Abstract. Atmospheric aerosols have a substantial impact on climate and remain one of the largest sources of uncertainty in climate forecasts. Accurate representation of their direct radiative effects is a crucial component of modern climate models. Direct computation of the radiative properties of aerosols is far too computationally expensive to perform in a climate model however, so optical properties are typically approximated using a parameterization. This work develops artificial neural networks (ANNs) capable of replacing the current aerosol optics parameterization used in the Energy Exascale Earth System Model (E3SM). A large training dataset is generated by using Mie code to directly compute the optical properties of a range of atmospheric aerosol populations given a large variety of particle sizes, wavelengths, and refractive indices. Optimal neural architectures for shortwave and longwave bands are identified by evaluating ANNs with randomly generated wirings. Randomly generated deep ANNs are able to outperform conventional multi-layer perceptron style architectures with comparable parameter counts. Finally, the ANN-based parameterization is found to dramatically outperform the current parameterization. The success of this approach makes possible the future inclusion of much more sophisticated representations of aerosol optics in climate models that cannot be captured through simple expansion of the existing parameterization scheme.

1 Introduction

Atmospheric aerosols have long been known as the single largest sources of uncertainty in climate modeling (Bellouin et al., 2020). They have a profound impact on atmospheric radiation, and ultimately the entire Earth system, both through their direct radiative effects (Hansen et al., 2005; Johnson et al., 2018) and interaction with clouds (Twomey, 1977; Albrecht, 1989; Fan et al., 2016). Difficulties arise in both accurately modeling aerosol populations (Liu et al., 2012) and in determining their subsequent impacts in these areas. While in many cases the underlying physics may be well understood, modeling complex small-scale processes is not computationally feasible within an Earth System Model (ESM), and instead these key physical processes are represented by parameterization schemes.

Recently, there has been a flurry of research that has leveraged new advances in machine learning (ML) to enhance climate and weather modeling (Boukabara et al., 2021). Various strategies have been used, including: emulation of an entire weather or climate model (or at least key fields) with deep learning (Scher, 2018; Weyn et al., 2020), nudging parameterization output (Watt-Meyer et al., 2021; Bretherton et al., 2022), enhancing model output (Wang et al., 2021; Geiss et al., 2022), replacing

25 key model physics such as the radiative transfer scheme (Krasnopolsky et al., 2012; Lagerquist et al., 2021), and replacing
the many parameterizations that approximate un-resolvable sub-grid scale processes (Krasnopolsky et al., 2013; Rasp et al.,
2018; Brenowitz and Bretherton, 2018). While many of these approaches have some overlap, most are not mutually exclu-
sive strategies for improving climate forecasts: conventional climate models must be used to generate training data for purely
30 data-driven ML models and, in the future, those physics-based ESMs may be significantly enhanced by replacing key param-
eterization schemes with ML-emulators for instance. Ideally, future climate models will leverage continued research in model
development in conjunct with multiple ML-based approaches to generate climate simulations with unprecedented accuracy.

This research focuses on developing an Artificial Neural Network (ANN) emulator to replace the current aerosol optics
parameterization developed by Ghan and Zaveri (2007) for internally mixed aerosols represented by the 4-mode version of
the Modal Aerosol Module (MAM4) (Liu et al., 2016) in the Energy Exascale Earth System Model's (E3SM) (Golaz et al.,
35 2019) Atmosphere Model (EAM) (Rasch et al., 2019). We perform a thorough neural architecture search using randomly
generated ANN wirings to identify ANN structures best suited to accurately representing aerosol optics with the fewest possible
parameters (i.e. at the lowest computational cost). Finally, we show that the ML-based parameterization can significantly
outperform the current parameterization in terms of accuracy, and even outperforms very high-resolution aerosol optics lookup
tables, which would be too large to use in EAM, but can be seen as a high-resolution extension of the current parameterization.

40 Section 2 of this paper provides background information on the radiative effects of atmospheric aerosols and the aerosol
optics parameterization currently used in E3SM. Section 3 discusses how training and testing datasets were generated and how
the neural network input and output variables are handled. Section 4 describes the randomly generated ANN approach in detail
and the network training procedure and evaluation of the neural architectures. Section 5 evaluates the accuracy of the final
ML-based parameterization. Finally, Section 6 provides a short summary of results and some concluding remarks.

45 **2 Background**

2.1 Radiative Effects of Atmospheric Aerosols

Atmospheric aerosols influence Earth's radiative budget both through direct interactions with radiation and modification of
clouds (Boucher et al., 2013). Both effects have long been major sources of uncertainty in climate simulations as chronicled
by over two decades of assessment reports from the Intergovernmental Panel on Climate Change (see Bellouin et al. (2020)
50 Table 1). Accurate representation of atmospheric aerosols in climate simulations is hindered by many challenges, including
complex aerosol-chemical and microphysical processes, aerosol-cloud-precipitation interactions, and aerosol-radiation inter-
actions. Even though the underlying physics have been studied in great detail and accurate physics and theory-based models
exist to represent the relevant processes, these models are far too computationally expensive to use in an ESM. Instead, such
processes are represented with simplified physical models and parameterizations that usually make sweeping simplifications
55 in their representation of aerosol processes and trade model accuracy for computational tractability.

One crucial component of an atmospheric model is a radiation scheme. Radiative transfer models are responsible for repre-
senting the radiative exchange of energy between space, the Earth's surface, and the many intervening layers of the atmosphere

resolved by an ESM. The radiative flux divergence computed by radiation code is used to determine heating rates in the atmosphere which ultimately impact large-scale atmospheric dynamics. E3SM uses the version of the Rapid Radiative Transfer Model (RRTM) (Mlawer et al., 1997; Mlawer and Clough, 1997) developed for use in general circulation models (RRTMG) (Iacono et al., 2008; Pincus and Stevens, 2013). RRTMG does not take information about aerosol populations as a direct input. Instead, the bulk optical properties of the aerosol populations in each grid-cell are first estimated based on (Ghan and Zaveri, 2007), and these properties (absorption efficiency, extinction efficiency, and asymmetry parameter) are passed to the radiative transfer scheme.

65 Estimation of the optical properties for aerosol populations in each model grid-cell is, on its own, a computationally daunting task. Scattering of light by particles is generally separated into three regimes that are defined by the difference between the wavelength of light (λ) and size of the particle (d): Rayleigh ($d \ll \lambda$), Mie ($d \approx \lambda$), and geometric ($d \gg \lambda$). In both the Rayleigh and geometric scattering regimes the optical properties of an aerosol particle vary smoothly as a function of its size. In the Mie regime however, absorption and scattering efficiencies can vary wildly as a function of changing particle diameter. 70 Mathematically, these undulations arise as the solution to Maxwell's equations applied to propagation of electromagnetic radiation over a spherical particle (Van de Hulst, 1957). Solutions can be found in the form of an infinite series, though these series are weakly converging, and sometimes require a large number of terms to accurately determine a particle's optical properties (Hansen and Travis, 1974; Bohren and Huffman, 1983). In any case, this is a scenario where underlying physics are understood and accurate numerical models to represent the physics have been developed, but they are far too computationally 75 expensive to use at a large scale (Wiscombe, 1979; Sunlin et al., 2018).

A significant portion of atmospheric aerosols have size parameters (the ratio of particle size to wavelength) within the Mie regime, particularly in the shortwave radiative bands used by EAM's radiative transfer code. Because of the computational difficulty of determining optical properties in this regime, parameterizations must be used to represent this physics in an ESM (Ghan and Zaveri, 2007; Pincus and Stevens, 2013). This parameterization must represent a high-dimensional manifold in a 80 space defined by aerosol size distribution, imaginary and real components of aerosol refractive indices, various aerosol species, and various wavelengths of light. The portion of this manifold that falls in the Mie regime is characterized by large fluctuations, particularly with respect to wavelength and particle size, and any function used to parameterize it will likely require a large number of parameters to adequately capture this variability. In this work, we focus on developing a parameterization of bulk aerosol radiative properties that is fast enough to use in an ESM and substantially more accurate than previous methods.

85 2.2 E3SM and the Modal Aerosol Module

This study focuses on updating the aerosol optics representation for E3SM, an ESM developed by the U.S. Department of Energy (Golaz et al., 2019). EAMv1 (Rasch et al., 2019) uses the 4-mode version of the Modal Aerosol Module (MAM4) (Liu et al., 2012, 2016) with improvements to represent aerosol processes (Wang et al., 2020), RRTMG for atmospheric radiative transfer (Iacono et al., 2008; Pincus and Stevens, 2013), and the Ghan and Zaveri (2007) parameterization for aerosol optics. 90 This parameterization is also used in other ESMs, including the Community Earth System Model v2.2 (NCAR, 2020), so the new parameterization developed in this study can be easily used in other ESMs.

MAM is a simplified model of aerosol populations that was developed to allow representation of key aerosol physics in climate simulations without being computationally prohibitive. Because of the complexity of the general dynamic equation for aerosols (Friedlander, 2000), several methods for representing aerosols in simulations of the atmosphere exist that have varying degrees of accuracy and computational complexity. These include bulk models (Lamarque et al., 2012), modal models (Liu et al., 2012), the sectional method (Gelbard et al., 1980), the quadrature method of moments (McGraw, 1997), and discrete models (Gelbard and Seinfeld, 1979). The key differences between these models are primarily their treatment of aerosol size distributions and mixing. Section 1 of Liu et al. (2012) and Table 1 of Zhang et al. (2020) provide overviews of different approaches to modeling aerosol populations.

100 The MAM approach breaks aerosols down into several modes based on species and approximate size. MAM4 includes Aitken, Accumulation, Coarse, and Primary Carbon modes. Each mode contains multiple aerosol species within a certain particle size range and MAM assumes internal mixing within modes and external mixing between modes (aerosol properties are averaged within each mode). The modal model assumes that the size distributions of each mode are log-normal and prescribes the log-standard deviations based on past observational studies. Major uncertainty in the modal approach stems from the limited representation of internal vs external mixing of aerosol species and the assumption of log-normal size distributions. It is reasonably accurate and very computationally efficient compared to other schemes however, and this makes it a good choice for long-duration ESM simulations.

2.3 The Ghan and Zaveri (2007) Aerosol Optics Parameterization

EAMv1 uses a parameterization to estimate the bulk optical properties of simulated aerosols. The parameterization is described in detail in Ghan and Zaveri (2007) with further relevant information found in Ghan et al. (2001) and Neale et al. (2012), but we will provide a brief overview of the method here because it will be useful for understanding subsequent sections of this paper. A diagram of the aerosol optics parameterization training/preparation and how it integrates with EAMv1 is provided in Figure 1 and may be a helpful reference while reading this section.

115 The existing optics parameterization estimates optical properties based on five input parameters: aerosol mode (corresponding to MAM modes), wavelength band, real refractive index, imaginary refractive index, and surface mode radius. Optical properties are pre-computed over a range of values in each of these five dimensions, and when called by the model, the parameterization estimates optical properties from these pre-computed values using a combination of Chebyshev and linear interpolation.

The pre-computed optical properties are generated as follows: for each wavelength band and aerosol mode, refractive index bounds are computed by taking the minimum and maximum refractive indices across all aerosols in that mode and water. The real refractive index range is spanned by 7 linearly spaced values and the imaginary refractive index range is spanned by 10 exponentially spaced values. Then a range of 200 plausible aerosol radii is generated between $0.001\mu\text{m}$ and $100\mu\text{m}$. The wavelength, refractive index, and radii data are fed to a Mie code (Wiscombe, 1979) to compute the optical properties for individual particles. Ultimately the parameterization uses bulk optical properties integrated over a size distribution however, so a range of 30 log-normal size distributions is assumed and the individual particle optical properties are integrated over

these size distributions. The size distributions are generated for surface mode radius values between $0.01\mu\text{m}$ and $25\mu\text{m}$ and spaced according to Chebyshev nodes. The optical properties are then fit with a 5th-order Chebyshev polynomial along the surface mode radius dimension and the 5 Chebyshev coefficients are saved rather than directly saving 30 optical property values (Vetterling et al., 1988). Ultimately a 3-dimensional matrix (real refractive index, imaginary refractive index, and surface mode radius) of Chebyshev coefficients is stored for each wavelength and aerosol mode combination, and four of these must be produced representing the four required output variables: shortwave absorption efficiency, shortwave extinction efficiency, shortwave asymmetry parameter, and longwave absorption efficiency. Because of its high dimensionality, the size of the data stored by the parameterization grows rapidly as the resolution with which it resolves the input parameters is increased. This is a major motivation for replacing the current parameterization with a neural network, because increasing accuracy by increasing resolution of the input parameter space rapidly becomes intractable in the existing parameterization.

When the parameterization is called by EAM, it is passed a surface mode radius and refractive index for each aerosol-mode/wavelength-band combination. The parameterization applies bi-linear interpolation along the refractive index dimensions of the table to estimate Chebyshev coefficients at an intermediate refractive index. Then, the 5th order Chebyshev polynomial generated with these coefficients is used to estimate the optical properties as a function of surface mode radius. This approach is very similar to using a lookup table, in that the optical properties have been pre-computed, with the major difference being that a combination of bi-linear and Chebyshev interpolation is used to resolve three of the dimensions as continuous functions of the input variables.

Errors are introduced at nearly every step in this process, including averaging of within-mode refractive properties, a limited number of wavelength bands treated by the model, assumed aerosol size distributions, interpolation of refractive indices and particle size distributions, and others. This approximation of well understood but un-resolvable physics is a frustrating but unavoidable facet of climate modeling. Here, we set out to replace the Chebyshev interpolation approach with a neural network emulator, which addresses the errors incurred by coarsely resolving the refractive index, surface mode radius, and particle radius information (evaluated in more detail in Section 5).

3 Data

3.1 Mie Code

Training a neural network to emulate Mie scattering first required generation of large training, validation, and testing datasets using established Mie solvers. We chose to refactor the Fortran code used to generate the existing parameterization's pre-computed optical properties into Python. The FORTRAN77 "miev0" Mie scattering code (Wiscombe, 1979, 1980), which was originally used to perform Mie calculations to generate the current EAM parameterization, was replaced by PyMieScatt (Sumlin et al., 2018), a Python-based Mie code. The machine learning libraries used in this study are also written in Python and this refactoring allowed for an end-to-end Python-based pipeline for creating the neural network emulator and will allow for easier and more flexible editing if new training data needs to be generated in the future. Furthermore, PyMieScatt has support for additional scattering models, such as shell-core optics, which we intend to integrate into the neural network emulator in the

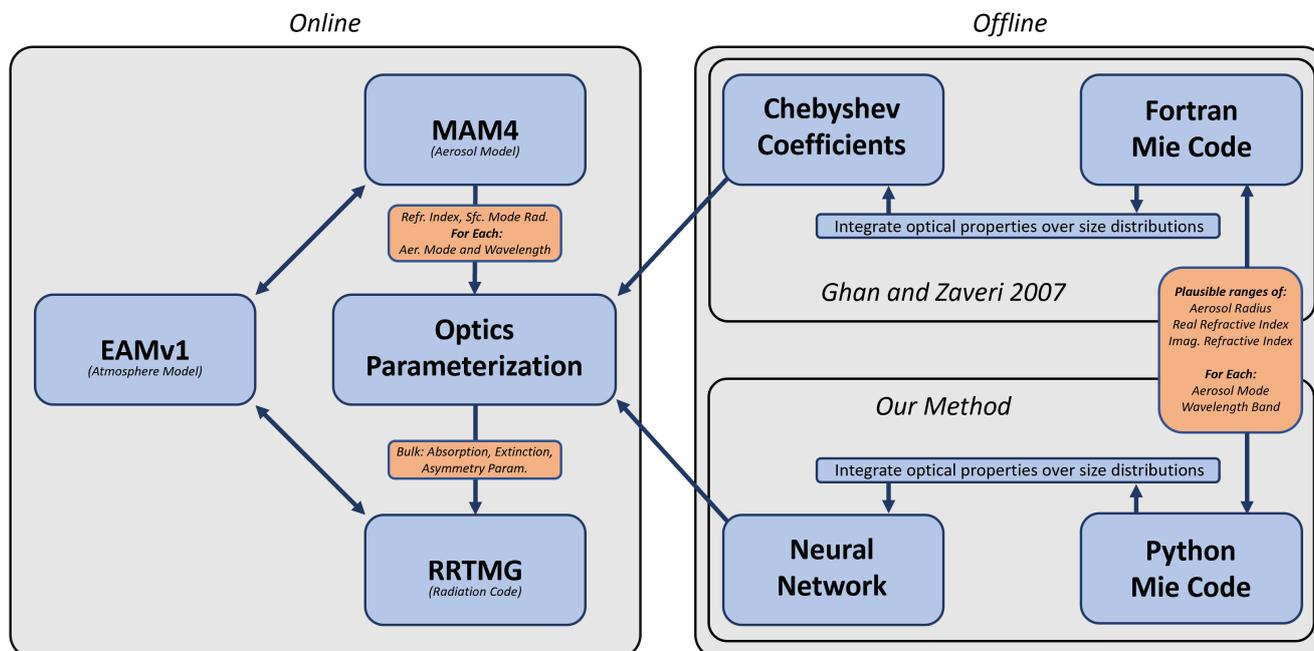

Figure 1. A diagram of the aerosol optics parameterization and how it integrates with EAM. The "online" section shows how the parameterization is used during a simulation and the "offline" portion shows the process of pre-computing optical properties and preparing the parameterization.

future. We have made all of the code written for this study available on the project's Github repository (see the "Code and Data
160 Availability" statement).

To ensure that using PyMieScatt did not introduce any additional errors or discrepancy with the original parameterization we performed a comparison to miev0. The optical properties of every refractive index, particle size, and wavelength combination used by the original parameterization were output and compared to the same optical properties computed using PyMieScatt. The maximum, 99.9th-percentile, and 99th-percentile absolute errors are shown in Table A1. Even the most extreme discrepancies
165 between the two schemes are negligible compared to other sources of error in the parameterization.

3.2 Training and Validation Data

For ANN training, we generated a large table of bulk aerosol optical properties similar to what is described in Section 2.3, but with significantly higher resolution in terms of its input variables. We used the same bounds for possible real and imaginary refractive index values, particle radii, and surface mode radius as in (Ghan and Zaveri, 2007), and similarly used exponential
170 vs linear spacing depending on the variable (the same wavelength bands and aerosol modes were used). The resolution of each of these variables was increased to 2049 particle radii, 257 surface mode radii, 129 imaginary refractive indices and 129 real refractive indices. This is in comparison to 200, 30, 10 and 7 values (respectively) in the original parameterization. The

resulting high-resolution table has about 20,000 times the number of entries, takes on the order of 1-day to compute using parallelized code on a modern CPU, and occupies several GB of RAM, making it inappropriate for direct use in an ESM.

175 When training a neural network, it is best practice to evaluate the ANN on a hold-out set of validation data after it is trained as a check for over-fitting to the training data. The validation data used here were drawn randomly from the high resolution table using half of the data points for training and half for validation. In this application, the boundaries of the optical property tables were chosen by Ghan and Zaveri (2007) to encompass all possible input values the parameterization could receive from the ESM, so we are not concerned about poor performance when extrapolating outside of the optics table. There is potential
180 for over-fitting to cause unexpected behaviour in the regions between points in the training set however, and this choice of validation set allows for detection of this type of over-fit if it occurs.

3.3 Testing Data

In addition to a validation set, when hyperparameter tuning is used or multiple models are tested, an additional set of “test” data should be held out to ensure that the validation set has not been over-fit by the hyperparameter or model selection. The test set
185 used in this study was generated separately from the training data by randomly generating input values from within the bounds of the optics table (with the inputs selected from continuous distributions instead of a discrete grid). This involved randomly selecting a wavelength band and aerosol mode, randomly selecting a real refractive index from a uniform distribution, and randomly selecting a surface mode radius and imaginary refractive index from log-uniform distributions. 10^6 random samples were generated this way for both the shortwave and longwave regimes. By nature of their random selection, these samples do
190 not coincide with the regular grid points used to generate the training and validation data. This test set was used to ensure that the randomly wired ANN approach did not lead to an overfit of the validation set. It also provides verification that the uniform spacing of the values in the training and validation sets do not lead to any overfit.

3.4 Benchmark Datasets

In addition to the high-resolution optics data used for training and validation, three other tables of optical properties were
195 generated at intermediate resolutions of: $1025 \times 129 \times 65 \times 65$, $513 \times 65 \times 33 \times 33$, and $257 \times 65 \times 17 \times 9$. Where the table dimensions have been listed in the order: (particle radii) \times (surface mode radii) \times (imaginary refractive index) \times (real refractive index). We have chosen to scale dimensions to a power of two plus one so that grid points in a table will be bisected by grid points in the next highest resolution table. These datasets have total parameter counts of 9.2×10^7 , 1.2×10^7 and 8.5×10^5 respectively. Note that the number of particle radii used to resolve the particle size distributions does not add to the size of the
200 optics table and is only used when the dataset is generated, but is important to the table’s accuracy. Also note that the total parameter count, in the shortwave table for example, is computed as: (number of surface mode radii) \times (number of imaginary refractive indices) \times (number of real refractive indices) \times (14 shortwave bands) \times (4 aerosol modes) \times (3 optical properties). These additional optics tables were evaluated by linearly interpolating their entries to query points in the test set described above, and the resulting errors are shown in Table 1 in Section 5. They provide an indication of how the resolution of the
205 training data might impact the accuracy of the trained neural network parameterization.

3.5 Neural Network I/O

Neural networks tend to perform better when input and output data have certain well-behaved distributions and formats. Several pre- and post-processing steps were used alongside the ANN to help ensure optimal performance. Each ANN has 9-inputs (in order): wavelength, real refractive index, imaginary refractive index, surface mode radius over wavelength, surface mode radius, and a “one-hot” encoding of the four aerosol modes (four values). The one-hot encoding is a common strategy for categorical inputs and usually leads to better performance than a single scalar input that encodes the category. All of the other input variables are scalar and are each standardized by first taking the log, then subtracting the mean and dividing by the standard deviation (except for real refractive indices where a log is not used). The means and standard deviations used to generate the training set are shown in Table A2 and are based on data from the training set. This yields dimensionless, zero-centered inputs with a standard deviation of one and without extreme skew or leptokurtosis.

The outputs of the ANN are also scaled to ensure that they are bounded by 0 and 1. This allows use of a sigmoid output function that constrains the ANN’s outputs to a reasonable range. The absorption efficiency is scaled by a factor of 2.2 while the extinction efficiency is scaled by 4.6. These values were determined empirically from the training set. The asymmetry parameter is already bounded by 0-1 and is not scaled. When the parameterization is used in an ESM these exact pre- and post-processing procedures will need to be followed.

Finally, several of the wavelength bands used by RRTMG have different associated ranges of refractive indices. To avoid training the ANNs on large regions of the input space that will never be queried by the ESM, we split up the problem by training three ANNs meant to operate on different sets of wavelengths for which the other input parameters occupy similar regions of the input space. One ANN processes all shortwave bands (denoted “SW” below); a second processes longwave bands: 3, 4, 5, 6, 9, 10, 11, 12, 13, 14, 15, and 16 (denoted “LW1”); and the final ANN processes longwave bands: 1, 2, 7, and 8 (denoted “LW2”; the LW2 bands are centered on $514\mu\text{m}$, $24.3\mu\text{m}$, $9.73\mu\text{m}$, and $8.87\mu\text{m}$). Specifically, longwave bands 1, 2, 7, and 8 are associated with real refractive indices that span nearly twice the range of the other longwave bands, and breaking these out to a separate dataset halves the size of the input space that must be used for training for the remaining longwave bands.

4 Randomly Wired Neural Networks

4.1 Background

Neural networks are powerful data fitting tools, and simple ANN designs can easily generalize to a wide variety of problems. Even so, specialized ANN architectures that have been optimized for a task will usually perform best. These task-specific ANN design choices often present a quandary however. The space of reasonable ANN designs is usually far too large to explore exhaustively and typically researchers will rely on heuristics, past experience, or simply convenience and popularity to choose an appropriate ANN architecture.

Various algorithmic approaches to Neural Architecture Search (NAS) (Elsken et al., 2019) and Hyper-Parameter Optimization (HPO) (Hutter et al., 2019) have become popular for addressing this problem. These algorithms usually involve training

many different neural networks with a range of parameter and design choices and selecting the best performing models. Search methods range from simple random or grid search to sophisticated algorithms such as evolutionary optimization (Angeline et al., 1994), Bayesian optimization (Bergstra et al., 2013), or reinforcement learning (Baker et al., 2017). Much of the recent (past 10 years) research in neural architecture search has focused on developing new convolutional neural network architectures for image processing (e.g. Zoph et al. (2018)). Elsken et al. (2019) and Yao (1999) provide reviews of this topic.

Most NAS strategies that test a variety of network wiring patterns are limited to exploring certain families of pre-defined network styles, or break up the search space by randomizing individual network “cells” that are then wired together in sequence. Xie et al. (2019) however, demonstrated a NAS strategy in which new convolutional neural network architectures were discovered through random wiring of network layers. Motivated by early observations during our work that inclusion of skip connections and more complex wirings contributed to performance for the aerosol optics problem, we chose to employ a similar approach here. While Xie et al. (2019) focus on convolutional neural networks, here we use ANNs constructed of fully connected layers. We designed an ANN generator that automatically produces ANNs with a random number of layers, random layer sizes, and random connections between layers. Ultimately the randomly generated wirings allow for the discovery of networks that substantially outperform simple multi-layer perceptrons.

4.2 Motivation

The physical parameterization problem discussed in this paper is particularly well suited for an ANN. The bulk aerosol optical properties used by the parameterization can be thought of as smooth, bounded, manifolds in a high dimensional space, and representing this type of dataset is an area where neural networks often excel. It is also a particularly data-rich problem because the only limits to the size of our training dataset are the computational and storage resources we would like to devote to generating training data (and ultimately an upper bound on training set resolution where neighboring data points become highly autocorrelated). In early experiments, we found that while simple feed-forward multi-layer perceptron style architectures with 1-2 hidden layers can provide much higher performance than the current EAMv1 parameterization discussed in Section 2.3, more complex architectures that included many smaller layers with skip connections could achieve even higher accuracy without an increase in the number of model parameters. Ultimately, when used in a climate model, the ANN-based parameterization will be evaluated many times (every time the radiative transfer code is called for each model grid cell). This means that reducing the network size as much as possible without significantly reducing accuracy is a worthwhile endeavor, and can save both computation-time and memory when the climate model is run. Additionally, because of the relatively small size (500-100,000 parameters) of the ANNs used here, they are cost effective to train. Together, these factors mean that this ML problem is ideal for NAS.

4.3 The Random ANN Generator

Our ANN generator randomizes network layer size, layer count, merge operators, and wiring. First, it randomly chooses a number of layers between 2 and 12, then randomly chooses the number of neurons per layer between 7 and 45. To facilitate

270 merging inbound tensors to a layer with element-wise addition, all layers in the network use the same number of neurons. Each hidden layer used in the network is a fully connected layer and applies a *tanh* transfer function to its outputs.

Once layer counts and size are selected, the ANN generator creates a random wiring between the layers by generating an adjacency matrix that represent layer connections. Several constraints must be enforced on the adjacency matrix to ensure that it represents a usable ANN architecture. Firstly, we require that the ANN is feed-forward. If each row in the adjacency matrix represents a layer in the order in which they will be evaluated in the ANN, this can be accomplished by enforcing the adjacency matrix is lower-triangular. For an ANN with N hidden layers this means there are $\frac{1}{2}(N^2 + N)$ valid layer connections. The number of active connections for an ANN is randomly chosen from a uniform distribution between 0 and $\frac{1}{2}(N^2 + N)$ and then this many entries in the lower triangular portion of the adjacency matrix are randomly turned on. Additionally, because the number of layers in the ANN is determined before the adjacency matrix is constructed, each layer must have at least one inbound and one outbound tensor. This is accomplished by iterating through each row and column of the adjacency matrix and randomly turning on one valid inbound and/or outbound connection if the corresponding layer has none.

Lastly, the number of inputs to each ANN are static (9-inputs) but we would like the outputs from each network layer to be a fixed size and any layer can be directly connected to the input layer. As a workaround, each ANN includes an additional fully connected layer with a number of neurons equal to the difference between the 9-inputs and the randomly selected network layer size. The outputs from this layer are appended to the actual inputs as a learnable padding.

Initial experiments on a subset of the training data were run using a single shortwave band (because of reduced training time on the smaller dataset) with additional randomizations including: variable layer sizes (ANNs that used different layer sizes internally exclusively used concatenation to merge tensors); randomly selected activation functions from: linear, tanh, ReLU, ELU, Leaky ReLU, and Parametric ReLU; and batch normalization (Ioffe and Szegedy, 2015), dropout (Srivastava et al., 2014), or no regularizer. These experiments showed that the *tanh* function provided slightly better performance than other transfer functions and that including batch normalization or dropout substantially reduced performance. We hypothesize that the reduced performance with dropout is related to the fact that we are testing relatively small networks. Because dropout layers generally force the ANNs to learn redundant representations of the data and the small ANNs used here only have limited capacity to represent the complex training data, requiring them to learn redundant representations of the data only reduces their skill. Additionally, the complexity of the training data and small size of the networks means that we are not particularly concerned about over-fits and do not expect to gain much from using regularization techniques. These additional types of randomizations were not included in final experiments.

4.4 Training Procedure

Each model was trained using the Adam optimizer with an initial learning rate of 0.001, $\beta_1 = 0.9$, and $\beta_2 = 0.999$ to optimize mean squared error. We used a batch size of 32 samples randomly selected from the training set and trained on 5×10^7 batches, reduced the learning rate to 0.0001 and trained for an additional 2×10^7 batches, and lastly reduced the learning rate to 0.00001 and trained for a final 1×10^7 batches. For the LW2-ANN the training dataset was smaller due to the smaller number of spectral bands, and sets of 2.5×10^7 , 1×10^7 and 5×10^6 batches were used instead. In a final training phase, once randomly generated

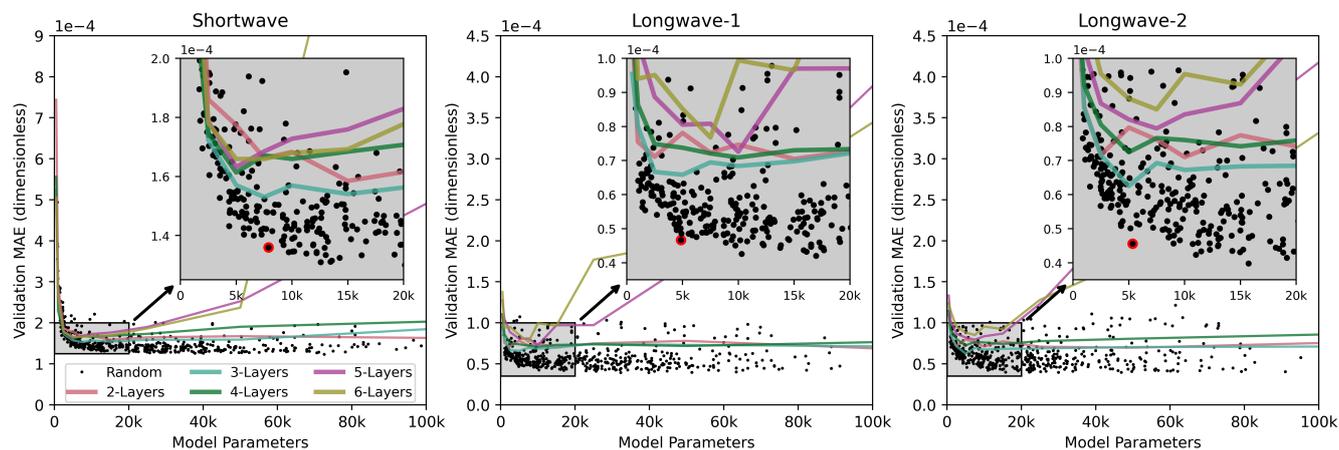

Figure 2. Validation set performance of randomly wired neural networks plotted against the network size. Each panel shows the results for a different wavelength region. The mean absolute error is computed on normalized optical properties (directly on the outputs from the neural networks) and are dimensionless. In each case, there is a clear elbow, beyond which increasing the network size does not substantially improve performance. In each panel, the inset shows a magnified region around this elbow. Solid lines indicate the performance of traditional feed forward multi-layer perceptron ANNs with 2-6 hidden layers.

models have been selected for each of the three groups of wavelength bands, the selected architectures were trained again from random initializations, this time with double the number of batches before each learning rate reduction and sampling batches from the combined training and validation sets. These final ANNs were evaluated on the randomly generated test set described in Section 3.3.

4.5 Random Network Selection

During the initial training stage, in which random networks were evaluated, 500 randomly wired ANNs were trained using the above procedure for each set of spectral bands. After training, each ANN was evaluated on the validation set, and Figure 2 shows scatter plots of each random ANN's performance in terms of mean absolute error (MAE) on the standardized ANN outputs plotted against the number of trainable parameters in the network. We also trained several benchmark ANNs for comparison to the random ANNs. Each of the benchmark networks is composed of 1 to 6 hidden layers wired in sequence with *tanh* transfer functions and represent the performance of conventional ANN architectures. Benchmark ANNs with a total of 10 different sizes in terms of total trainable parameters were used. 5-copies of each unique benchmark ANN layer-count and parameter-count combination were trained and only the best performing models were retained to ensure that poor performance at a particular ANN size was not simply due to an unlucky random initialization or training sample selection. This means that a total of 300 benchmark ANNs were trained for each combination of spectral bands. The performance of these benchmark ANNs is also indicated in Figure 2 by solid lines, though the 1-layer ANNs performed almost an order of magnitude worse than the others and are omitted from the figure.

Each panel in Figure 2 shows a similar pattern in terms of ANN performance versus size: skill improves rapidly with increasing size until it plateaus somewhere between 1,000-20,000 trainable parameters. Additional size increases yield only very small performance gains. The approximate location of the elbow in each of these performance vs size plots is expanded in an inset panel in each figure panel. Based on these inset plots we subjectively chose ANNs for each group of wavelength bands that appear to provide a good balance between network size and skill. The selected ANNs are denoted in Figure 2 with red circles, and diagrams of the wirings for the selected networks are shown in Figure 3. Note that later, in Section 5 errors will be reported after re-scaling the standardized network outputs for comparison to the Ghan and Zaveri (2007) scheme, so here we report the ANN's MAE on the test set computed directly on the ANN output as in Figure 2. SW: 1.4×10^{-4} , LW1: 4.7×10^{-5} , LW2: 3.7×10^{-5} . The comparable performance on the test set to the validation set indicates that the chosen ANNs did not overfit the training and validation data.

The ANNs that were ultimately chosen based on their performance versus parameter count generally had a high number of small layers with a high degree of connectivity. In fact, the ANN chosen for the second set of longwave bands (Figure 3 "LW2") is only missing a single connection and would otherwise be a densely connected ANN (Huang et al., 2017) (note that here, a "densely connected network" refers to a multi-layer network in which each layer output is fed to all subsequent layers, not to be confused with the term "dense layer" which is sometimes used to refer to fully connected layers).

The performance of the benchmark ANNs provides some insight into ANN design. Firstly, we note that 1-layer ANNs were also tested but typically performed nearly an order of magnitude worse than other ANNs and are not shown in Figure 2. This suggests that using almost any multi-layer architecture, regardless of construction, can yield substantial performance gains. Secondly, the 2-6 layer sequential models are outperformed by the majority of randomly wired ANNs that have similar parameter counts. This result is helpful for this specific use case, where the ANN's memory and compute requirements at inference time are of particular importance, and by evaluating many ANN architectures we have identified ANNs with significantly higher accuracy than conventional architectures with no increase in inference cost. Finally, the multi-layer sequential models with more than 3-layers begin to perform worse than their shallower counterparts. It appears that the inclusion of skip connections has likely allowed the random networks to train successfully despite their depth (high layer count). While this concept has been thoroughly explored in the context of building very deep convolutional neural networks (He et al., 2016) it has only rarely been applied to ANNs with fully connected layers, though some early examples of this approach do exist (Lang and Witbrock, 1988). Taken together, these results indicate that significant performance gains may be achieved in other applications of ANNs in the Earth Sciences and Earth system modeling through in-depth exploration of task-optimized network architectures.

5 Evaluation

The ANNs were ultimately evaluated on the randomly generated hold-out test set described in Section 3.3. The existing aerosol optics parameterization was also evaluated along with linear interpolation applied to several high-resolution tables of aerosol optical properties that were generated at a range of resolutions (described in Section 3.4). This includes the very high resolution table used for training. MAE for each of the output parameters and sets of wavelength bands are listed in Table 1. The ANN

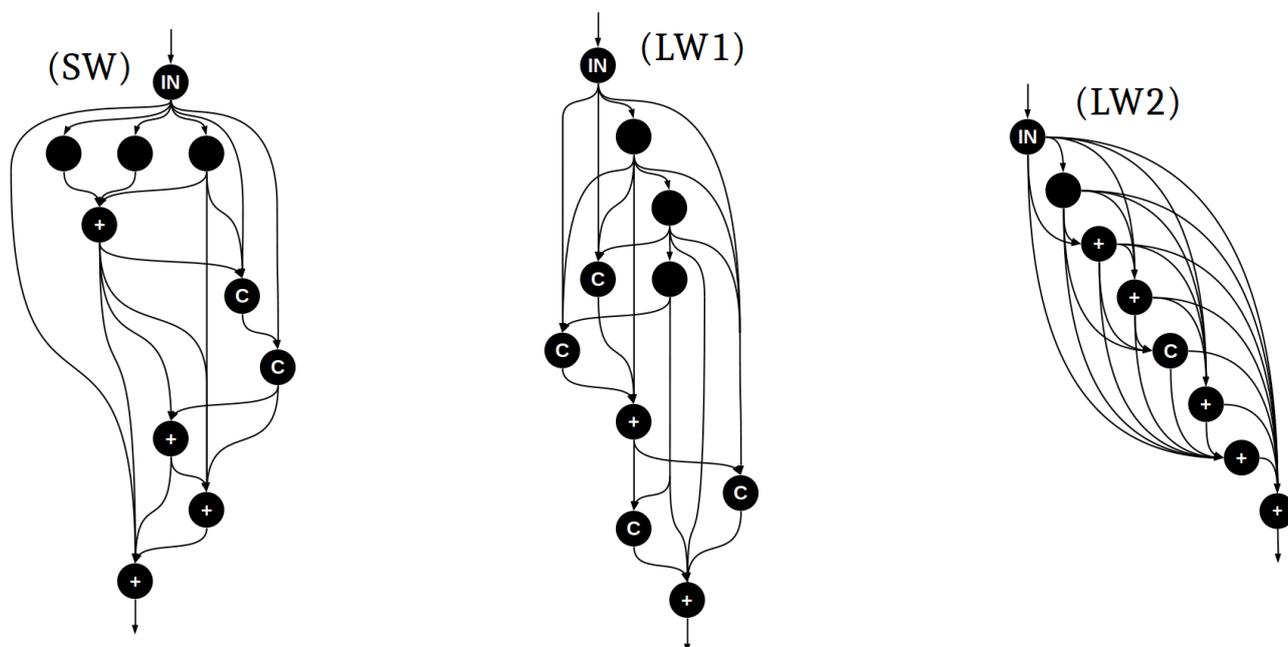

Figure 3. Wiring patterns of the three randomly generated neural networks that were selected for use in the optics emulator. Nodes represent “dense” (fully connected) layers. “C” and “+” indicate whether inbound tensors are combined by concatenation or addition. All hidden layers have the same number of neurons within each network: SW: 26, LW1: 17, LW2: 25 (the nine inputs are padded to reach the appropriate size and the output layer has either 3 or 1 neurons).

shows a substantial performance improvement over the existing parameterization, with MAEs about two orders of magnitude
 355 smaller. This is particularly notable for the shortwave extinction efficiencies where the existing parameterization has an MAE
 of .26 but the ANN has an MAE of 0.001. Extinction efficiencies range from about 0 to 4.5 so an MAE of .26 is substantial.
 The performance of the additional interpolated optics tables behaves about as expected, with the MAE decreasing in proportion
 to table size. It can also be seen that to achieve performance comparable to the ANN a lookup table with approximately 10^9
 parameters is required. This is far too large to be used in an ESM.

360 The very low MAE shown in Table 1 is encouraging, but ideally a parameterization should perform well over the full range
 of possible inputs and a low MAE could potentially still be achieved in the presence of outlier cases with high error. Figure
 4 shows histograms of the absolute error for each sample in the test set. Here, we see that in addition to outperforming the
 benchmark optics tables and existing parameterization on average, the most extreme errors produced by the ANN are also far
 smaller than those produced by the other schemes. Finally, Figure 5 shows a joint-histogram of bulk aerosol optical properties
 365 estimated by the existing parameterization and by direct computation with Mie code for all samples in the test set. Separate joint
 histograms are not included for the ANN outputs, instead a red contour in each of the joint histograms denotes the boundary
 containing all samples. Drawing the training set from a regular grid over the input space has ensured good coverage of possible

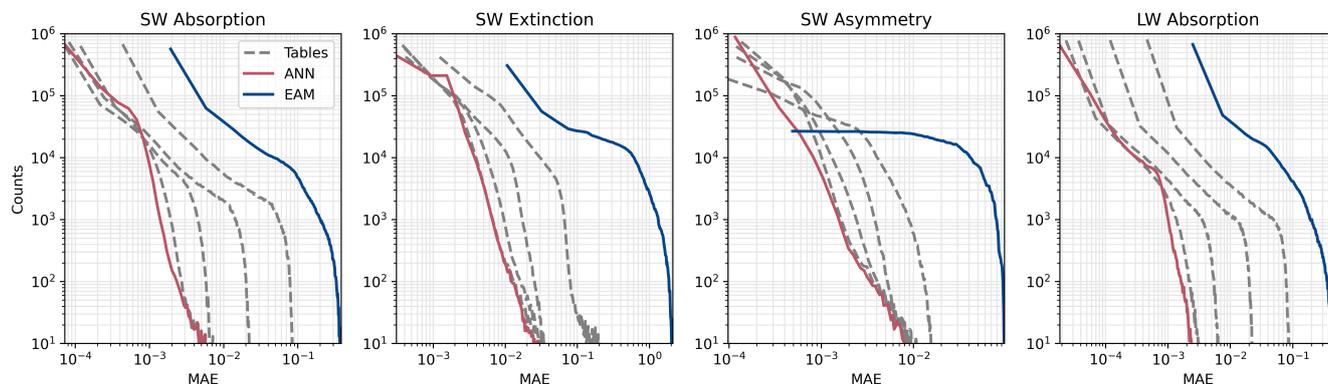

Figure 4. Error histograms for estimates of the bulk aerosol optics test dataset. These panels show the distribution of errors on a log-log histogram to make outlier cases with high error more apparent. The blue and magenta lines represent the Chebyshev polynomial based parameterization and the neural network respectively. The gray lines represent the error from applying linear interpolation to pre-computed optics datasets of varying resolution, with the highest resolution tables appearing to the left and progressively coarser tables to the right.

input values, while generating the test set from random points in the input space helps demonstrate that the ANN will not perform unexpectedly when interpolating within the region defined by the training data. Together, Figures 4 and 5 demonstrate that the ANN parameterization not only provides a dramatic performance improvement over the current approach, but can also be expected to perform exceedingly well for the full range of possible input data, with no extreme cases of high error. The ANN is therefore an accurate and reliable replacement for the current bulk aerosol optics parameterization.

6 Conclusions

This work has demonstrated the effectiveness of machine learning for emulating the aerosol optical properties that are crucial to climate simulation. A neural network is capable of producing bulk optical property estimates that are substantially more

Table 1. Mean absolute error for bulk shortwave optical property estimates using different methods

Method	Approx. Params.	$Q_{\text{Abs.}}(\text{SW})$	$Q_{\text{Ext.}}(\text{SW})$	$g(\text{SW})$	$Q_{\text{Abs.}}(\text{LW})$
ANN:	10^4	1.9×10^{-4}	1.0×10^{-3}	1.1×10^{-4}	9.8×10^{-5}
Ghan and Zaveri (2007):	10^5	2.4×10^{-2}	2.6×10^{-1}	2.5×10^{-2}	1.9×10^{-2}
Table:	10^6	5.1×10^{-3}	8.7×10^{-3}	1.7×10^{-3}	3.3×10^{-3}
Table:	10^7	1.3×10^{-3}	2.6×10^{-3}	5.5×10^{-4}	8.8×10^{-4}
Table:	10^8	4.0×10^{-4}	1.1×10^{-3}	2.7×10^{-4}	2.5×10^{-4}
Table:	10^9	1.6×10^{-4}	7.5×10^{-4}	2.0×10^{-4}	9.0×10^{-5}

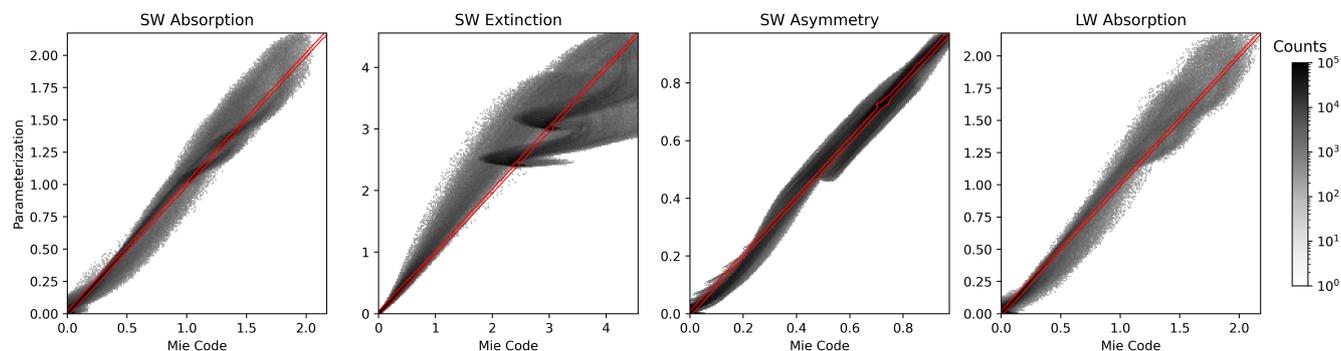

Figure 5. Scatter plot-like joint histograms comparing optical properties from the Chebyshev interpolation based parameterization and Mie code. Grey shading indicates the density of data-points. The red contour contains all outputs from the neural network, which all lie very close to the 1-to-1 line.

accurate than those produced by the existing (Ghan and Zaveri, 2007) parameterization in E3SM and CESM and does so with an order of magnitude smaller memory requirements. The compute requirements for evaluating an ANN with 10^4 parameters is larger than the compute used by the current approach, but this parameterization is evaluated every time EAM calls radiation code, and evaluating the ANN requires negligible compute compared to the radiation code, so impact on model run-time should be negligible. Additionally, the ANN outperforms lookup-table based optics emulators that resolve aerosol optical properties at much higher resolution than the existing scheme. Testing over a wide range of possible input data showed that the neural network performs well over the possible input space and will not produce any outlier errors or unexpected results within this range.

While this work has developed a replacement for an existing parameterization that has much higher accuracy, the use of a neural network could allow emulation of more sophisticated aerosol optics models. Our next step is to develop a neural network based parameterization that represents a shell-core aerosol optics model and perform comparisons of E3SM simulations using different aerosol optics models.

In addition to developing a new parameterization, we applied a recently developed (Xie et al., 2019) neural architecture search strategy that randomizes wiring patterns in deep neural networks. Key findings were that deeper ANNs significantly outperformed a single layer ANN of comparable size. Also, the majority of randomly constructed ANN architectures (which include skip connections) outperformed conventional multi-layer perceptron networks. In the context of this study, the NAS allowed us to identify neural architectures that provide a substantial performance improvement with no increase in network size.

Our findings also provide some insights into ANN design. The fact that the majority of randomly wired networks outperform multi-layer networks with serially connected layers indicates that inclusion of skip connections may be critical for this type of problem. In image processing, convolutional neural networks with a large number of layers and skip connections (He et al., 2016; Huang et al., 2017) were identified as superior to serially connected designs several years ago, and have dominated deep

learning research since. While using skip connections in networks constructed of fully connected layers is certainly not a new idea (Lang and Witbrock, 1988), it has received comparatively little attention in recent machine learning literature. This work
400 indicates that inclusion of skip connections could be an effective way to train smaller regressor and function fitting neural networks to fit complicated data or surfaces.

There has recently been significant push to leverage new advances in machine learning to replace the various existing parameterizations used by climate and weather models with more performant and/or accurate representations. Our results indicate that when using neural networks for this type of application, significant performance improvements can be achieved by
405 taking care to design or select network architectures optimized for the target task, and the use of randomly generated network architectures to identify optimal ANNs was extremely effective in this application. This, and similar NAS algorithms, have received relatively little attention in the Earth sciences, and random network wiring may be a fruitful strategy for developing neural network based parameterizations and physics emulators in the future.

Code and data availability. The code created as part of this research is available from the project's Github repository: https://github.com/avgeiss/aerosol_optics_ml, which has been archived with a DOI using Zenodo: <https://doi.org/10.5281/zenodo.6767169>.

Table A1. Errors between optical properties computed with PyMieScatt and miev0.

	$Q_{\text{Abs.}}$	$Q_{\text{Sca.}}$	g
Max Abs. Err.	1.8×10^{-3}	1.6×10^{-2}	9.6×10^{-2}
99.9 %-ile	1.1×10^{-3}	1.5×10^{-3}	8.0×10^{-4}
99 %-ile	3.3×10^{-4}	4.3×10^{-4}	4.4×10^{-4}

Table A2. Constants used to standardize ANN inputs. For all variables but real refractive index standardization is done after taking the natural logarithm. 1×10^{-6} is added to the imaginary refractive index before taking the logarithm.

(μ/σ)	Real Ref. Ind.	Imaginary Ref. Ind.	Surf. Mode Rad. (R_{surf})	Wavelength (λ)	R_{surf}/λ
