a,b) significant wave height (ΔH_s , in m), (c,d) peak period (ΔT_p , in s) and (e,f) scaling for wave setup ($\Delta \sqrt{H_s L_p}$, in m).

380 Projected changes in the 99th percentile of significant wave height, peak period and wave setup scaling are illustrated in Figure 8 for the end of the century under two climate change scenarios. Changes in the 99th percentile of peak period are moderate as it generally represents a decrease of less than 2.5 % for the SSP5-8.5 scenario (Fig. 8c,d). For the significant wave height, projected changes in the 99th percentile under SSP5-8.5 scenario are large with a decrease of more than 30 cm or 12 % in the southern part of the domain. For both scenarios, projected changes in the 99th percentile of significant wave height are quite different from those in the mean state, as reported in Morim et al., 2018. This is associated with different changes in the extreme wind speed forcing compared to those in the mean state (not shown). For example, for the SSP5-8.5 scenario, the large decrease in the extreme wind speed (Fig. 3b) and thus in the significant wave height is located in the North Atlantic south of 45 °N and north of 55 °N (Fig. 7b). This is consistent with other studies (Aarnes al., 2017; Meucci et al., 2021) in which the largest decrease in the 99th percentile of significant wave height is also found in the southern domain (Fig. 8b). In the English Channel, Celtic Sea and French Atlantic coasts, the model even exhibits an increase in the extreme significant wave height that has not been reported in other studies for both scenarios (Fig. 8a,b). This increase is however consistent with projected changes in extreme wind speed shown in Fig. 3b for the English Channel. In the Mediterranean Sea, the SSP5-8.5 and SSP1-2.6 scenarios exhibit significant wave height projected changes of a different sign (Fig. 8a,b) associated with different projected changes in extreme winds (not shown). Over the whole domain, as projected changes in extreme peak periods are small, projected changes in extreme wave setup scaling are mostly governed by those in extreme significant wave height (Fig. 8e,f) in contrast to the projected changes in mean state of Figure 7. For instance, along the north Iberian coasts, projected changes in wave setup scaling show a decrease of 2 m or 4 %, with 70 % of the changes due to those in significant wave height and 30

% due to changes in peak period. In terms of sea level equivalent, the decrease in extreme wave setup can reach between -2.8 cm and -4.9 cm using (1), as for the mean state of Figure 7.

400 3.2.2 Projected changes in wave roses

405 **Figure 9: Projected changes (SSP5-8.5 scenario) in directional distribution of significant wave height for the 2081-2100 period (narrow angle bins, dark colors) relative to 1986-2005 (wide angle bins, pale colors) in IBI-CCS-WAV at star locations of Fig. 2a: North Atlantic buoy 6200093 (first row), Belle-Ile buoy 6200074 (second row). The significant wave height and mean wave direction have been classified according to their origin: wind wave (a,c) and primary swell (b,d). Colors indicate wave height distribution in each direction bin.**

Projected changes in the directional distributions are shown on wave roses at the two locations validated in Figure 6. The wave roses have been decomposed into the wind wave and primary swell contributions. The significant wave height roses due to the primary swell contribution (Fig. 9b,d) are very close to the significant wave height roses of Fig. 6, showing that most waves are due to the primary swell at this location. At Belle-Ile buoy 6200074, the wave rose exhibits a change in the main direction of the wind-wave under the SSP5-8.5 scenario (Fig. 9c). Over the historical period, the main direction is west-southwest whereas it would be shifted clockwise to west-northwest direction (20 °) at the end of the century under the SSP5-8.5 scenario (Fig. 9c). In this zone, a clockwise shift in the wave direction has already been documented in Morim et al., 2019. This shift seems to come mainly from small waves with significant wave height less than 50 cm. For the primary swell at Belle-Ile, we observe a slight strengthening of the swell from the west direction, and thus a reduction of the wave components coming from the southwest (Fig. 9d). The results are quite different for North Atlantic buoy 6200093. Projected changes exhibit a slight strengthening of the wind-wave heights in the southwest, west-southwest direction bins with an occurrence increased by a few percent (Fig. 9a). Also, for North Atlantic buoy 6200093, the projected changes in the primary swell are larger than at Belle-Ile buoy 6200074. The occurrence of the west direction has increased by 5 % (Fig. 9b). Finally, a slight decrease in swells with significant wave heights of more than 4m is found under the SSP5-8.5 scenario for the west and west-northwest directions (Fig. 9b).

In Sect. 3.2, as reported in other studies, we observed a general decrease in mean and extreme significant wave height and peak period over the domain and a clockwise mean wave direction change along the French Atlantic coasts. As IBI-CCS-WAV seems to be representative of other studies, we can use it to assess methodological modelling questions such as the impact of considering the hourly water level variations on the wave model.

4 Impact of non-linear wave-water level interactions accounted for in the regional wave model

4.1 Impact for the entire coastal domain

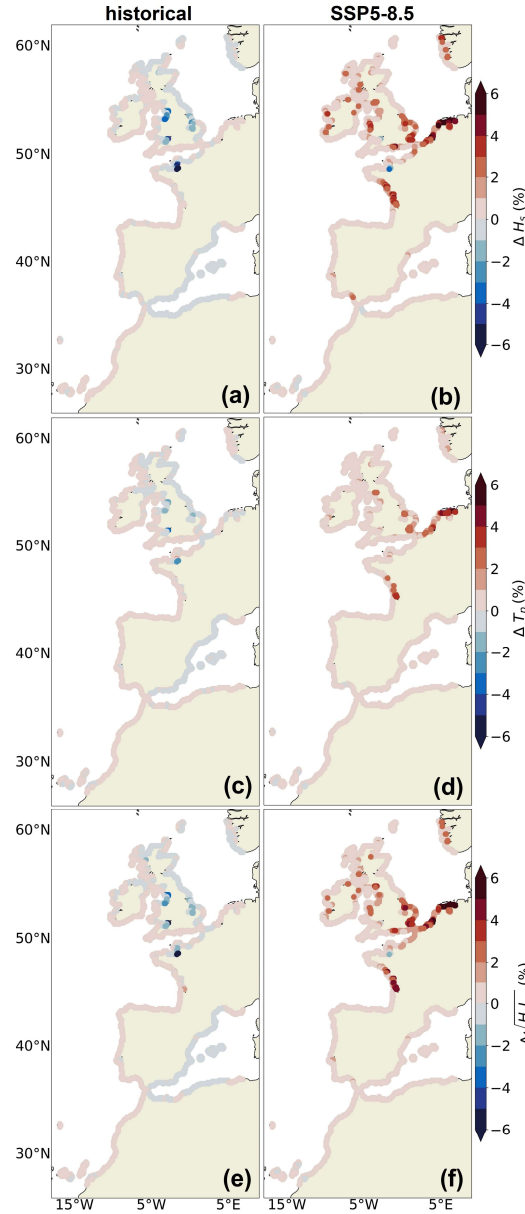

Figure 10: Impact of the inclusion of the hourly water level variations in the wave model on the mean state of (a,b) significant wave height (first row, ΔH_s , in %), (c,d) peak period (second row, ΔT_p , in %) and (e,f) wave setup scaling (third row, $\Delta \sqrt{H_s L_p}$, in %). The first column shows the relative differences of mean state between IBI-CCS-WAV_ssh and IBI-CCS-WAV for the 1986-2005 period. The second column shows the relative differences of mean state between IBI-CCS-WAV_ssh and IBI-CCS-WAV for the 2081-2100 period under the SSP5-8.5 scenario.

The impact of accounting for hourly water level variations in the wave model on the mean state of wave conditions is shown in Figure 10 by comparing IBI-CCS-WAV_ssh to IBI-CCS-WAV. Except for a few places, like in the Bay of Mont-Saint-Michel or the mouth of some rivers in the United Kingdom, the impact of including the water level variations on the wave model has no impact on average as shown in the first column of Fig. 10. This suggests that there are no strong non-linear effects between waves and water level that would make an impact on the mean state on average for the majority of the coastal domain.

Differences in the wave projections due to the inclusion of hourly water level changes are illustrated in the second column of Fig. 10 at the end of the century (2081-2100) under the SSP5-8.5 scenario. Sea level projected changes in the IBI-CCS ocean model during the 21st century are mainly dominated by the mean sea level rise, with rather small changes in tides and storm surges (Chaigneau et al., 2022). Therefore, as IBI-CCS-WAV and IBI-CCS-WAV_ssh are forced by the same winds, Figure 10 mostly shows the impact of mean sea level rise on waves, even if not completely linear. In IBI-CCS, the mean sea level rise averaged over the IBI domain reaches +80 cm in 2100 compared to the 1986-2005 period under the SSP5-8.5 scenario considering changes in tides and storm surges too (Chaigneau et al., 2022). Until the end of the paper, the mean sea level rise

term will also consider projected changes in the mean state of tides and storm surges. This long-term mean sea level rise has an overall effect on the coastal points of the large continental shelf where shallow and intermediate water dynamics prevail (Fig. 2a). The significant wave height projections are up to +3 cm larger (e.g. +6 % larger than in IBI-CCS-WAV) along the French Atlantic coasts and in the southern North Sea (Fig. 10b). This result agrees with Arns et al., 2017 who showed that water depth changes induced by sea level rise were leading to waves of greater amplitude and period, breaking closer to the shore. The impact of the sea level rise on the mean state of significant wave height leads to an impact of the same order of magnitude (up to +6 %) on the wave setup scaling mean state (Fig. 10f). For the peak period, the impact is moderate (Fig. 10d). In the southern North Sea, projected changes in significant wave height are small (Fig 7b) and therefore an added impact of +3 cm due to the sea level rise corresponds to more than 70 % of the projected total changes under SSP5-8.5 scenario.

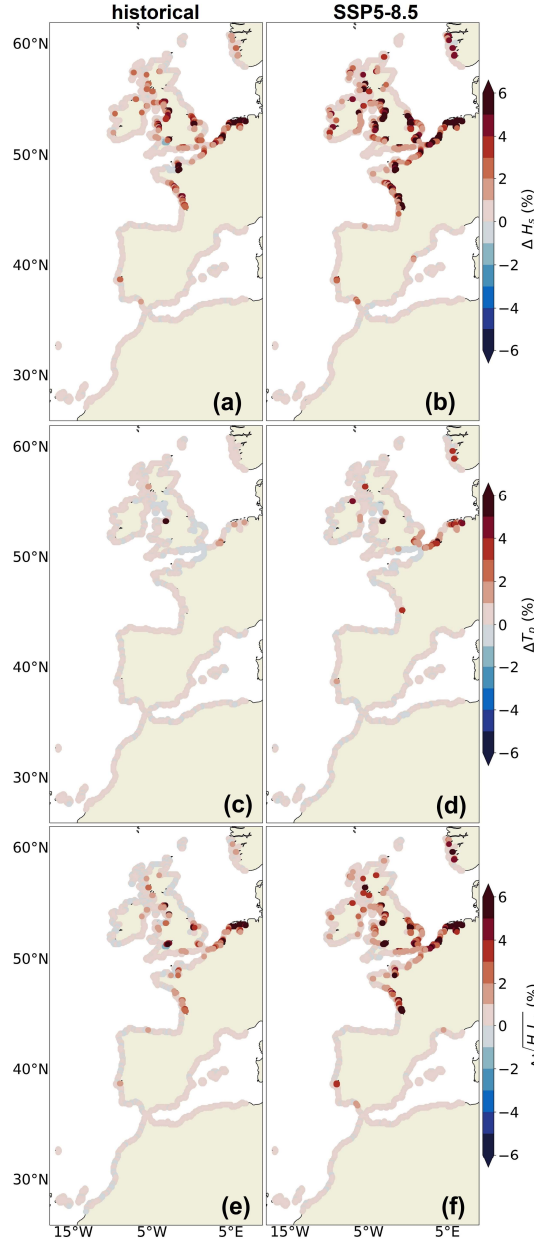

Figure 11: Impact of the inclusion of the hourly water level variations in the wave model on the 99th percentile of (a,b) significant wave height (first row, ΔH_s , in %), (c,d) peak period (second row, ΔT_p , in %) and (e,f) wave setup scaling (third row, $\Delta \sqrt{H_s L_p}$, in %). The first column shows the relative differences of the 99th percentile between IBI-CCS-WAV_ssh and IBI-CCS-WAV for the 1986-2005 period. The second column shows the relative differences of the 99th percentile between IBI-CCS-WAV_ssh and IBI-CCS-WAV for the 2081-2100 period under the SSP5-8.5 scenario. Note that the color bars are saturated in red for some points for (a), (b) and (f).

The impact of accounting for the hourly water level variations in the wave model on the 99th percentile is shown in Figure 11 by comparing IBI-CCS-WAV_ssh to IBI-CCS-WAV. The impact over the historical period is substantially more important when considering the 99th percentile instead of the mean state (Fig. 11, first column). The coastal points of the large continental shelf are quite impacted (southern North Sea, English Channel, seas around the United Kingdom, French Atlantic coasts) and particularly macro-tidal locations (Fig. 2b) such as the Bay of Mont-Saint-Michel, the Bristol Channel and the eastern Irish

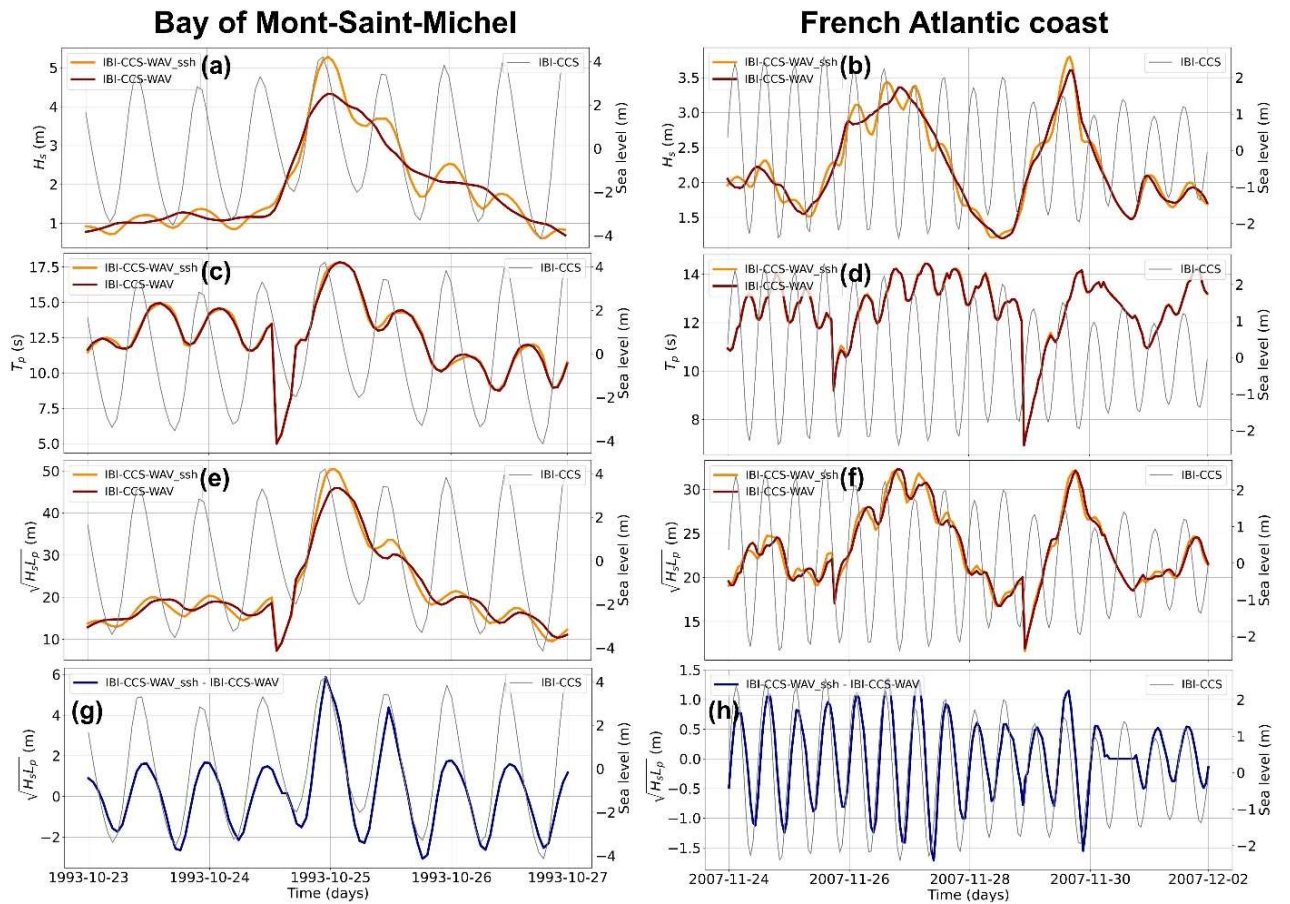

Sea. In these areas, the historical 99th percentile of significant wave height and wave setup scaling is up to +8% and +6 % higher respectively when considering water level variations, mostly dominated by tidal variations.

470 The impact of including the hourly water level variations on the projections of the 99th percentile is larger due to the combination of the impact of tidal range and mean sea level rise. For the significant wave height, the projected 99th percentile is increased by up to +6 cm or +10 % and for the wave setup scaling it represents an increase of up to +8 % (Fig. 11 second column). As projected changes in the extreme significant wave heights and peak periods in IBI-CCS-WAV are quite small at the coast (Fig. 8b,c), especially on the French Atlantic coasts and on the North Sea coasts (<10 cm, <0.3 s), an impact of the

475 hourly water level variations of +6 cm or +0.1 s represents more than 80 % of the projected changes in IBI-CCS-WAV_{ssh}. These results highlight that wave-water level non-linear interactions should be considered for applications on wave extreme events in particular in coastal zones subject to large water level variations or on large continental shelves, with implications for estimates of both past and future sea level changes.

4.2 Impact at two locations: Bay of Mont-Saint-Michel and French Atlantic coast

480 The largest impact of including water level variations for wave modeling is found during extreme events, as shown in Figure 11. In Sect. 4.2, the focus is on two specific French regions where an impact of non-linear wave-water level interactions on the wave extremes has been identified in Figures 11. In the Bay of Mont-Saint-Michel, strong hourly water level variations occur due to the large tidal range in the region (about 10 meters, Fig. 2b). For the French Atlantic coast, the tidal range is large (4 meters, Fig. 2b) but smaller than in the Bay of Mont-Saint-Michel.

485

Figure 12: Time series of incoming wave conditions for the Bay of Mont-Saint-Michel (first column) and for the French Atlantic coast (second column) during an extreme significant wave height event. The two locations are marked on Fig. 2b. The curves represent IBI-CCS-WAV (dark red curve) and IBI-CCS-WAV_{ssh} (dark yellow curve) and 3 variables are displayed: (a,b) significant wave height (H_s , in m), (c,d) peak period (T_p , in s), (e,f) scaling for wave setup ($\sqrt{H_s T_p}$, in m) and (g,h) differences in the wave setup scaling between the two simulations. Water level variations are shown in thin gray lines, with the right y-axis on each panel.

490

Time-series of significant wave height, peak period, wave setup scaling and differences in the wave setup scaling for two extreme significant wave height events are illustrated in Figure 12. The events selected in the model did not actually occur since the global climate model forcing is not in phase with the observed forcing. The significant wave height and wave setup scaling time-series from IBI-CCS-WAV_{ssh} oscillate in phase with the tide in IBI-CCS-WAV_{ssh}, illustrating the consideration of hourly water levels in the regional wave model (Fig. 12a,b,e,f). In the case of the Bay of Mont-Saint-Michel, due to the large tidal range, the highest significant wave height, reached on day 25/10/1993 during high tide, is 1 m larger (+25

495

500 %) in IBI-CCS-WAV_ssh than in IBI-CCS-WAV. The impact of the water level variations on the peak period is however almost zero (Fig. 12c). In both IBI-CCS-WAV and IBI-CCS-WAV_ssh, diurnal variations of the peak period appear due to tidal current that shortens or lengthens the dominant wave period (Ardhuin et al., 2012). The impact of the inclusion on the wave model of the hourly water level variations on the wave setup scaling (Fig. 12e) is balanced by the effects on the significant wave height and peak period of the water level variations. For the peak of day 25/10/1993, the differences of the wave setup scaling between IBI-CCS-WAV and IBI-CCS-WAV_ssh can reach 6 meters (Fig. 12g). Differences in the wave setup can reach +8.4 cm to +14.7 cm for the peak event using parameterization (1) with beach slopes of 4 % and 7 %. As the Bay of Mont Saint-Michel has one of the highest tidal ranges in the IBI domain, the impacts found correspond to the upper bound with the settings of our model.

510 For the French Atlantic coast, due to a lower tidal range of 4 meters, the impact of including the hourly water level variations on the extreme wave conditions is less important (Fig. 12, second column). For the event of 29/11/2007, differences between IBI-CCS-WAV_ssh and IBI-CCS-WAV are of +25 cm (+6%) for the significant wave height and of +1 m (+3 %) for the wave setup scaling (Fig. 12b,f). In terms of wave setup, this would result in differences between +1.4 cm and +2.45 cm with parameterization (1) which is substantially lower than in the Bay of Mont-Saint-Michel.

515 However, it can be pointed out that the most significant increase in wave height occurs in both cases at high tide. These results are in agreement with Lewis et al., 2019 and Calvino et al., 2022 who both showed a significant increase in wave height at high tide at a finer scale. In Calvino et al., 2022, this impact seems to be explained mainly by the effect of bottom friction, which is less important at high tide as there is more water. In our case, additional analyses would be needed to understand which is the primary process included in the model (Sect. 2.1) responsible for the non-linear interactions.

4.3 Impact on extreme events in terms of return periods

520 It was shown in Sect. 4.1 that the impact of the inclusion of the hourly water level variations in the wave model had a larger effect on the 99th percentile than on the mean state of wave conditions. To better document the impacts on extreme events, we now focus on high return periods, such as the 100-year return level. In Sect. 4.3, a nonstationary extreme value analysis (EVA) is performed for each location time series by using the approach described by Mentaschi et al., 2016. This method is used to detect long-term trends in the extremes and to filter out the variability on time scales shorter than 30 years. For each location and wave time series, the output of the EVA analysis is a time-varying generalized Pareto distribution (GPD).

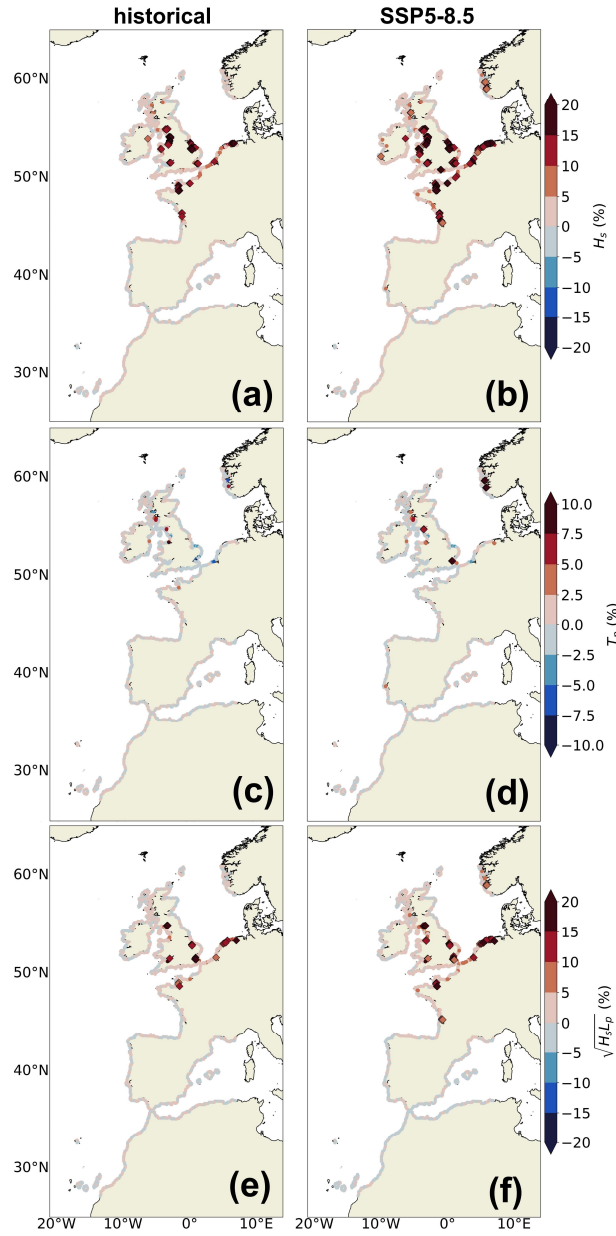

Figure 13: Impact of the inclusion of the hourly water level variations in the wave model on the 100-year return level of (a,b) significant wave height (first row, ΔH_s , in %), (c,d) peak period (second row, ΔT_p , in %) and (e,f) wave setup scaling (third row, $\Delta \sqrt{H_s L_p}$, in %). The first column shows the relative differences of the 100-year return level between IBI-CCS-WAV_ssh and IBI-CCS-WAV for the year 1985 (representative of the 1970-2000 period). The second column shows the relative differences of the 100-year return level between IBI-CCS-WAV_ssh and IBI-CCS-WAV for the year 2085 (representative of the 2070-2100 period) under the SSP5-8.5 scenario. The large diamonds represent the locations where the differences between both simulations are significant (i.e. where the confidence intervals associated with the 100-year return level calculation are disjoint). Note that the colorbars are saturated in red for some points for (b).

Projected changes in the 100-year return level under SSP5-8.5 scenario (not shown) are globally consistent with projected changes in the 99th percentile of significant wave height, peak period and wave setup scaling of Figure 8. Therefore, we use the IBI-CCS-WAV and IBI-CCS-WAV_ssh simulations to assess the influence of the inclusion of hourly water level variations in the wave model during high return period events. As for the 99th percentile, the coastal points of the large continental shelf of Figure 13 are highly impacted and particularly macro-tidal locations (Fig. 2b). However, the differences between IBI-CCS-WAV and IBI-CCS-WAV_ssh for the 100-year return level are of a larger amplitude than the differences for the 99th percentile of Figure 11 for the whole domain. At the end of the century, the consideration in the wave model of the combination of the tidal range, storm surges and mean sea level rise lead to greater values in extreme significant wave height and wave setup scaling by up to +20 % and +10 % respectively. However, these large impacts are found in locations where the projected changes for the 21st century are generally small since the largest projected changes are located in the southern domain. In spite of this, the effect of sea level on waves should be important to consider when analyzing extreme wave events but also when analyzing extreme water level events even if fewer locations are concerned for the wave setup scaling.

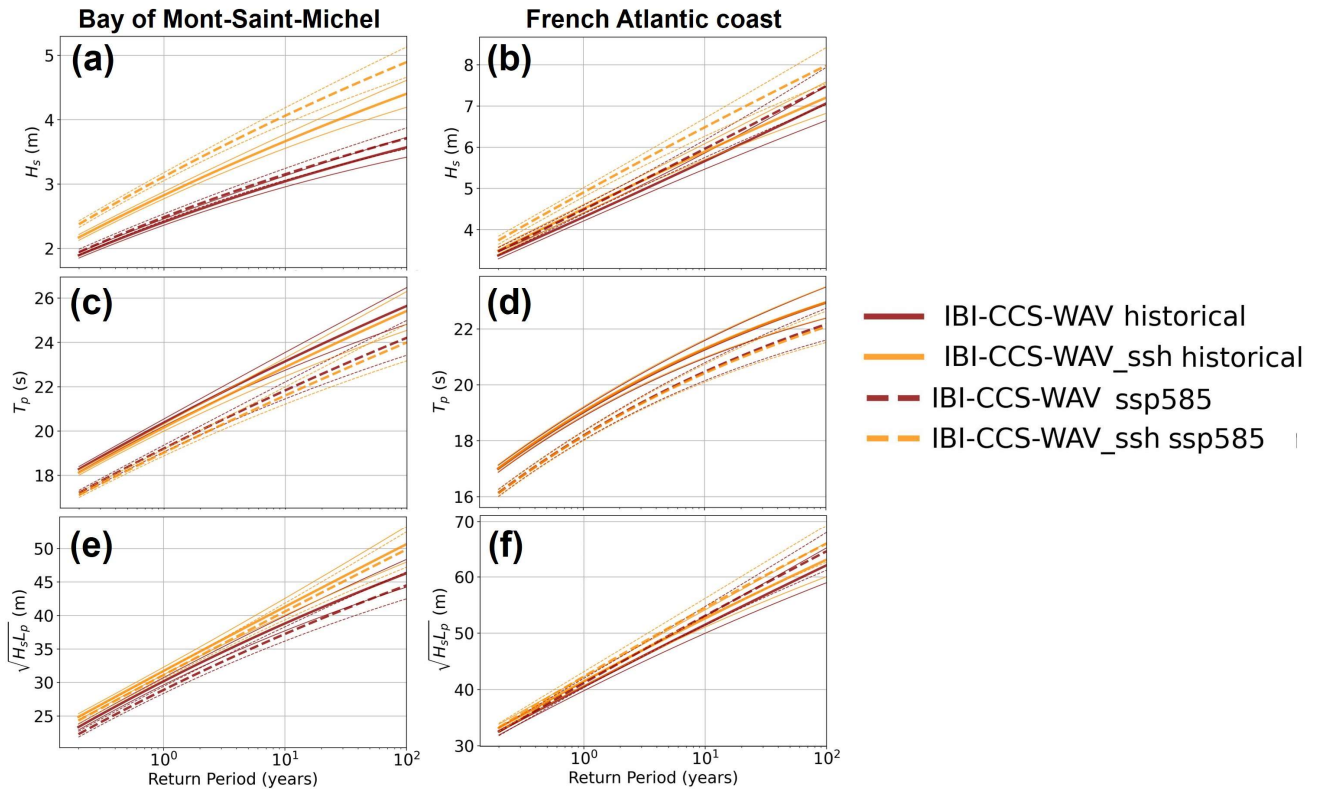

Figure 14: Return period curves of incoming wave conditions for IBI-CCS-WAV (dark red curves) and IBI-CCS-WAV_ssh (dark yellow curves) for the Bay of Mont-Saint-Michel (first column) and for the French Atlantic coast (second column) (Fig. 2b). The solid lines represent the year 1985 (representative of the 1970-2000 period) and the dashed lines the year 2085 (representative of the 2070-2100 period) for the SSP5-8.5 scenario. The rows show 3 variables: (a,b) significant wave height (H_s , in m), (c,d) peak period (T_p , in s) and (e,f) scaling for wave setup ($\sqrt{H_s L_p}$, in m). The thin solid and dashed lines are the confidence intervals (corresponding to 1 sigma confidence) associated with the extreme value analysis (EVA).

The return period curves for the Bay of Mont-Saint-Michel and for the French Atlantic coast are displayed in Figure 14 for the two simulations IBI-CCS-WAV and IBI-CCS-WAV_ssh. In the Bay of Mont-Saint-Michel, the differences between the two simulations are very important for the 1970-2000 period (dark curves) for the significant wave height (Fig. 14a). It is especially the case for high return periods such as the 100-year return level. As the confidence intervals for the two simulations are disjoint, the differences are considered significant. For the 2070-2100 period under the SSP5-8.5 scenario, the differences between the two simulations are even larger due to the mean sea level rise of about +80 cm. For example, in the case of the significant wave height, the 100-year return level is +35 % larger when considering the water level variations and for the wave setup scaling it represents an increase of +11 %. In terms of wave setup, using parameterization (1), the differences in the wave setup can reach from +7 cm to +12.25 cm for the 100-year return level depending on the beach slope. This value seems small but is important to consider in the context of threshold exceedance calculations to predict coastal flooding. For the French Atlantic coast, the confidence intervals between IBI-CCS-WAV and IBI-CCS-WAV_ssh are not distinct. Therefore, the differences due to the inclusion of the water level variations on the wave model are not considered significant. Overall, the longer the return periods, the larger the differences between the two simulations.

5 Discussion

5.1 Model resolution limitations

In our study, the impact of including the hourly water level variations in the wave model is limited by several resolution aspects. The first limitation is the horizontal resolution of the wave model. The model resolution of $1/10^\circ$ (~ 10 km) is conditioned by the computational cost due to the length of the simulations needed to address the question of extremes in a climate scale. It does not allow a very fine representation of the coastline and of the bathymetry in the coastal zones. For instance, to maintain a realistic balance between the 10 km horizontal resolution and the water depth, the minimum bathymetry is set to 6 m (i.e. time-mean minimum of 6 m) because it would have been unrealistic to have a bathymetry of 1 m within a 10 km grid point. In consequence, the wave model has fewer intermediate and shallow water areas than a higher resolution model and thus less non-linear interactions. Another limitation that may limit the non-linear interactions between waves and water level is the resolution of the atmospheric forcing from the global climate model (Sect. 2.3.2). Given that winds are the major drivers of extreme wave events in our study, the relative coarse resolution of the atmospheric drivers (~ 50 km) implies that

generated waves are more representative of a large-scale forcing than of coastal processes. Therefore, the results are not representative of the real situation at the coast but rather give a regional information.

5.2 Limitations associated with the use of parametrizations for the wave setup

580 Limitations in the use of parametrizations to estimate wave setup are thoroughly discussed in Melet et al., 2020; Lambert et al., 2020, including sensitivity analyses of the wave setup and runup contributions to different empirical parametrizations. The generic parametrization of Stockdon et al., 2006 used to compute the wave setup in our study is indeed subject to intrinsic limitations. A major limitation is that the formulation is only representative of sandy beaches. Other parameterizations (Guza and Thornton, 1981; Holman, 1986; dissipative case of Stockdon et al., 2006 or for a review Dodet et al. 2019) exist but they
585 are often limited to specific coastal environments (e.g. dissipative sandy beaches, rocky cliffs) and have been calibrated with relatively few field data. The calibration therefore does not cover all the spectra of the environmental conditions.

For our large-scale study, another major limitation is that the parameterization relies on the specification of a beach slope. As explained in Melet et al., 2020, the beach slope evolves over different time scales (extreme events, seasonal, interannual, and in response to sea level rise) and spatial scales (from alongshore at a given local beach to regional scales) and generally ranges
590 between 0.01 and 0.20 (Komar, 1998). At the moment, however, no observations of the foreshore beach slope applicable in empirical formulations is available worldwide or in Europe. Therefore, a time and space constant beach slope value is commonly used for global and regional studies (Serafin et al., 2017; Melet et al., 2018, 2020a), as done in this study. In Melet et al., 2020, a beach slope of 0.04 is used, corresponding to the median value of local values at 308 sites along the global ocean coastlines. In Serafin et al., 2017, a constant beach slope of 0.05 is used corresponding to the regional mean based on
595 observations for the west coast of USA. In Vos et al., 2020, regional beach slopes are provided for the coasts of southeastern Australia and USA California based on satellite data. The spatial mean of these regional estimates is 0.06 ± 0.02 for the Australia and 0.07 ± 0.02 for California. All these values for β are in the tested range of 0.04-0.07.

5.3 Limitations associated with the applicability of the parametrization to coastal points

To calculate the wave setup for the coastal points of our regional domain, we chose to use the simple parameterization of
600 Stockdon et al., 2006 based on deep water parameters. However, the coastal points are theoretically not purely deep water as shown in Figure 2a (yellow dotted lines). Yet, this approach, used in other climate studies (Melet et al., 2018, 2020a; Lambert et al., 2020), appears pragmatic given the model resolution limitations (Sect. 5.1) and the processes accounted for in the wave model (Sect. 2.1).

5.4 Impact of the absence of depth-induced wave breaking

605 Very close to the coast, the depth-induced wave breaking is a fundamental depth-dependent process that can have a first-order effect on the shallow water wave statistics and thus on the wave setup. As explained in Sect. 2.1, the physics associated with the explicit representation of coastal breaking waves is not activated. Such an approach is justified because our primary interest is to calculate the wave setup contribution to include it in further analyses on extreme water levels and the parameterization used to compute this contribution is based on deep water parameters (Sect. 2.5) that are not supposed to be affected by coastal
610 wave breaking. In consequence, as the regional wave model does not have a very fine representation of the bathymetry or the coastline (Sect. 5.1) and does not resolve the wave transformations in the coastal zones, the estimates provided in this study only partially represent the processes responsible for the wave-water level non-linear interactions.

With the coastal wave breaking included, the significant wave heights should be substantially impacted in shallow waters. The
615 impact of the inclusion of the water level variations in the wave model would also probably differ. A perspective for this study would be to take into account coastal wave breaking and to apply new specific wave setup formulations which would not require deep water characteristics or to use a wave model that directly resolve the wave setup.

5.5 Impact of waves on sea level

The aim of the study was to better understand the non-linear interactions between waves and sea level. In the modeling
620 framework of the paper, only the effect of sea level on waves is accounted for. However, both are coupled in reality with waves impacting on sea level. For instance, Bonaduce et al., 2020 have studied the contribution of wave processes to sea level variability over the European Seas with ocean-wave coupled simulations at an eddy-resolving spatial resolution of 3.5 km. They highlighted the occurrence of mesoscale features of the ocean circulation and a modulation of the surge at the shelf break due to the effect of the wave forcing on sea level. More importantly, they also reported a large contribution of wave induced
625 processes to sea level extremes which are up to 20 % higher on the European continental shelf due to these wave processes. By considering these processes into the ocean model, as the water level would be higher, the impact on the wave model would be larger which means increased wave-water level feedbacks.

5.6 Implications of the results on extreme wave projections

Marine flooding hazards cannot be quantified based on wave setup alone but wave setup can locally partially balance or enhance water levels at the coast (Melet et al., 2020a). Depending on the location (wave regimes, local ocean processes involved, sign of the extreme wave projected changes, amplitude of the projected changes in ocean processes), the inclusion of the non-linear interactions could thus enhance or balance the future wave extremes and may be important to consider for future flooding hazard calculations. The results presented in this study highlight that wave-water level non-linear interactions can be substantial for extreme wave height and wave setup, but are region dependent. For instance, the extreme wave projections are directly dependent on the water level variations forcing. In our case, the future water level variations and therefore a large part of the non-linear interactions are mainly associated with the mean sea level rise of about +80 cm and less so to changes in tides or storm surges. In other regions, large projected changes in tides or storm surges could impact the future waves conditions. For instance, Pickering et al., 2017 and Haigh et al., 2019 showed changes up to + 20 cm in the M2 component in the China Sea and in the Gulf of Saint Lawrence. Then, the future wave extremes could also be substantially more impacted in areas subject to larger mean sea level rise such as along the eastern coasts of the United States, in the Gulf of Mexico and in the Caribbean Sea where a rise of +1.4 m is expected at the end of the century under scenario SSP5-8.5 (Fox-Kemper et al., 2021).

6 Conclusions

Several studies have shown that water depth changes induced by sea level rise can induce changes in the wave field at a fine spatial scale (Hoeke et al., 2015; Arns et al., 2017; Lewis et al., 2019; Idier et al., 2019; Calvino et al., 2022). The aim of the present paper was to characterize, at a larger scale, the sensitivity of historical and projected sea states to the non-linear interactions between waves and water level changes (tides, storm surge, mean sea level rise), notably during extreme events. To address this question, a regional wave model has been adapted to include the wave-water level interactions over the northeastern Atlantic for the 1950-2100 period.

As a first step, the regional wave model has been presented and validated over the 1993-2014 period. Comparisons to observations and a wave reanalysis showed an overall good performance of the model. Secondly, as we used a single forcing climate model, projected regional changes in mean and extreme wave conditions were compared to previous studies. They were shown to be representative of other published projections over the northeastern Atlantic region, with a general decrease in mean and extreme significant wave height and peak period.

The impact of including hourly water level variations in the wave model was assessed over the historical period and for 21st century projections for the mean state and extremes of wind-wave characteristics and wave setup, the latter contributing to coastal sea level hazards such as coastal flooding. For the historical period, wave-water level interactions on the mean wave state and wave setup were found to be small. The impact of water level changes on wave conditions over the historical period is substantially more important when considering the 99th percentile or 100-year return level along the coasts of the large continental shelf and particularly in large tidal range areas. For example, in the Bay of Mont-Saint-Michel where the tidal range is of 10 meters, extreme significant wave heights were found to be larger by 1 meter (or +25 %) during a historical extreme wave event when considering hourly water level variations in the wave model. The corresponding increase in wave setup reached +8.4 cm and +14.7 cm, when considering beach slopes of 4 % and 7 % respectively. However, these values are the upper bound of the sensitivity of significant wave height and wave setup to wave-water level interactions with the settings of our model, as the Bay of Mont-Saint-Michel is subject to one of the largest tidal ranges of the IBI domain.

Mean sea level rise and, to a lesser extent, changes in tidal amplitudes and storm surges reach +80 cm in 2100 compared to the 1986-2005 mean under the SSP5-8.5 high-emission climate change scenario over the northeastern Atlantic (Chaigneau et al. 2022). This mean sea level rise has an overall effect in our regional projections of the mean wave state over the large continental shelf where shallow and intermediate water dynamics prevail. Significant wave heights are projected to be up to +3 cm (or +6 %) higher along the French Atlantic coasts and in the southern North Sea by the end of the 21st century due to water depth changes. The impact of accounting for wave-water level interactions on the wave setup mean state is of the same order of magnitude (+6 %). However, it should be noted that these impacts are found in locations where projected changes in significant wave height over the 21st century are generally small since the largest projected changes are located in the southern part of the regional domain. The main impact of the inclusion of hourly water level variations in the wave model is found during extreme events (99th percentile or 100-year return level) at the end of the 21st century. For high return period events, the consideration in the wave model of the combination of tides, storm surges and sea level rise lead to greater values in extreme significant wave height by up to +20 % for many locations at the end of the 21st century. The impact on the wave setup can be up to +10 % but fewer locations are concerned. Overall, the inclusion of water level variations on the wave model had almost no impact on the peak period.

However, as the regional wave model does not have a very fine representation of the bathymetry or the coastline and does not resolve the depth-induced wave breaking in the shallow areas, the estimates provided in this study only partially represent the processes responsible for the wave-water level non-linear interactions. Moreover, the results found might be dependent on the parametrization used to compute the wave setup and therefore on the beach slopes.

685 In conclusion, our results advocate for the inclusion of wave-water level non-linear interactions in modelling studies of wave extremes at this resolution or higher, in particular when significant wave heights are of interest. These non-linear interactions should be accounted for when threshold exceedances are calculated for example in order to prevent coastal flooding or to build coastal protection structures in a climate change context.

700 Services (Copernicus, 2022a: reanalysis data, <https://doi.org/10.48670/moi-00030>; Copernicus, 2022b: observational data, <https://doi.org/10.13155/53381>).

Author contribution:

AM designed the study. LA prepared the regional wave model configuration. SLC adapted the regional wave model to consider hourly variations of sea level and performed the regional wave simulations. AAC performed the sea level regional simulations and did the analyses of the study. AM, AV, GR, SLC and LA supervised the project. AM wrote the introduction, SLC wrote the Methods section and AAC wrote the Results, Discussion and Conclusions sections. All authors contributed to manuscript revisions and read and approved the submitted version.
