## Abstract.

The gas-phase reaction of isoprene with the nitrate radical (NO<sub>3</sub>) was investigated in experiments in the outdoor SAPHIR chamber at atmospherically relevant conditions specifically with respect to the chemical lifetime and fate of nitrato-organic peroxy radicals (RO<sub>2</sub>). Observations of organic products were compared to concentrations expected from different chemical mechanisms: (1) The Master Chemical Mechanism, which simplifies the NO<sub>3</sub> isoprene chemistry by only considering one RO<sub>2</sub> isomer. (2) The chemical mechanism derived from experiments in the Caltech chamber, which considers different RO<sub>2</sub> isomers. (3) The FZJ-NO<sub>3</sub> isoprene mechanism derived from quantum chemical calculations, which in addition to the Caltech mechanism includes equilibrium reactions of RO<sub>2</sub> isomers, unimolecular reactions of nitrate RO<sub>2</sub> radicals and epoxidation reactions of nitrate alkoxy radicals. Measurements using mass spectrometer instruments give evidence that the new reactions pathways predicted by quantum chemical calculations play a role in the NO<sub>3</sub> oxidation of isoprene. Hydroperoxy aldehydes (HPALD), which are specific for unimolecular reactions of nitrate RO<sub>2</sub>, were detected even in the presence of an OH scavenger excluding the possibility that concurrent oxidation by hydroxyl radicals (OH) is responsible for their formation. In addition, ion signals at masses that can be attributed to epoxy compounds, which are specific for the epoxidation reaction of

nitrate alkoxy radicals, were detected. Measurements of methyl vinyl ketone (MVK) and methacrolein (MACR) concentrations confirm that the decomposition of nitrate alkoxy radicals implemented in the Caltech mechanism cannot compete with the ring-closure reactions predicted by quantum-chemical calculations. The validity of the FZJ-NO<sub>3</sub> isoprene mechanism is further supported by a good agreement between measured and simulated hydroxyl radical (OH) reactivity. Nevertheless, the FZJ-NO<sub>3</sub> isoprene mechanism needs further investigations with respect to the absolute importance of unimolecular reactions of nitrate RO<sub>2</sub> and epoxidation reactions of nitrate alkoxy radicals. Absolute concentrations of specific organic nitrates such as nitrate hydroperoxides would be required to experimentally determine product yields and branching ratios of reactions but could not be measured in the chamber experiments due to the lack of calibration standards for these compounds. The temporal evolution of mass traces attributed to products species such as nitrate hydroperoxides, nitrate carbonyl, nitrate alcohols as well as hydroperoxy aldehydes observed by the mass spectrometer instruments demonstrates that further oxidation by the nitrate radical and ozone at atmospheric concentrations is small on the time scale of one night (12 hours) for typical oxidant concentrations. However, oxidation by hydroxyl radicals present at night and potentially also produced from the decomposition of nitrate alkoxy radicals can contribute to their nocturnal chemical loss.

## 1 Introduction

Isoprene ( $C_5H_8$ ) is an unsaturated compound and the most abundant emitted non-methane hydrocarbon in the atmosphere. Circa 500 Tg per year of isoprene is emitted by plants as co-product of photosynthesis activity (Guenther et al., 2012). The high reactivity of isoprene towards the most important daytime oxidant, the hydroxyl radical (OH), results in a chemical lifetime of a few hours for typical atmospheric conditions, so that the majority of isoprene is oxidized during the day. However, isoprene can also be present in significant quantities after sunset, when the production rate of OH radicals is low, so that oxidation by the nitrate radical ( $NO_3$ ) or ozone can gain in importance (Brown et al., 2009; Edwards et al., 2017).

Oxidants add preferentially to the C=C double bonds in isoprene initiating a cascade of radical reactions. Theoretical studies of the OH-initiated oxidation of isoprene showed that the primary organic peroxy radicals ( $RO_2$ ) formed after the OH addition are unstable at atmospheric temperatures. The  $RO_2$  isomers continuously equilibrate in a thermal equilibrium with the alkyl radical through oxygen elimination and re-addition reactions at a time scale that is short relative to the chemical lifetimes of the  $RO_2$  radicals at atmospheric conditions (Peeters et al., 2009, 2014). As a consequence, fast H-shift reactions of minor  $RO_2$  isomers can constitute a large loss process for the entire  $RO_2$  pool. This applies to the 1,6-H-migration reactions of the Z- $\delta$ - $RO_2$  isomers produced from the isoprene + OH reaction (Peeters et al., 2014). These H-migrations lead eventually to the regeneration of OH radicals. Because this type of radical regeneration does not require the presence of nitric oxide (NO), it can significantly enhance radical concentrations in forested environments (Novelli et al., 2020). The OH initiated oxidation of isoprene has been investigated in laboratory (Crounse et al., 2011; Berndt et al., 2019) and simulation chamber studies (Fuchs et al., 2013; Novelli et al., 2020), which contributed to the refinement of the chemical mechanism proposed by the theoretical studies. The results can partly explain high OH radical concentrations observed in field experiments in rainforests (Lelieveld et al., 2008; Whalley et al., 2011).

In contrast to daytime, the loss of  $RO_2$  radicals due to the reaction with NO does not play a role at night in the absence of near emission sources because NO production from the photolysis of  $NO_2$  is stopped and NO is rapidly titrated to  $NO_2$  by the reaction with ozone. In some situations, ozone can also be locally completely consumed in the night if there are high NO emissions for example from traffic or from power plants. In this case, NO can accumulate. However, for these conditions, the nitrate radical is rapidly lost in the reaction with NO. Therefore, it is unlikely that nitrate  $RO_2$  radicals and NO exist simultaneously. Thus, nitrate  $RO_2$  from the reaction of  $NO_3$  with organic compounds are expected to react mainly with hydroperoxy radicals ( $HO_2$ ), other organic peroxy radicals, the nitrate radical or they may undergo unimolecular reactions.

In previous chamber and laboratory studies investigating the reaction of isoprene with  $NO_3$ , the fate of  $RO_2$  was often assumed to be dominated by  $RO_2$  self- and cross-reactions and  $RO_2$  reactions with  $NO_3$  due to high reactant concentrations (Barnes et al., 1990; Kwok et al., 1996; Perring et al., 2009; Kwan et al., 2012). A chamber study by Schwantes et al. (2015) focussed on the product distribution from the reaction of nitrate  $RO_2$  with  $HO_2$  because this reaction pathway is generally the dominant loss path in the atmosphere. Chamber studies by Rollins et al. (2009) and Ng et al. (2008) were also designed to reproduce atmospheric chemical conditions, for which the nitrate  $RO_2$  reacts in various pathways.

60 Near-explicit chemical mechanisms such as the Master Chemical Mechanism (Jenkin et al., 2015) and the isoprene mechanism developed by Wennberg et al. (2018) (called Caltech mechanism in this work) were partly built by using results from these studies. In addition, it has been proposed that the nitrate RO<sub>2</sub> radicals formed from the reaction of the nitrate radical with isoprene can interconvert at ambient temperature (Wennberg et al., 2018; Vereecken et al., 2021). This can enhance the importance of unimolecular reactions of specific RO<sub>2</sub> if the chemical lifetime of the RO<sub>2</sub> radicals is long enough that concentrations  
65 can re-equilibrate.

Furthermore, the theoretical study by Vereecken et al. (2021) revealed that unimolecular reactions of alkoxy radicals formed in the radical reaction chain subsequent to the addition of NO<sub>3</sub> to isoprene lead to the production of epoxide RO<sub>2</sub>, influencing the distribution of organic products. This newly identified chemistry is ~~only~~ included **only** in the FZJ-NO<sub>3</sub> isoprene mechanism published by Vereecken et al. (2021).

70 The aim of this study is to compare the NO<sub>3</sub> isoprene chemistry of different available explicit mechanisms (MCM, Caltech and FZJ-NO<sub>3</sub>) with respect to the fate of nitrato-organic peroxy radicals and the distribution of organic products for a series of chamber experiments performed at atmospherically relevant night-time conditions.

## 2 Methods

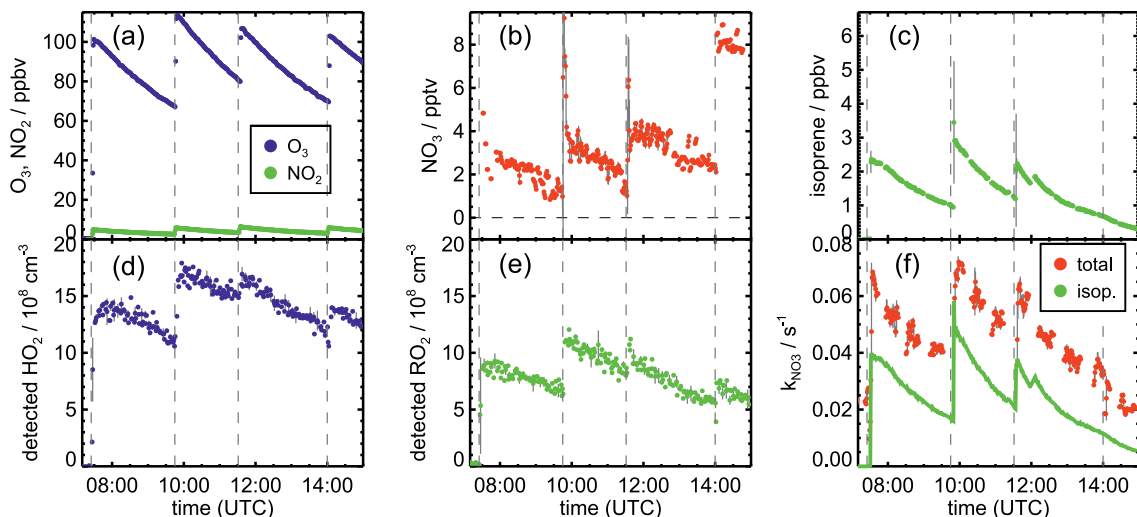

### 2.1 Experiments in the SAPHIR chamber

75 The experiments discussed in this work were performed in the atmospheric simulation chamber SAPHIR ~~chamber~~ (Rohrer et al., 2005) at Forschungszentrum Jülich in 2018. The chamber is a 270 m<sup>3</sup> double-wall reactor. It is operated at a slight overpressure of 35 Pa to prevent ambient air from leaking into the chamber. The space between the 2 films is continuously flushed with pure nitrogen to prevent contamination of the inner chamber. The walls are made of Teflon film (FEP) and are thus chemically inert while the full solar spectrum is transmitted into the chamber (Bohn and Zilken, 2005). Night-time can be  
80 simulated by a shutter system that covers the chamber. Synthetic air used for flushing the chamber and for replenishing losses due to sampling of instruments and leakage is produced from evaporating and mixing high purity liquid nitrogen and oxygen (purity: 99.9999 %, Linde). Inside the chamber, 2 fans are operated to ensure homogeneous mixing of air. The temperature inside the chamber is similar to ambient temperature and ranged between 291 and 308 K with maximum values in the afternoon for the experiments in this work.

85 Reactive trace gases added to the chamber in the experiments were ozone produced by a silent discharge ozonizer (O3onia), isoprene (C<sub>5</sub>H<sub>8</sub>, purity: 99 %, Sigma Aldrich), propene (purity: 99.8 %, Linde), CO (purity: 99.997 %, Linde) and NO<sub>2</sub> (purity: 99.2 %, 519 ppmv in nitrogen, Linde). Addition of gaseous species were controlled by calibrated mass flow controllers. Isoprene was injected as a liquid with a syringe into a hot volume and the vapour was flushed into the chamber together with the replenishment flow of zero air.

90 Four experiments performed on 09, 10, 12, and 13 August 2018 (Experiment #1, #2, #3, #4) are analysed in this work (Table 1, Fig. 1, 2, A1, A2). Before each experiment, the chamber was flushed overnight with a high flow of zero air, so that concentrations of trace gases from previous experiments were below the limit of detection of instruments. The chamber roof

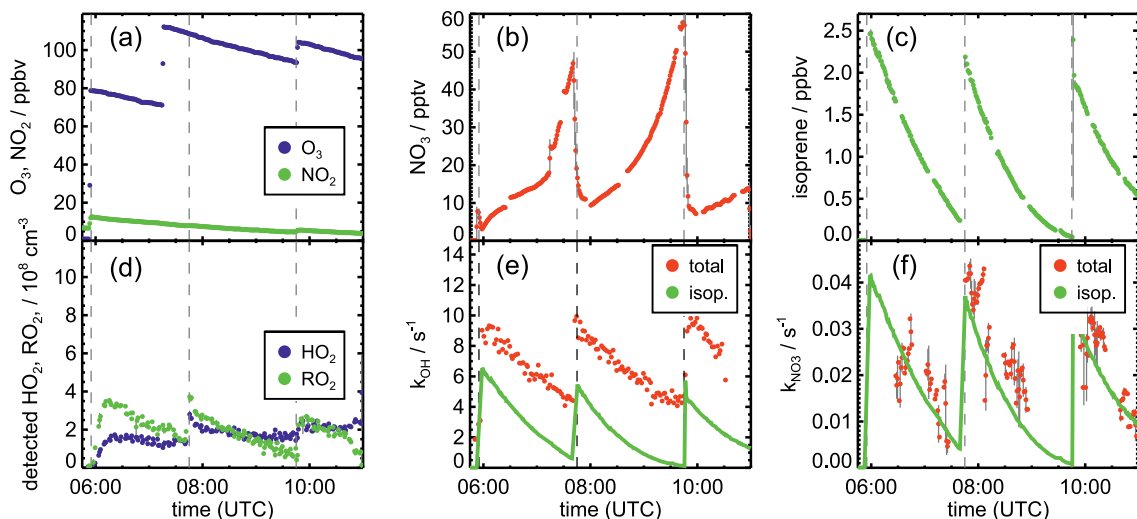

**Figure 1.** Measurements of radical and trace gas concentrations and  $\text{NO}_3$  reactivity in the experiment on 09 August 2018 (Experiment #1) investigating the oxidation of isoprene by  $\text{NO}_3$ . Between 100 and 200 ppmv propene was present to produce  $\text{HO}_2$  radicals by its ozonolysis. OH radicals, which are produced in the ozonolysis reaction, are rapidly converted to  $\text{HO}_2$  in the reaction with 70 to 120 ppmv CO that was injected at the start of the experiment. OH reactivity was dominated by the high CO concentration and is not shown.  $\text{NO}_3$  reactivity does not include reactivity from organic radicals and  $\text{NO}_2$ .  $\text{NO}_3$  reactivity from isoprene is calculated from measured isoprene concentrations and reaction rate constants recommended in the literature (Mellouki et al., 2021). The difference between measured reactivity and reactivity from isoprene can be attributed to propene in this experiment. Observed  $\text{RO}_2$  radicals only include a fraction of the total  $\text{RO}_2$  because the LIF instrument cannot detect all  $\text{RO}_2$  species formed in the reaction of isoprene with  $\text{NO}_3$  (Vereecken et al., 2021).

was always closed to simulate night-time conditions. Experiments were performed in dry synthetic air.  $\text{NO}_3$  was produced by the reaction of  $\text{NO}_2$  and  $\text{O}_3$ . Typical mixing ratios after the injection were 5 ppbv  $\text{NO}_2$  and 100 ppbv  $\text{O}_3$ .  $\text{NO}_3$  production rates ranged between 0.9 and 11 ppbv/hour. Highest  $\text{NO}_3$  production rates were reached in the experiment on 13 August 2018 (Experiment #4) and lowest rates in the experiment on 10 August 2018 (Experiment #2).

After  $\text{NO}_3$  production started, isoprene was added. The injection of all three species was repeated after a few hours, when most of the isoprene had been consumed. Only  $\text{NO}_2$  and  $\text{O}_3$  were re-injected to enhance  $\text{NO}_3$  production in the last part of the experiments, except for the experiment on 10 August 2018 (Experiment #2). In the experiment on 09 August 2018 (Experiment #1), propene was injected to enhance  $\text{HO}_2$  concentrations by radical production via its ozonolysis. Excess CO was additionally injected to convert OH radicals to  $\text{HO}_2$ .

In the experiments in this work, no measurable secondary organic aerosol was formed, so that loss of products species on aerosol did not play a role (Brownwood et al., 2021).

The total amount of isoprene that was consumed by  $\text{NO}_3$  was  $(3.2 \pm 0.5)$  ppbv,  $(2.5 \pm 0.5)$  ppbv,  $(4.8 \pm 0.5)$  ppbv, and  $(11.6 \pm 1.2)$  ppbv in the experiments on 09, 10, 12, and 13 August 2018 (Experiment #1, #2, #3, #4), respectively (Brownwood et al., 2021). Approximately 10 % of the total isoprene consumed in the experiment reacted with ozone except

**Figure 2.** Measurements of radical and trace gas concentrations and OH and NO<sub>3</sub> reactivity in the experiment on 13 August 2018 (Experiment #4) investigating the oxidation of isoprene by NO<sub>3</sub>, when the total amount of oxidized isoprene was highest. OH and NO<sub>3</sub> reactivity from isoprene is calculated from measured isoprene concentrations and reaction rate constants recommended in the literature (Mellouki et al., 2021). NO<sub>3</sub> reactivity does not include reactivity from organic radicals and NO<sub>2</sub>. Observed RO<sub>2</sub> radicals only include a fraction of the total RO<sub>2</sub> because the LIF instrument cannot detect all RO<sub>2</sub> species formed in the reaction of isoprene with NO<sub>3</sub> (Vereecken et al., 2021).

for the experiment on 09 August 2018 (Experiment #1), when 25 to 30 % of isoprene was lost in the reaction with ozone due to the low NO<sub>3</sub> and high ozone concentration. In addition, measurements of OH radicals suggest that up to 10 % of isoprene reacted with OH in the experiments without OH scavenger. However, OH concentration measurements were close to the limit  
110 of detection of the instrument, so that the fraction of isoprene that reacted with OH is rather uncertain. Overall, the dominant loss for isoprene was due to the reaction with NO<sub>3</sub> radicals (80 to 90 % of the total loss in most of the experiments).

The chemical conditions in the experiments were chosen such that the chemical loss of nitrated RO<sub>2</sub> radicals differed between the experiments (Table 1). Similar as for typical night-time conditions in the nocturnal residual layer in the absence of nearby sources, nitric oxide concentrations were zero, so that RO<sub>2</sub> reacted only with either HO<sub>2</sub>, RO<sub>2</sub> or NO<sub>3</sub> or re-arranged  
115 in unimolecular RO<sub>2</sub> reactions (Vereecken et al., 2021).

In the experiment on 09 August 2018 (Experiment #1), the ozonolysis of propene increased the HO<sub>2</sub> concentration and therefore increased the relative importance of the peroxy radical loss towards the reaction with HO<sub>2</sub>. In the experiments on 10, 12 and 13 August 2018 (Experiment #4), the concentrations of NO<sub>3</sub> precursor species, HO<sub>2</sub>, O<sub>3</sub> and NO<sub>2</sub>, and of isoprene were varied. As a consequence, RO<sub>2</sub> concentrations differed between these experiments and therefore also the relative importance  
120 of RO<sub>2</sub> loss reactions.

## 2.2 Instrumentation

A large suite of instruments detected inorganic and organic species during the experiments. Isoprene and its oxidation products were measured by a proton transfer reaction time-of-flight mass spectrometer (VOCUS PTR-MS, Aerodyne, Krechmer et al. (2018)). The instrument was calibrated for isoprene, methyl vinyl ketone and methacrolein. The sensitivity of the instrument  
125 for isoprene was higher by a factor of 1.4 in dry air than in humid air in which calibration measurements were performed (Brownwood et al., 2021). Measured concentrations were corrected for this humidity effect. No calibration standards were available for organic nitrate products such as nitrated alcohols, carbonyls, hydroperoxides and epoxides.

Organic compounds were also detected by 2 other chemical ionization mass spectrometer instruments (CIMS) that used either  $\text{Br}^-$  (Albrecht et al., 2019; Wu et al., 2021) or  $\text{I}^-$  as reagent ions (Tsiligiannis et al., 2022). These instruments detected  
130 various oxygenated organic product species, but were not calibrated to provide concentrations. Details of the measurements by the  $\text{Br}^-$  CIMS instrument can be found in Wu et al. (2021) and by the  $\text{I}^-$  CIMS instrument in Tsiligiannis et al. (2022).

The high resolution of the mass spectrometer instruments allowed to attribute the ion mass signals ( $m/z$ ) to sum formulas of organic compounds (Table A1). In this work, ion signals that were highest among all signals are discussed, most of which can be attributed to products of the isoprene oxidation (Wu et al., 2021; Tsiligiannis et al., 2022). Compared to the CIMS  
135 instruments, the precision of measurements by the VOCUS PTR-MS instrument was higher for organic compounds that contain few oxygens. In general, the sensitivity of CIMS instruments can be different for different isomers and functional groups, so that a change in the distribution of isomers could partly explain observed differences between instruments (Lee et al., 2014a; Xiong et al., 2015, 2016). In addition, changes in the operational conditions of the instrument such as the temperature of the ionization region can lead to a variability of the instrument's sensitivity (Robinson et al., 2022).

140 The total organic nitrate concentration was measured by 2 instruments, in which the total  $\text{NO}_2$  concentration was detected either by a custom-built (Sobanski et al., 2016) or commercial cavity ring-down instrument (Keehan et al., 2020) after thermal dissociation of nitrate compounds in a heated inlet (TD-CRDS). A common data set from both instruments was created for this campaign. Details of these measurements can be found in Brownwood et al. (2021). These instruments also measured  $\text{NO}_2$  in the sampled air in a separate mode or second measurement channel. In addition,  $\text{NO}_2$  concentrations were measured by  
145 another custom-built cavity ring-down instrument (Liebmann et al., 2018) and a commercial chemiluminescence instrument combined with a blue-light converter (Eco-Physics).  $\text{NO}_2$  concentration measurements from all instruments were combined to one common, quality-checked data set (Brownwood et al., 2021). Ozone concentrations were measured by a commercial instrument using UV-absorption (Ansyco).

$\text{NO}_3$  and  $\text{N}_2\text{O}_5$  concentrations were measured with 2 custom-built instruments applying cavity-ring-down spectroscopy  
150 (Wagner et al., 2011; Sobanski et al., 2016).  $\text{NO}_3$  was detected at 662 nm and the sum of  $\text{NO}_3$  and  $\text{N}_2\text{O}_5$  in a second channel, in which the inlet and cavity is heated to thermally decompose  $\text{N}_2\text{O}_5$ . Measurements were combined to one data set taking also into account that  $\text{NO}_3$  and  $\text{N}_2\text{O}_5$  can be expected to be in a thermal equilibrium for conditions of the experiments in this work.

HO<sub>2</sub>, OH and RO<sub>2</sub> radical concentrations were determined by a laser-induced fluorescence instrument (Fuchs et al., 2011, 2012; Cho et al., 2021). OH radicals are excited at 308 nm in a low-pressure cell and their fluorescence is measured by gated single-photon counting. The fluorescence cell for the detection of only OH radicals was equipped with a chemical modulation reactor (CMR), which allows to account for potential interferences in the measurements (Cho et al., 2021). In another fluorescence cell, HO<sub>2</sub> radicals are chemically converted to OH in their reaction with NO. RO<sub>2</sub> radicals are converted eventually to OH in a third measurement channel (ROxLIF) that consists of an RO<sub>2</sub> converter, in which RO<sub>2</sub> and OH radicals are firstly converted to HO<sub>2</sub> in the presence of NO and CO, and a fluorescence cell downstream of the converter, in which the sum of all radicals is detected by OH fluorescence after HO<sub>2</sub> has reacted with excess NO. Recent studies confirmed that not all nitrate RO<sub>2</sub> radicals can be detected by the ROxLIF method as they do not form HO<sub>2</sub> or OH radicals after reacting with NO (Ashbourn et al., 1998; Novelli et al., 2021; Vereecken et al., 2021).

OH reactivity ( $k_{\text{OH}}$ , the inverse of the chemical lifetime of the OH radical) was determined by a laser flash photolysis instrument, in which the time resolved decay of artificially produced OH radicals is observed (Fuchs et al., 2017). If, as in this work, the OH-reactivity from inorganic compounds is known, the contribution from organic compounds can be derived and compared to values based on the measurements of single compounds (Tan et al., 2021; Hantschke et al., 2021). In general, differences between measured and calculated OH reactivity can be used to determine if the detection of organic products that are reactive towards OH are complete.

The NO<sub>3</sub> reactivity was also measured in this work (Liebmann et al., 2017; Dewald et al., 2020). The concentration of artificially produced NO<sub>3</sub> is measured by cavity ring-down spectroscopy after reaction with either ambient or zero air in a flow tube. The NO<sub>3</sub> reactivity can be then calculated from the relative change of NO<sub>3</sub> concentrations between the two modes. In order to obtain the NO<sub>3</sub> reactivity from organic compounds, the contribution of NO<sub>2</sub> and NO<sub>3</sub> losses in the flow tube were accounted for. NO<sub>3</sub> reactivity from HO<sub>2</sub> and RO<sub>2</sub> radicals is not detected by the instrument due to loss of radicals in the inlet system (Dewald et al., 2020).

### 2.3 Modelling of trace gas concentrations

Trace gas concentrations were calculated using a chemical box model. In this work, three near-explicit chemical models have been applied: (1) The Master Chemical Mechanism version 3.3.1 (MCM) (Jenkin et al., 1997; Saunders et al., 2003; Jenkin et al., 2015), (2) the isoprene oxidation mechanism as introduced in the review article by Wennberg et al. (2018) and available at Bates and Wennberg (2017) (Caltech), and (3) the NO<sub>3</sub> isoprene mechanism based on theoretical calculations by Vereecken et al. (2021) and detailed in the supplement of Vereecken et al. (2021) (FZJ-NO<sub>3</sub> mechanism).

The Caltech mechanism includes reactions of isoprene and isoprene product species but does not include further reactions of organic products that are not specific products from the oxidation of isoprene such as glyoxal or methyl glyoxal. In this work, the Caltech mechanism is therefore extended with chemistry from the MCM for those species.

The FZJ-NO<sub>3</sub> mechanism only includes the reaction steps subsequent to the initial addition of NO<sub>3</sub> to isoprene, but the chemistry of organic products was not investigated in Vereecken et al. (2021). The chemistry of the trace gases not considered in Vereecken et al. (2021) is taken from the Caltech mechanism. The isoprene OH oxidation scheme is applied as described

**Table 1.** Chemical conditions in the experiments in this work. Experiments analysed in this work were performed in dry air. Mixing ratios of trace gases give the range of values reached right after their injection.

	Experiment #1 09 August 2018	Experiment #2 10 August 2018	Experiment #3 12 August 2018	Experiment #4 13 August 2018
O <sub>3</sub> / ppbv	70–120	40–70	70–110	75–110
NO <sub>2</sub> / ppbv	2–6	3–5	4–12	10–25
isoprene / ppbv	1–2.5	0.5–2	0.3–3	0–8
propene / ppbv	100–200	0	0	0
CO / ppmv	70–120	<0.1	<0.1	<0.1
NO <sub>3</sub> / pptv	1–10	5–40	5–60	10–500
<i>T</i> / K	295–299	292–300	288–308	291–298
data reference	Fuchs et al. (2018a)	Fuchs et al. (2018b)	Fuchs et al. (2018c)	Fuchs et al. (2018d)

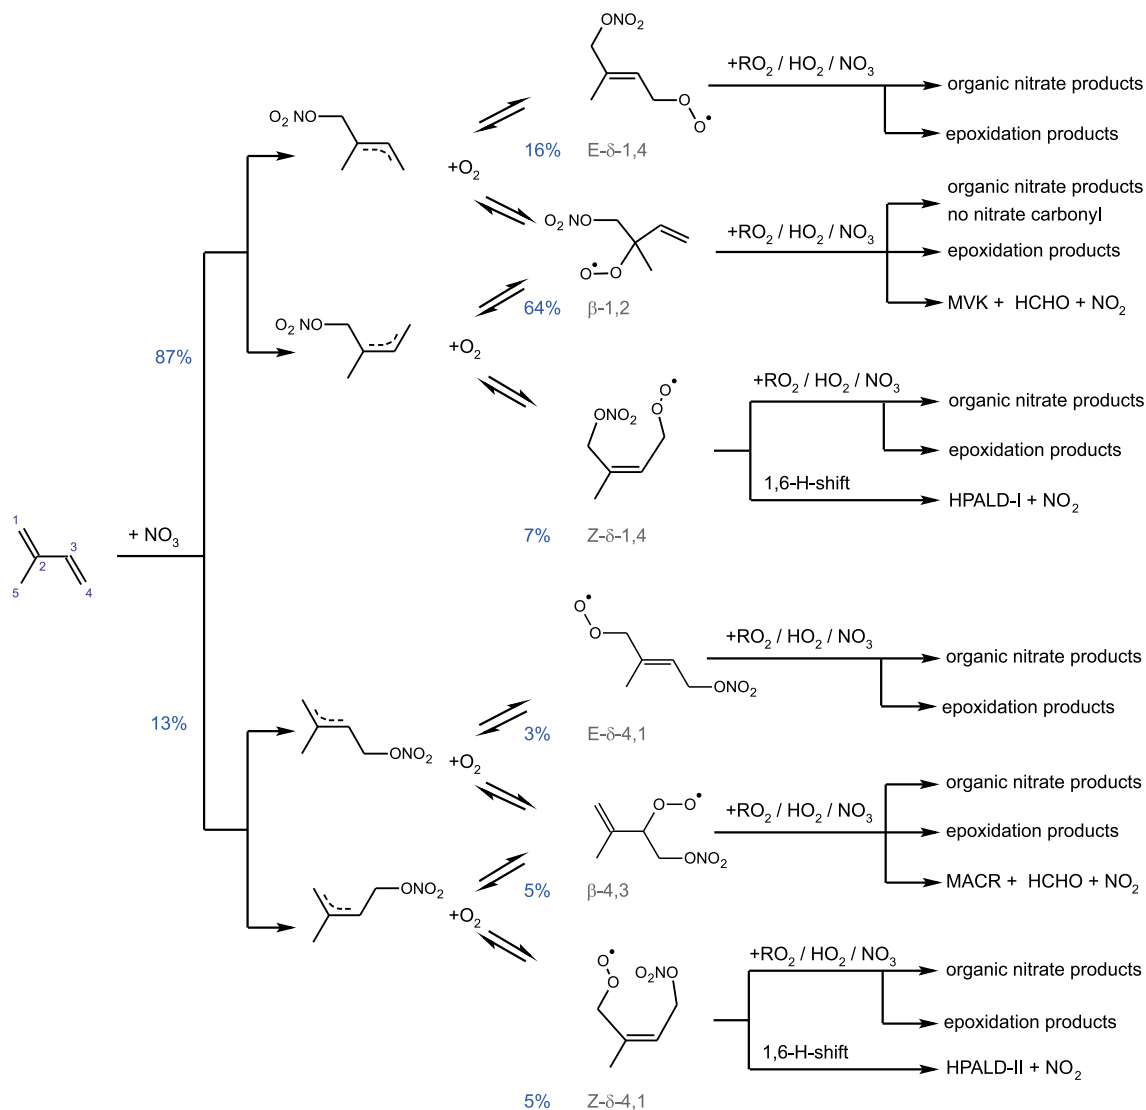

in the work by Novelli et al. (2020), where the OH oxidation of isoprene was investigated in chamber experiments. Further chemistry of organic products that are not specific for the oxidation of isoprene are taken from the MCM. Chemical loss of first-generation organic products which are not included in either the Caltech or the MCM models is estimated from similarities to other organic products.

In the model runs, the injections of trace gases in the experiments were implemented as source reactions, which are effective during the short period of time during the injection. The rates are adjusted, such that the concentration change of the injected trace gas matches the observed increase in the concentration at the time of the injection. Physical parameters such as temperature and pressure were constrained to measured values. NO<sub>3</sub> was also constrained to measured values, in order to decouple its modelled concentrations from wall reactions of NO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>, which are dependent on the chemical conditions of the experiment and hence hard to characterize accurately (Dewald et al., 2020). With NO<sub>3</sub> concentrations constrained to measurements, the measured decay of isoprene, which is dominated by the reaction with NO<sub>3</sub> for most of the time, is well described by the model, confirming that measured NO<sub>3</sub> concentrations are consistent with the chemical loss of isoprene.

### 3 NO<sub>3</sub> oxidation mechanisms of isoprene

The initial reaction steps in the oxidation of isoprene by NO<sub>3</sub> (Vereecken et al., 2021) are similar to the oxidation by OH. H-atom abstraction from isoprene by NO<sub>3</sub> is estimated to be at least 2 orders of magnitude slower than NO<sub>3</sub> addition, based on the available literature data on aliphatic and allylic H-abstraction reactions (Canosa-Mas et al., 1991; Atkinson et al., 2006) and therefore not further considered in this work.

NO<sub>3</sub> adds to either of the C=C double bonds leading to allyl-resonance stabilized alkyl radicals. Reversible oxygen addition and elimination reactions produce 3 different RO<sub>2</sub> stereoisomers each from the addition of NO<sub>3</sub> on carbon C<sub>1</sub> and C<sub>4</sub> (Fig. 3).

**Figure 3.** Schematic reaction mechanism of the reaction of isoprene with  $\text{NO}_3$  as described in Vereecken et al. (2021). This includes fast inter-conversion of nitrate  $\text{RO}_2$  isomers by oxygen addition and elimination reactions. Only  $\text{RO}_2$  isomerization reactions (Vereecken et al., 2021) which can compete with bimolecular reactions for typical night-time conditions are shown. Percentage values given next to the structure of  $\text{RO}_2$  radicals are yields when equilibrium concentrations are established for typical night-time conditions such as in the experiments in this work.

The different  $\text{RO}_2$  isomers rapidly reach equilibrium concentrations.  $\text{NO}_3$  adds preferably on carbon  $\text{C}_1$  (yield of 87 %). The yield is higher in comparison to the corresponding OH addition (yield of 61 %). The additions on the inner carbons ( $\text{C}_2$  and  $\text{C}_3$ ) are expected to be of minor importance (Vereecken et al., 2021) and are not further considered in this work.

210 The isoprene NO<sub>3</sub> mechanisms investigated in this work differ significantly in the treatment of the initially formed RO<sub>2</sub>. The FZJ-NO<sub>3</sub> mechanism includes 6 RO<sub>2</sub> isomers formed subsequently to the NO<sub>3</sub> addition (Fig. 3). Specifically, the Z- and E-RO<sub>2</sub> isomers of the  $\delta$ -RO<sub>2</sub> isomers are distinguished. In contrast, the Caltech mechanisms only treats  $\delta$ - and  $\beta$ -RO<sub>2</sub> isomers separately but does not include the equilibrium reactions between RO<sub>2</sub> isomers. The MCM simplifies the addition of NO<sub>3</sub> to isoprene even more by only considering the addition of NO<sub>3</sub> on carbon C<sub>1</sub> leading to the  $\delta$ -RO<sub>2</sub> radical.

215 It is important to distinguish between Z- and E-RO<sub>2</sub> isomers because isomer-specific unimolecular H-shift reactions need to be considered. Competitive unimolecular H-shift-reactions only occur for the Z- $\delta$ -RO<sub>2</sub> (Vereecken et al., 2021) leading to the formation of hydroperoxy aldehydes (HPALD) (Fig. 3). Due to the re-equilibration reactions between RO<sub>2</sub> isomers, these reaction channels can gain in importance if the rate of this RO<sub>2</sub> loss reaction (0.01 to 0.05 s<sup>-1</sup>) is faster than the chemical loss due to bimolecular RO<sub>2</sub> reactions. This will often be the case for night-time conditions, when mainly slow bimolecular RO<sub>2</sub> reactions with NO<sub>3</sub>, HO<sub>2</sub> and other RO<sub>2</sub> radicals occur.

The distribution of organic products from the NO<sub>3</sub> oxidation of isoprene depends highly on the competition between the different RO<sub>2</sub> loss reactions. The bimolecular reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> radicals leads to the formation of nitrate hydroperoxides (NISOPPOOH). Whereas one NISOPPOOH isomer is the exclusive product of the RO<sub>2</sub>+HO<sub>2</sub> reaction in the MCM, the Caltech and FZJ-NO<sub>3</sub> mechanisms include not only different isomers but also the decomposition of the initially  
225 formed HO<sub>2</sub>-RO<sub>2</sub> reaction complex into an OH radical and a nitrate alkoxy radical with a yield of approximately 50 % for nitrate  $\beta$ -RO<sub>2</sub> radicals.

Nitrate alkoxy radicals can also be the product of RO<sub>2</sub>+RO<sub>2</sub> reactions, but this reaction channel competes with the production of nitrate carbonyls (NC<sub>4</sub>CHO) and nitrate alcohols (ISOPCNO<sub>3</sub>). Alkoxy radicals are additionally formed from the reaction of nitrate RO<sub>2</sub> with NO<sub>3</sub> accompanied by the production of NO<sub>2</sub>. The nitrate alkoxy radicals are expected to rapidly  
230 decompose (Novelli et al., 2021; Vereecken et al., 2021). In the MCM, the decomposition leads exclusively to the formation of one isomer of the nitrate carbonyl product (NC<sub>4</sub>CHO) together with an HO<sub>2</sub> radical. A similar mechanism is implemented in the Caltech and FZJ-NO<sub>3</sub> mechanisms for most of the various nitrate alkoxy radical species except for those radicals produced from the most abundant  $\beta$ -1,2-RO<sub>2</sub> isomer, from which nitrate carbonyl species cannot be formed.

[The yield of ROOR compounds from the gas-phase reaction of RO<sub>2</sub>+RO<sub>2</sub> radicals is expected to be small. Due to their low volatility, however, ROOR compounds are important for the formation of SOA \(Ng et al., 2008\).](#)  
235

In the Caltech mechanism, decomposition of these nitrate alkoxy radicals leads instantly to the formation of methyl vinyl ketone (MVK) or methacrolein (MACR) together with formaldehyde and NO<sub>2</sub>. This was determined from chamber experiments reported in Schwantes et al. (2015), in which a high yield of MVK was found, when nitrate RO<sub>2</sub> mainly reacted with HO<sub>2</sub>. The fate of nitrate alkoxy radicals was also investigated by Vereecken et al. (2021). Quantum chemical calculations show  
240 that the decomposition reaction is slower than the ring-closure reactions leading to epoxide products. In contrast, 4-membered ring closure (barrier  $\sim$  25 kcal/mol, Vereecken (2022)) requires breaking the planar double bond to bring the radical O-atom in an appropriate position for bonding. 5- to 6-membered ring closure (barrier  $\sim$  13-29 kcal/mol, Vereecken et al. (2021)) are also favourable.

Differences between the chemical mechanisms also exist concerning the type of chemical loss reactions of first-generation  
245 stable organic products. Reactions with OH are considered in all mechanisms applying similar reaction rate constants. In  
addition, the MCM includes loss of isoprene organic nitrates due to ozonolysis reactions.

## 4 Results

Results of the model calculations are shown in Fig. 4 for the experiment on 09 August 2018 (Experiment #1), when high HO<sub>2</sub>  
concentrations were present, and therefore the main loss path for RO<sub>2</sub> was the reaction with HO<sub>2</sub>. Figure 5 shows results for the  
250 experiment on 13 August 2018 (Experiment #4), when RO<sub>2</sub> loss was distributed among all pathways that are relevant during  
night-time (Brownwood et al., 2021) and the amount of oxidized isoprene was highest. Results from the other experiments  
are shown in the Appendix (Fig. A5, A6). In all figures, ion mass signals of the VOCUS PTR-MS instrument for which no  
calibration was available were scaled to concentrations predicted by the FZJ-NO<sub>3</sub> model.

Highest HO<sub>2</sub> concentrations of up to  $17 \times 10^8 \text{ cm}^{-3}$  were measured in the experiment on 09 August 2018 (Experiment  
255 #1), when HO<sub>2</sub> was enhanced by production of OH radicals in the ozonolysis of propene, which were rapidly converted to  
HO<sub>2</sub> in the presence of excess CO (Fig. 1, Panel (d)). In the other experiments, measured HO<sub>2</sub> concentrations were between  
1 and  $5 \times 10^8 \text{ cm}^{-3}$  with highest values in the experiment on 13 August 2018 (Experiment #4). As discussed in Vereecken  
et al. (2021), the measured HO<sub>2</sub> concentrations are much higher than predicted by model calculations for experiments in this  
work (up to a factor of 10) except for the experiment on 09 August 2018 (Experiment #1). Although it is possible that part  
260 of the measured HO<sub>2</sub> radicals is due to an interference (Vereecken et al., 2021), the HO<sub>2</sub> radical concentrations predicted by  
the model are too low to explain observed OH radical concentrations for example during the last part of the experiment on  
13 August 2018 (Experiment #4) (Section 5.5). Therefore, the measured HO<sub>2</sub> radical concentrations are used in the further  
analysis in this work.

A large fraction of nitrate RO<sub>2</sub> radicals cannot be detected by the LIF instrument used in this work (Novelli et al., 2021;  
265 Vereecken et al., 2021) because the detection scheme of the instruments requires that HO<sub>2</sub> or OH radicals are formed subse-  
quent to the reaction of RO<sub>2</sub> with NO. However, this is only the case for some of the nitrate RO<sub>2</sub> radicals from the reaction of  
isoprene with NO<sub>3</sub> (Section 2.1). Therefore, measured RO<sub>2</sub> concentrations, which are maximum around  $1 \times 10^9 \text{ cm}^{-3}$  (Fig. 1  
and 2, Panel (d)), need to be regarded as lower limits.

In all experiments, significant amounts (up to 1 ppv) of methyl vinyl ketone (MVK) and methacrolein (MACR) were  
270 detected by the VOCUS PTR-MS instrument.

VOCUS PTR-MS, Br<sup>-</sup>-CIMS and I<sup>-</sup>-CIMS instruments also recorded ion signals from oxygenated organic compounds in  
the experiments that can be attributed to the sum formulas of a number of other product species including non-nitrate (HPALD:  
C<sub>5</sub>H<sub>8</sub>O<sub>3</sub>) and nitrate organic compounds (NISOPOOH: C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub>, NC<sub>4</sub>CHO: C<sub>5</sub>H<sub>7</sub>NO<sub>4</sub>, ISOPCNO<sub>3</sub>: C<sub>5</sub>H<sub>9</sub>NO<sub>4</sub>) and  
epoxide products that are expected to be formed subsequent to the ring-closure reaction of alkoxy radicals (Reaction R9, R17,  
275 C<sub>5</sub>H<sub>8</sub>O<sub>4</sub>, C<sub>5</sub>H<sub>8</sub>O<sub>3</sub>, C<sub>5</sub>H<sub>9</sub>NO<sub>6</sub>, C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub>, C<sub>5</sub>H<sub>7</sub>NO<sub>5</sub>, Fig. 6).

**Figure 4.** Comparison of results from model calculations applying the different isoprene  $\text{NO}_3$  chemistry mechanisms for the experiment on 09 August 2018 (Experiment #1), when  $\text{HO}_2$  concentrations were enhanced and excess CO was present as OH scavenger. MVK, MACR, NISOPOOH, ISOPCNO<sub>3</sub> and NC<sub>4</sub>CHO are produced from all mechanisms, whereas the other species are only produced from either 1,6-H-shift reactions or ring-closure reactions of nitrate alkoxy radicals only implemented in the FZJ-NO3 mechanism. Grey and black dots are measured values. Measured organic peroxy radical concentrations only include part of the total  $\text{RO}_2$  because the LIF instrument cannot detect a fraction of nitrate  $\text{RO}_2$  (Vereecken et al., 2021). Organic products were detected by the VOCUS PTR-MS instrument, which was only calibrated for MVK and MACR. All other traces are scaled to match best the results from the FZJ-NO3 mechanism.

Ion signals shown in Fig. 4, 5, A5, A6 were the highest signals observed in the mass spectrometer instruments except for the ion signal corresponding to a  $\text{C}_4\text{H}_7\text{NO}_5$  compound observed by the  $\text{I}^-$ - and  $\text{Br}^-$ -CIMS instruments. A species with this sum formula cannot be attributed to a major product species expected from the chemical mechanism. This is discussed in detail in Tsiligiannis et al. (2022).

280 Signals at the mass corresponding to NISOPOOH were highest among all product signals observed by the VOCUS PTR-MS instrument. The signal can include nitrate epoxides that are produced from the ring-closure reactions of alkoxy radicals (Section 5.3) and from the reaction of NISOPOOH with OH, which have the same mass. However, their contribution of nitrate epoxides from the ring-closure reactions to the sum of product concentrations from both reactions is expected to be low for most of the time in the experiments in this work, specifically in the experiment on 09 August 2018 (Experiment #1),  
 285 when  $\text{HO}_2$  concentrations favoured  $\text{RO}_2 + \text{HO}_2$  reactions and an OH scavenger was present (Fig. 4, Panel (a)). Fragmentation,

**Figure 5.** Comparison of results from model calculations applying the different isoprene NO<sub>3</sub> chemistry mechanisms for the experiment on 13 August 2018 (Experiment #4), when the amount of oxidized isoprene was highest. MVK, MACR, NISPOOH, ISOPCNO<sub>3</sub> and NC<sub>4</sub>CHO are produced from all mechanisms, whereas the other species are only produced from either 1,6-H-shift reactions or ring-closure reactions of nitrate alkoxy radicals only implemented in the FZJ-NO<sub>3</sub> mechanism. Grey and black dots are measured values. Measured organic peroxy radical concentrations only include part of the total RO<sub>2</sub> because the LIF instrument cannot detect a fraction of nitrate RO<sub>2</sub> (Vereecken et al., 2021). Organic products were detected by the VOCUS PTR-MS instrument, which was only calibrated for MVK and MACR. All other traces are scaled to match best the results from the FZJ-NO<sub>3</sub> mechanism.

though, may reduce the sensitivity of the VOCUS PTR-MS instrument for NISPOOH at the corresponding mass as shown by Li et al. (2022) for other hydroperoxide species.

Signals from all three mass spectrometry instruments (Fig. A7, A8, A9, A10) can be compared by scaling them to best match modelled concentrations of organic products applying the FZJ-NO<sub>3</sub> chemical mechanism.

- 290 The relative behaviour of signals is similar for all instruments with a few exceptions: (1) In the experiment on 09 August 2018 (Experiment #1), the signals of the Br<sup>-</sup>-CIMS instrument appear to be systematically lower after 10:00 UTC for unknown reasons (Fig. A7). (2) In the experiment on 13 August 2018 (Experiment #4), the loss rate of C<sub>5</sub>H<sub>9</sub>NO<sub>4</sub> compounds appears to be slower in the signal of the Br<sup>-</sup>-CIMS instrument than in the other mass spectrometer instruments (Fig. A10, Panel (c)) and expected from model calculations. This could be explained if other (fragments of) products were detected at that mass by the
- 295 Br<sup>-</sup>-CIMS instrument, but not by the other instruments. (3) The loss rate of C<sub>5</sub>H<sub>10</sub>O<sub>3</sub> compounds observed by the I<sup>-</sup>-CIMS instrument appears to be faster than observed by the VOCUS PTR-MS instrument and expected from model calculations in

**Figure 6.** Loss reactions of the most abundant  $\beta$ -1,2-RO<sub>2</sub> species. Coloured arrows indicate the preferred reaction channel for the nitrate alkoxy radical in the different chemical models (yellow: Caltech; blue: FZJ-NO3). Dashed red arrows indicate corresponding reactions of the  $\delta$ -RO<sub>2</sub> species which is the only RO<sub>2</sub> represented in the MCM. Coloured boxes indicate species that were observed by the VOCUS PTR-MS instrument. Though nitrate carbonyl products (NC<sub>4</sub>CHO) cannot be formed from this specific nitrate  $\beta$ -RO<sub>2</sub> from isoprene, they are formed from other nitrate radicals and thus nitrate carbonyls were also observed by the VOCUS PTR-MS instrument.

the experiment on 13 August 2018 (Experiment #4) (Fig. A10, Panel (f)). The difference in the observed temporal evolution of C<sub>5</sub>H<sub>10</sub>O<sub>3</sub> compounds could be explained if the sensitivity of the instrument was lower for the hydroperoxide species than for the epoxide species, both of which are detected at the same mass (Section 5.5). Differences would become most obvious during this part of the experiment because these compounds have vastly different chemical lifetimes with respect to the reaction with OH, which was likely the dominant loss process for this part of the experiment. In some parts of the experiments, measurements by the I<sup>-</sup>-CIMS instrument exhibited an oscillating behaviour, which is most likely an instrumental artefact (for example Fig. A10, Panel (b)).

Some species produced from different loss pathways can be structurally different but have the same sum formula. These isomers cannot be distinguished by the mass spectrometers (Fig. 6): (1) Nitrate hydroperoxides (NISOPOOH) have the same mass as some nitrate epoxide species (Reaction R16). This applies for nitrate epoxides formed from the reaction of OH with NISOPOOH, which does not play a major role for conditions of the experiments, but also for specific nitrate epoxide products

formed subsequently to the ring-closure reaction of nitrate alkoxy radicals predicted by the FZJ-NO<sub>3</sub> mechanism (Vereecken et al., 2021). (2) Hydroperoxy aldehydes (HPALD) produced from unimolecular 1,6-H-shift reactions of the nitrate Z- $\delta$ -RO<sub>2</sub> isomers have the same mass as one epoxide product formed also from the ring-closure reaction of nitrate alkoxy radicals (sum formula C<sub>5</sub>H<sub>8</sub>O<sub>3</sub>, [Reaction R14](#)). NO<sub>2</sub> is eliminated, so that these products do not contain nitrate functional groups.

The temporal behaviour of products depends on their production and destruction rates. They are formed from the same pool of nitrate RO<sub>2</sub> radicals from the reaction of isoprene with NO<sub>3</sub> which is the rate limiting step for their production. The temporal evaluation of their concentrations at later times of the experiment when isoprene had been consumed is determined by the rate of loss processes, which can be chemical loss and dilution in these experiments.

Mainly measurements by the VOCUS PTR-MS instrument are discussed in the next sections. However, the conclusions do not depend on the choice of the instrument as can be seen by the overall good agreement in time-series of ion signals at the same mass of instruments (Fig. A7, A8, A9, A10). Results are also independent on the choice of scaling measured ion mass signals of the VOCUS PTR-MS instrument to the model results of the FZJ-NO<sub>3</sub> mechanism (A11).

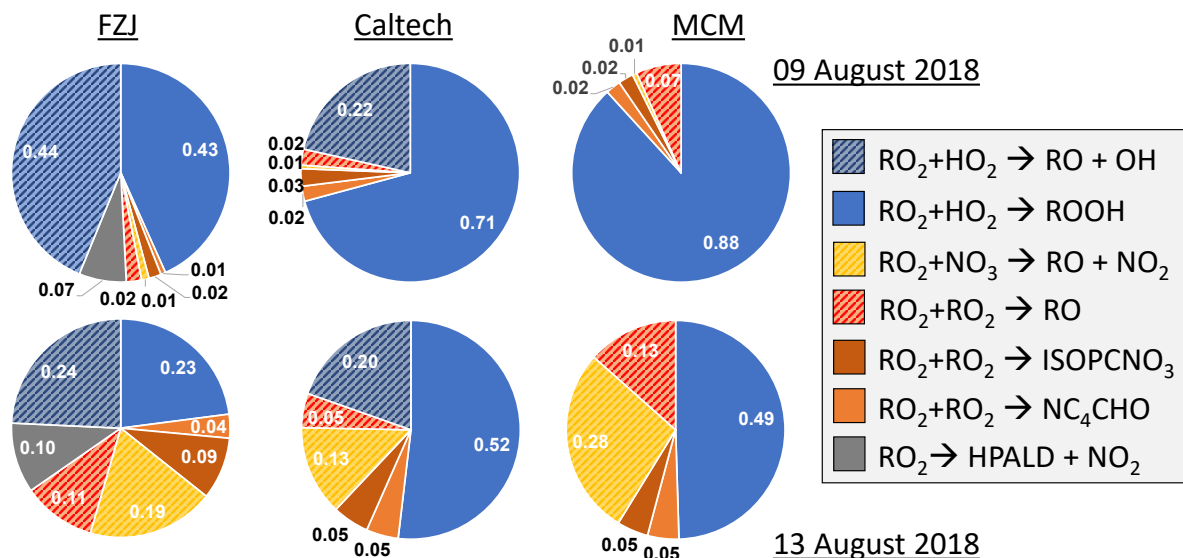

## 5 Discussion

### 5.1 Chemical lifetime of nitrate RO<sub>2</sub> radicals

Using the RO<sub>2</sub> chemistry as implemented in the FZJ-NO<sub>3</sub> mechanism and measured HO<sub>2</sub> concentrations results in overall loss rates of nitrate RO<sub>2</sub> of around 0.035, 0.005, 0.008 and 0.014 s<sup>-1</sup> in the experiments on 09, 10, 12, and 13 August 2018 (Experiment #1, #2, #3, #4). This implies chemical lifetimes between 30 s and several minutes, which are similar to values at atmospheric night-time conditions. RO<sub>2</sub> loss rates are 20 to 50 % lower if the chemistry implemented in the Caltech mechanism or MCM is applied.

Overall, differences of the RO<sub>2</sub> loss rates derived from the three mechanisms are mainly related to differences of the distribution of nitrate RO<sub>2</sub> isomers, for which chemical lifetimes vary. In addition, implementation of unimolecular RO<sub>2</sub> reactions shorten their chemical lifetime in the FZJ-NO<sub>3</sub> mechanism (Fig. 3, 6). Differences of RO<sub>2</sub> loss rates between the chemical mechanisms are lowest for the experiment on 09 August 2018 (Experiment #1), in which the RO<sub>2</sub> loss is dominated by the reaction with HO<sub>2</sub> (Fig. 7, A3). ~~leading to an~~ [In this experiment, the overall loss rate was highest](#), so that unimolecular RO<sub>2</sub> reactions implemented in the FZJ-NO<sub>3</sub> mechanism were less competitive.

If HO<sub>2</sub> concentrations are used as derived from model calculations, the total RO<sub>2</sub> loss rates are lower by 30 to 50 % than shown here due to the low predicted HO<sub>2</sub> concentrations (Vereecken et al., 2021). The contribution of the different RO<sub>2</sub> loss channels shifts towards higher contributions from RO<sub>2</sub> reactions with other RO<sub>2</sub> radicals and with NO<sub>3</sub> (Fig. A4). In addition, unimolecular reactions further gain in importance due to the longer chemical lifetime of RO<sub>2</sub> radicals.

**Figure 7.** Relative distribution of loss rates of nitrate  $\text{RO}_2$  for the experiment on 09 August 2018 (Experiment #1), when  $\text{HO}_2$  concentrations were enhanced, and for the experiment on 13 August 2018 (Experiment #4), when the amount of oxidized isoprene was highest. The total  $\text{RO}_2$  loss rate was  $0.035$  and  $0.014 \text{ s}^{-1}$  in the experiment on 09 August 2018 (Experiment #1) and 13 August 2018 (Experiment #4), respectively. Calculations of the loss rates of  $\text{RO}_2$  radicals in bimolecular reactions make use of measured  $\text{HO}_2$  and  $\text{NO}_3$  concentrations. Total  $\text{RO}_2$  concentrations and concentrations of speciated nitrate  $\text{RO}_2$  were derived from model calculations applying either the FZJ- $\text{NO}_3$ , Caltech or MCM mechanism. The chemical mechanisms differ with respect to the number of nitrate  $\text{RO}_2$  isomers that are considered, the type of  $\text{RO}_2$  loss reactions and products of loss reactions (Fig. 3 and 6). Reactions leading to nitrate alkoxy radicals are indicated by a dotted pattern.

## 5.2 Production of nitrate alkoxy radicals

Alkoxy radicals play an important role in determining the differences in the concentrations of organic products, obtained by model calculations applying the three mechanisms (Fig. 4, 5, A5, A6). These differences are not only due to differences in the fate of alkoxy radicals, but also due to differences in the formation rates of alkoxy radicals which are formed from nitrate  $\text{RO}_2$  radicals reacting with  $\text{NO}_3$ ,  $\text{RO}_2$ , and  $\text{HO}_2$  radicals.

In all three mechanisms, the initial product from the reaction between nitrate  $\text{RO}_2$  and  $\text{NO}_3$  is a nitrate alkoxy radical and  $\text{NO}_2$  (Fig. 6, Reaction R3). Dewald et al. (2020) analysed  $\text{NO}_3$  reactivity measurements performed in the same experiments and concluded that the reaction rate constant of the reaction of nitrate  $\text{RO}_2$  with  $\text{NO}_3$  would need to be around  $5 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ , which is nearly a factor of 2 higher than the generic reaction  $\text{RO}_2 + \text{NO}_3$  rate constant based on the measured rate constant for  $\text{CH}_3\text{O}_2 + \text{NO}_3$  used in the MCM and the Caltech mechanisms. With this rate constant, the loss rate of nitrate  $\text{RO}_2$  in the reaction with  $\text{NO}_3$  is between  $0.001$  and  $0.003 \text{ s}^{-1}$  in the experiments on 10, 12 and 13 August 2018 ((Experiment #2, #3, #4), contributing between 5 and 20 % of the total nitrate  $\text{RO}_2$  loss rate if the FZJ- $\text{NO}_3$  mechanism is applied (Fig. 7, A3).

Rate constants of RO<sub>2</sub> + RO<sub>2</sub> reactions for nitrate RO<sub>2</sub> in the Caltech mechanism were derived from the measurement of isomer specific product distributions in the experiments of Schwantes et al. (2015). From their findings, a reaction rate constant of  $7 \times 10^{-14} \text{ cm}^3 \text{ s}^{-1}$  for the self- and cross-reaction of the most abundant nitrate  $\beta$ -1,2-RO<sub>2</sub> radical was found. As this rate refers to a tertiary radical instead of a primary, it is significantly slower than the rate constant used in the MCM of  $1.3 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ . Rate constants for other nitrate RO<sub>2</sub> were estimated in the Caltech mechanism to be in the range of  $10^{-12}$  and  $10^{-13} \text{ cm}^3 \text{ s}^{-1}$ . In the FZJ-NO<sub>3</sub> mechanism, all the rates for the nitrate RO<sub>2</sub> self- and cross-reactions were calculated from structure activity relationship (Jenkin et al., 2019) resulting in an even lower rate constant for the self- and cross-reaction of the tertiary  $\beta$ -1,2-RO<sub>2</sub> of only  $3 \times 10^{-16} \text{ cm}^3 \text{ s}^{-1}$  and for the cross-reactions of this radical with other primary nitrate RO<sub>2</sub> of 2 to  $10 \times 10^{-14} \text{ cm}^3 \text{ s}^{-1}$ . The rates of the reactions within the pool of the other nitrate RO<sub>2</sub> are on the same order of magnitude as the values in the Caltech mechanism.

Only RO<sub>2</sub> concentrations derived from model calculations can be used to estimate the loss rate of nitrate RO<sub>2</sub> in RO<sub>2</sub> + RO<sub>2</sub> reactions (=alkoxy radical production rate) because the instrument detecting RO<sub>2</sub> could only measure low limit concentrations (Vereecken et al., 2021). This gives average RO<sub>2</sub> loss rates between  $0.0005 \text{ s}^{-1}$  and  $0.002 \text{ s}^{-1}$ . The contribution to the total loss rate is less than 10 % in the experiments on 09, 10, 12 August 2018 (Experiment #1, #2, #3, #4) but increased to up to 20 % in the experiment on 13 August 2018 (Experiment #4), when also the production rate of nitrate RO<sub>2</sub> was highest (Fig. 7).

A yield of 60 % for the formation of alkoxy radicals (Fig. 6, Reaction R4) is generally applied for RO<sub>2</sub>+RO<sub>2</sub> radical reactions for primary and secondary RO<sub>2</sub> (Jenkin et al., 2019). In the case of the most abundant nitrate-organic peroxy radical (tertiary  $\beta$ -1,2-RO<sub>2</sub>) from the reaction of isoprene with NO<sub>3</sub>, however, the yield is nearly 100 % for its self-reaction and 80 % if this nitrate RO<sub>2</sub> reacts with other RO<sub>2</sub> because the formation of a nitrate carbonyl product (NC<sub>4</sub>CHO) is not possible (Fig. 6, Reaction R5). Formation of peroxides (ROOR) is considered in the Caltech and FZJ-NO<sub>3</sub> mechanisms with a small yield of 3.5 %. The MCM does not distinguish between nitrate RO<sub>2</sub> isomers. Therefore, this increase in the yield of alkoxy radicals is only implemented in the Caltech and FZJ-NO<sub>3</sub> mechanisms. With respect to the total yield of alkoxy radicals, the high yield for the  $\beta$ -RO<sub>2</sub> is partly compensated by the lower rate constants of RO<sub>2</sub>+RO<sub>2</sub> radical reactions in the FZJ-NO<sub>3</sub> and Caltech mechanisms than applied in the MCM.

As discussed in Schwantes et al. (2015), reactions of nitrate  $\beta$ -RO<sub>2</sub> and HO<sub>2</sub> can also result in the formation of nitrate alkoxy radicals together with an OH radical (Fig. 6, Reaction R2). A yield of 50 % is assumed in the Caltech and FZJ-NO<sub>3</sub> mechanisms (Section 5.3).

Overall, the total yield of alkoxy radicals produced in the reactions of nitrate RO<sub>2</sub> differ significantly between the 3 mechanisms. In the FZJ-NO<sub>3</sub> mechanism, the total yield is around 50 %. The value is similar in all experiments analysed in this work, but the type of reactions producing the alkoxy radicals shifts depending on the availability of reaction partners (Fig. 7). Alkoxy radicals yields are 25 and 40 % lower in the Caltech mechanism than in the FZJ-NO<sub>3</sub> mechanism. The value is mainly due to the shift in the RO<sub>2</sub> isomer distribution towards  $\delta$ -RO<sub>2</sub> isomers. Lowest total yields of alkoxy radicals between 7 and 40 % are obtained if the MCM is applied because the MCM does not include alkoxy radical production from the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub>.

### 5.3 Fate of nitrate alkoxy radicals

The fate of the alkoxy radicals is very different between the three mechanisms which impacts the distribution of organic products. In the MCM, the only pathway for nitrate alkoxy radicals produced from isoprene is their decomposition forming a nitrate carbonyl ( $\text{NC}_4\text{CHO}$ ) together with an  $\text{HO}_2$  radical (Fig. 6, Reaction R7). This pathway is not possible for the alkoxy radical from the  $\beta\text{-RO}_2$  radicals, which are absent in the MCM mechanism but included in the FZJ- $\text{NO}_3$  and Caltech mechanisms. Therefore, the overall yield of nitrate carbonyls ( $\text{NC}_4\text{CHO}$ ) from the subsequent chemistry of nitrate alkoxy radicals is highest if the MCM mechanism is applied in comparison to the results from the other 2 mechanisms.

In the Caltech mechanism, alkoxy radicals from  $\beta\text{-RO}_2$  radicals decompose exclusively to MVK or MACR together with a formaldehyde and an  $\text{NO}_2$  molecule (Fig. 6, Reaction R8 Wennberg et al. (2018)). Therefore, nitrate carbonyl concentrations predicted by the Caltech model are at least a factor of 4 lower than calculated when applying the MCM. Small concentrations of nitrate carbonyls are also produced from reactions of nitrate  $\delta\text{-RO}_2$  radicals.

Vereecken et al. (2021) calculated that ring-closure reactions leading to the formation of nitrate epoxy alkyl radicals are much faster than the decomposition reaction for the nitrate  $\beta\text{-RO}$  alkoxy isomer Fig. 6, Reaction R9, R17), so that MVK and MACR production from this reaction is suppressed. Products from the epoxide pathway are discussed in Section 5.4. Differences between  $\text{NC}_4\text{CHO}$  concentrations predicted by the FZJ- $\text{NO}_3$  and Caltech mechanism are due to differences in the initial distribution of nitrate  $\text{RO}_2$  isomers. The FZJ- $\text{NO}_3$  mechanism favours the  $\beta\text{-1,2-RO}_2$  radicals (Section 3) that do not produce  $\text{NC}_4\text{CHO}$  and overall react slower with other  $\text{RO}_2$  than with the other nitrate  $\text{RO}_2$  radicals.

The VOCUS PTR-MS instrument detected ion signals at the expected mass of  $\text{NC}_4\text{CHO}$  with the sum formula  $\text{C}_5\text{H}_7\text{NO}_4$  in all experiments. Due to the lack of calibration, this measurement cannot be used to test the validity of any of the three chemical mechanisms. However,  $\text{NC}_4\text{CHO}$  concentrations would be roughly consistent with predictions by the Caltech and FZJ- $\text{NO}_3$  mechanisms if a sensitivity similar to that for ketones without nitrate functional groups (acetone, MVK, pentanone, nopinone) is assumed.

MVK and MACR are formed in all three mechanisms from the oxidation of isoprene by OH and ozone. Yields from the ozonolysis of isoprene are 0.17 and 0.41 for MVK and MACR, respectively (Nguyen et al., 2016). In the absence of NO as for typical night-time conditions, MVK and MACR are produced from the reaction of OH derived  $\text{RO}_2$  radicals with other  $\text{RO}_2$  or  $\text{HO}_2$  radicals. The overall yield of MVK from the OH oxidation of isoprene in experiments in this work depends on the fate of  $\text{RO}_2$  radicals, but is expected to be small due to the slow  $\text{RO}_2 + \text{RO}_2$  reaction rate and small yields in the range of a few percent from the  $\text{RO}_2 + \text{HO}_2$  reaction (Wennberg et al., 2018). In addition to the production from OH and  $\text{O}_3$  reactions, the Caltech mechanism includes a strong source for MVK through the decomposition of nitrate  $\beta\text{-1,2-RO}_2$  radicals produced from the  $\text{NO}_3$  oxidation.

In all experiments, analysed in this work, measured MVK and MACR concentrations are consistent with predictions by the MCM and FZJ- $\text{NO}_3$  mechanisms (Fig. 4, 5). In contrast, predictions by the Caltech mechanism are up to a factor of 2 to 4 higher than measured values. Discrepancies are highest in experiments in which a high fraction of the nitrate alkoxy radicals are formed from the reaction of nitrate  $\text{RO}_2$  with  $\text{NO}_3$  with an alkoxy radical yield of 1 (13 August 2018, Fig. 5)

and are lowest in the experiment in which nitrate RO<sub>2</sub> mainly reacted with HO<sub>2</sub> (09 August 2018, Fig. 4). The good model-measurement agreement for MVK+MACR concentrations obtained using the FZJ-NO<sub>3</sub> and MCM mechanisms confirms that the decomposition of the nitrate alkoxy radicals is negligible as predicted by Vereecken et al. (2021) and unlike predicted by the Caltech mechanism.

#### 5.4 Epoxide products from ring-closure reactions of nitrate alkoxy radicals

Epoxide formation from ring-closure reactions of nitrate alkoxy radicals leading to epoxy-RO<sub>2</sub> radicals is ~~only~~ implemented **only** in the FZJ-NO<sub>3</sub> mechanism (Fig. 6, Reaction R9, R17, Vereecken et al. (2021)).

Nitrate epoxides can be formed from bimolecular reactions of epoxy-RO<sub>2</sub> radicals with RO<sub>2</sub> and HO<sub>2</sub> (Fig. 6, Reaction R12, R16, R19, R26) and from nitrate epoxy alkoxy radicals produced by the reaction of epoxy-RO<sub>2</sub> radicals with NO<sub>3</sub> (Fig. 6, Reaction R13, R21). One of the epoxy-RO radicals exclusively undergoes a 1,5-H-shift reaction for conditions of the experiments and decomposes to an epoxide and NO<sub>2</sub> (Fig. 6, Reaction R14). Another epoxy-RO radical can decompose into a C<sub>5</sub> nitrate epoxide releasing HO<sub>2</sub> (Fig. 6, Reaction R22). This reaction competes with a 1,5-H-shift reaction, in which a C<sub>4</sub> nitrate together with an HO<sub>2</sub> radical and formaldehyde (HCHO) are formed (Fig. 6, Reaction R23).

Epoxy-RO<sub>2</sub> can also undergo unimolecular reactions (Vereecken et al., 2021) that compete with bimolecular reactions. The fastest unimolecular reaction is a 1,6-H-shift reaction with a rate constant of  $3.7 \times 10^{-3} \text{ s}^{-1}$  at room temperature leading to a C<sub>5</sub> epoxy product (C<sub>5</sub>H<sub>8</sub>O<sub>4</sub>) together with NO<sub>2</sub> (Fig. 6, Reaction R11). This loss rate is lower than the loss rate due to bimolecular reactions, which are on the order of  $10^{-2} \text{ s}^{-1}$  for conditions of the experiments in this work but high enough that low concentrations of this epoxide product may be formed (Fig. 5, Panel (f)).

The mass spectrometer instruments cannot distinguish between hydroxy nitrate epoxides formed from the reaction of epoxy-RO<sub>2</sub> radicals with other RO<sub>2</sub> radicals and nitrate hydroperoxides (NISOPOOH) because ~~both~~ **they** have the same sum formula, C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub>. The concentration of epoxide C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub> species is expected to be at most 30 to 40 % of the concentration of NISOPOOH in the experiment on 13 August 2018 (Fig. 5), when RO<sub>2</sub> concentrations were highest. Their concentration is expected to be less than 10 % of NISOPOOH in the experiment on 09 August 2018 (Fig. 4, Panel (a)), when RO<sub>2</sub> reactions with HO<sub>2</sub> dominated the overall RO<sub>2</sub> loss. Therefore, ion mass signals corresponding to C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub> species cannot be used to estimate the importance of the epoxidation reaction pathways.

Bimolecular reactions of epoxy-RO<sub>2</sub> can also lead to the formation of products with sum formulas that are specific for the epoxidation chemistry. Different isomers of nitrate carbonyls with the sum formula C<sub>5</sub>H<sub>7</sub>NO<sub>5</sub> are produced from reactions of epoxy-RO<sub>2</sub> with other RO<sub>2</sub> radicals or with NO<sub>3</sub> (Fig. 6, Reaction R19, R22). In addition, C<sub>5</sub>H<sub>9</sub>NO<sub>6</sub> compounds are formed from reactions of nitrate epoxy-RO<sub>2</sub> with HO<sub>2</sub> (Fig. 6, Reaction R12, R26). Mixing ratios of these epoxides are ~~calculated~~ **predicted** to be highest with mixing ratios of 1 ppbv in the experiment on 13 August 2018 (Experiment #4), when the total isoprene consumption by NO<sub>3</sub> reactions was highest. Values are similar to mixing ratios of other products obtained in this experiment (Fig. 5, Panel (g)).

The mass spectrum measured by the VOCUS PTR-MS instrument shows clear signals at the masses of ~~these~~ **these epoxy nitrate** compounds. The count rates are much lower than signals of other products, although expected concentrations are in the same

range. This could be due to a lower sensitivity of the instrument for nitrate epoxides than for other organic nitrates. However, this could also indicate a lower than assumed production rate of alkoxy radicals for example from the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> (Section 5.5).

A C<sub>4</sub>-nitrate with the sum formula C<sub>4</sub>H<sub>5</sub>NO<sub>4</sub> produced subsequent to the 1,5-H reaction of the nitrate alkoxy radical (Fig. 6, Reaction R23–R25) was not detected by the VOCUS PTR-MS instrument in the experiments in this work, though significant mixing ratios of up to 0.6 ppbv are calculated by the FZJ-NO<sub>3</sub> mechanism in the experiment on 13 August 2018 (Experiment #4), when the amount of oxidized isoprene was highest (Fig. 5, Panel (i)). There is no obvious reason why the sensitivity of the instrument for this compound would be lower than for other compounds. Only the I<sup>−</sup> CIMS instrument detected a very small signal (less than 30 cnts) at the corresponding mass, which is at least a factor of 100 smaller than ion signals of masses at other products shown in Fig. A10).

The formation of this compound competes with the decomposition of the epoxy alkoxy radical leading to an epoxy-C<sub>5</sub> compound with the sum formula C<sub>5</sub>H<sub>7</sub>NO<sub>5</sub> that is observed in the mass spectrum of the VOCUS PTR-MS instrument (Fig. 6, Reaction R22). The fact that the C<sub>4</sub> nitrate is not observed in the mass spectrum could indicate that the 1,5-H reaction is not competitive or that the branching ratio of 2 epoxy-alkyl radicals from the nitrate alkoxy radical disfavors the epoxy-alkyl radical that eventually leads to the formation of the C<sub>4</sub> nitrate (Fig. 6, Reaction R17). Rate constants of the epoxidation chemistry calculated in Vereecken et al. (2021) have an uncertainty of a factor of 2 to 4. Therefore, low rate constants that weaken the formation of the C<sub>4</sub> nitrate are within the uncertainty of calculations.

Two further epoxy compounds which have lost the nitrate functional group by eliminating NO<sub>2</sub> are expected to be formed. One has the sum formula C<sub>5</sub>H<sub>8</sub>O<sub>3</sub> and is a product of a fast 1,5-H-shift reaction of an epoxy-alkoxy radical (Fig. 6, Reaction R14). The sum formula is the same as hydroperoxy aldehydes (HPALD) that are formed from 1,6-H-shift reactions of the primary nitrate  $\gamma$ -RO<sub>2</sub> radical (Fig. 3). The contribution of the epoxy species to the sum of epoxy compounds and HPALD is calculated to be small with values of less than 15 % in all experiments.

The other epoxy compound without a nitrate functional group is produced from a 1,6-H-shift reaction of one of the nitrate epoxy-RO<sub>2</sub> (Fig. 6, Reaction R11). Due to the relatively low reaction rate constant, only small mixing ratios of maximum 0.15 ppbv of this compound with the sum formula C<sub>5</sub>H<sub>8</sub>O<sub>4</sub> are modelled in for the experiment on 13 August 2018 (Experiment #4) (Fig. 5, Panel (f)). Nevertheless, a corresponding signal is observed in the mass spectrum of the VOCUS PTR-MS instrument that can be attributed to this compound.

## 5.5 Reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub>

The chemical loss rates of nitrate RO<sub>2</sub> towards reaction with HO<sub>2</sub> was 0.032 s<sup>−1</sup> (90 % of the total loss rate) in the experiment with high HO<sub>2</sub> concentrations (09 August 2018, Experiment #1). The contribution to the total loss rate was 40 to 50 % with loss rates between 0.002 and 0.007 s<sup>−1</sup> in the other experiments (Fig. 6). In general, this reaction can proceed via several reaction

pathways (Rollins et al., 2009; Kwan et al., 2012; Schwantes et al., 2015):

485 Nitrate hydroperoxide (NISOPOOH) is the only product in the MCM (Reaction R1) and a major product in the Caltech and FZJ-NO<sub>3</sub> chemical mechanisms (Fig. 6, Reaction R1). The Caltech and FZJ-NO<sub>3</sub> mechanisms assume that the yield of nitrate alkoxy radicals is approximately 0.5 if nitrate  $\beta$ -RO<sub>2</sub> radicals react with HO<sub>2</sub> (Reaction R2). The fate of nitrate alkoxy radicals is discussed above (Section 5.3). Predictions of NISOPOOH concentrations by the three mechanisms differ significantly. NISOPOOH concentrations predicted by the FZJ-NO<sub>3</sub> mechanism are approximately half of the concentration  
490 calculated by the MCM and concentrations predicted by the Caltech mechanism are between both values. This is mainly due to the different distribution of nitrate  $\beta$ - and  $\delta$ -RO<sub>2</sub> radicals in the FZJ-NO<sub>3</sub> and Caltech mechanisms.

The VOCUS PTR-MS instrument was not calibrated for NISOPOOH, so that its concentrations could not be determined. The high count rate [observed by this instrument and the 2 other CIMS instruments](#) and the uncertainty in the branching ratio of Reactions R1 and R2 appear to support a high yield of NISOPOOH from the reaction of HO<sub>2</sub> with nitrate RO<sub>2</sub>.

495 Alkoxy radical formation from the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> is accompanied by the formation of OH (Fig. 6, Reaction R2), which can be responsible for the formation of products that are specific for the OH oxidation of isoprene as observed in experiments designed to investigate the NO<sub>3</sub> oxidation mechanism of isoprene.

OH concentrations were measured in the experiments in this work, but concentrations were around the limit of detection of the instrument (a few 10<sup>5</sup> cm<sup>-3</sup>) in most experiments. Model calculations for the experiment on 13 August 2018 (Experiment  
500 #4), when reactant concentrations were highest, result in significant OH concentrations between 5 and 8 × 10<sup>5</sup> cm<sup>-3</sup> and also model results indicate that OH concentrations could have been in the range of a few 10<sup>5</sup> cm<sup>-3</sup> (Fig. 5, Panel (j)). A large fraction of OH, however, is produced by the reaction of HO<sub>2</sub> with NO<sub>3</sub>, both of which are constrained to measured values in the model calculations. As discussed in Vereecken et al. (2021), model calculations without constraining HO<sub>2</sub> to measured values cannot reproduce measured HO<sub>2</sub> concentration suggesting shortcomings of the model to describe HO<sub>2</sub> source and/or  
505 sink reactions.

This is further analysed by comparing results of model runs, in which either HO<sub>2</sub> concentrations are constrained to measurements or HO<sub>2</sub> is calculated by the model (Fig. 8). In the unconstrained case, modelled HO<sub>2</sub> concentrations are much lower than measurements. This reduces the OH concentration by a factor of 3 due to the lower production of OH from the reaction of HO<sub>2</sub> with NO<sub>3</sub>. During the part of the experiment, when isoprene is oxidized by NO<sub>3</sub>, differences between measured and  
510 modelled OH concentrations tend to be smaller if HO<sub>2</sub> is not constrained to measured values. At later times of the experiment after 13:30 UTC, when isoprene had been consumed and NO<sub>3</sub> concentrations were enhanced by additional injections of NO<sub>2</sub> and O<sub>3</sub> (Fig. 2, Panel (b)), measurements show a steeper increase of OH concentrations than model calculations with unconstrained HO<sub>2</sub>. This further indicates that modelled HO<sub>2</sub> concentrations might be too low.

If the yield of alkoxy radicals and therefore also of OH from the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> was lower than 50 %  
515 as assumed in the Caltech and FZJ-NO<sub>3</sub> mechanisms, modelled OH concentrations would be even lower. Sensitivity model

**Figure 8.** Comparison of results from model calculations applying the FZJ-NO<sub>3</sub> mechanism for the experiment on 13 August 2018 (Experiment #4) with HO<sub>2</sub> concentrations being either constrained or unconstrained to measurements. A large fraction of OH is produced from the reaction of HO<sub>2</sub> with NO<sub>3</sub>, so that lower than measured HO<sub>2</sub> concentrations in the unconstrained model run lead to low OH concentrations. Because HO<sub>2</sub> + RO<sub>2</sub> reactions contribute significantly to the total loss of RO<sub>2</sub>, modelled RO<sub>2</sub> concentrations are higher in the unconstrained model run. RO<sub>2</sub> measurements by the LIF instrument does not include all RO<sub>2</sub> radicals (Vereecken et al., 2021), so that measured concentrations are lower than modelled values.

runs show that modelled OH concentrations would only decrease by 1 to  $3 \times 10^5 \text{ cm}^{-3}$  directly after the isoprene injections, when nitrate RO<sub>2</sub> concentrations are also highest, in this case. However, such differences are in the range of the accuracy of measurements, which was a few  $10^5 \text{ cm}^{-3}$  due to the subtraction of an OH background signal that was determined by using a chemical modulation system (Cho et al., 2021).

520 Overall, considering the uncertainties in the measured OH concentrations and in the modelled OH due to the uncertainty in the OH production from the HO<sub>2</sub> + NO<sub>3</sub> reaction, differences between model results and measured values are too small to draw conclusions about the yield of alkoxy radicals from model-measurement comparison of OH concentrations.

## 5.6 Production of hydroperoxy aldehydes (HPALD) from nitrate RO<sub>2</sub> isomerization reactions

Only the FZJ-NO<sub>3</sub> mechanism includes unimolecular loss reactions of nitrate RO<sub>2</sub> (Fig. 3). The reaction rate constants of the 1,6-H shift reactions of the *Z*- $\delta$ -RO<sub>2</sub> isomers have a strong temperature dependence (Vereecken et al., 2021). Values range between 0.016 to 0.023 s<sup>-1</sup> for the *Z*- $\delta$ -1,4-RO<sub>2</sub> isomer and 0.045 and 0.06 s<sup>-1</sup> for the *Z*- $\delta$ -4,1-RO<sub>2</sub> isomer for temperatures experienced in the experiments in this work.

Although The fraction of *Z*- $\delta$ -RO<sub>2</sub> isomer to the total RO<sub>2</sub> concentration is only between 5 and 6 % for the *Z*- $\delta$ -1,4-RO<sub>2</sub> and between 1 and 2 % for the *Z*- $\delta$ -4,1-RO<sub>2</sub> isomer. The overall bulk RO<sub>2</sub> isomerization rate is around 0.002 s<sup>-1</sup> making the 1,6-H-shift reaction competitive with bimolecular reactions in all experiments except for the one with high HO<sub>2</sub> concentrations (09 August 2018, Experiment #1). Its contribution of unimolecular reactions to the overall loss rate is expected to be between 10 and 30 % depending on the total RO<sub>2</sub> loss rate (Fig. 7). This is similar or even higher than for analogous, much faster 1,6-H-shift reactions in the OH-initiated isoprene oxidation ( $k(298\text{ K}) \approx 0.5\text{ s}^{-1}$ , Peeters et al. (2014)) due to significantly longer RO<sub>2</sub> lifetimes during the night than during the day.

HPALD concentrations predicted by the model applying the FZJ-NO<sub>3</sub> mechanism are between 0.1 and 1.2 ppbv depending on the chemical conditions with different availability of reaction partners for competing bimolecular reactions. HPALD mixing ratios are calculated to be highest in the experiment on 13 August 2018 (Experiment #4), when the total concentration of oxidized isoprene was high. Approximately 10 to 15 % of the HPALD that is predicted by the FZJ-NO<sub>3</sub> mechanism is due to OH oxidation of isoprene also producing HPALD from 1,6-H-shift reactions. This The modelled HPALD concentration from the OH reaction can be seen as an upper limit might be less, however, due to the uncertainty of the modelled OH concentration (Section 5.5). It is worth noting that the fast 1,6-H-shift reactions rate of *Z*- $\delta$ -RO<sub>2</sub> isomers from the OH oxidation of isoprene (bulk loss rate  $\approx 0.006\text{ s}^{-1}$ ) makes these reactions very competitive with bimolecular reactions for night-time conditions (loss rate in the experiments in this work: 0.005 to 0.014 s<sup>-1</sup>, Section 5.1).

Although the absolute importance of HPALD formation from H-shift reactions of nitrate RO<sub>2</sub> radicals is uncertain, HPALD is clearly formed from the oxidation of isoprene by NO<sub>3</sub>. This is demonstrated by the observation of a signal at the mass of HPALD in the experiment on 09 August 2018 (Experiment #1), when an OH scavenger was present, so that HPALD could not be produced by OH reactions. In this experiment, HO<sub>2</sub> + RO<sub>2</sub> reactions were favoured, so that also formation of the epoxides with the same mass is expected to be small (Fig. 4, Panel (c)). Therefore, the signal on the mass of HPALD can be attributed to HPALD formation from the oxidation of isoprene by NO<sub>3</sub> in this experiment.

The relative importance of HPALD formation is expected to be highest for conditions of the experiment on 10 August 2018 (Experiment #2), when the total loss rate of RO<sub>2</sub> due to bimolecular reaction are calculated to be is between 0.005 and 0.006 s<sup>-1</sup>. In this case, approximately 25 to 30 % of the isoprene consumed by NO<sub>3</sub> would form HPALD. Brownwood et al. (2021) calculated the yield of total organic nitrates from measurements for the same experiments analysed in this work and found a yield of (94  $\pm$  20) % for this experiment. Values ranged between (112  $\pm$  13) % and (140  $\pm$  24) % in the other experiments. The lowest yield of organic nitrates is obtained in the experiment with the longest RO<sub>2</sub> lifetime (10 August 2018, Experiment #2) supporting that more non-nitrate organic products such as HPALD are formed in this experiment than

in the other experiments. The signal of the VOCUS PTR-MS instrument, however, does not clearly scale with the expected differences in the HPALD yield in concentrations predicted for the experiments in this work. This and the overall high yields of organic nitrates indicate that the impact of unimolecular reactions producing HPALD might be overestimated in the FZJ-NO<sub>3</sub> mechanism. Uncertainties in the quantum-chemical calculations, from which reaction rates are taken in the FZJ-NO<sub>3</sub> mechanism, are a factor of 2 to 3, so that unimolecular RO<sub>2</sub> reaction might be less competitive with bimolecular RO<sub>2</sub> reactions for atmospheric conditions.

Overall, experiments in this work and previous chamber experiments demonstrate that HPALD formation from 1,6-H shift reactions of Z- $\delta$  RO<sub>2</sub> isomers play a role for atmospheric night-time conditions.

## 5.7 Night-time loss rate of organic nitrate products and hydroperoxy aldehydes (HPALD)

Chamber experiments in this work were designed to also investigate further oxidation of the organic products. This was achieved by re-injecting O<sub>3</sub> and NO<sub>2</sub> to enhance NO<sub>3</sub> production after most of the isoprene had reacted away (Fig. 2, 1, Panel (a)). Highest product concentrations were achieved in the experiment on 13 August 2018 (Experiment #4), when the amount of isoprene that was oxidized was highest. Therefore, the further discussion concentrates on this experiment (Fig. 5). In addition, information from the experiment on 09 August 2018 (Experiment #1) (Fig. 4), when an OH scavenger was present, is used to remove the effect of the OH oxidation.

Reaction rate constants of nitrate products from the oxidation of isoprene with OH and O<sub>3</sub> implemented in the Caltech mechanism are listed in Wennberg et al., (2018). They are based on laboratory experiments with synthetic standards of isoprene hydroxy nitrate isomers (Wennberg et al., 2018; Lee et al., 2014b). Values are assumed to be applicable for other organic nitrates such as nitrate carbonyls and nitrate hydroperoxides. Specific additional reaction channels increasing the reaction rate constants are considered. Only part of the loss reactions listed in Wennberg et al. (2018) are implemented in the code of the Caltech mechanism (Bates and Wennberg, 2017) that is applied in model calculations in this work.

Rate constants for the reaction of the first generation organic nitrates with ozone (Reaction R28, R31, R34, R37) are in the range of 10<sup>-17</sup> to 10<sup>-19</sup> cm<sup>3</sup>s<sup>-1</sup> in Lee et al. (2014b) with rates being relevant for only  $\delta$ -nitrate alcohols and -hydroperoxides for typical oxidant concentrations during the night but too slow for  $\beta$ -species. As only  $\delta$ -species are implemented in the MCM, the overall relevance of these ozonolysis loss reactions are overestimated under atmospheric conditions in the MCM (Table 2). As assumed in that work, Reaction rate constants can be expected to be similar for the different first-generation organic nitrates according to structure-activity-relationship (Jenkin et al., 2020). Therefore, up to factor of 10 higher reaction rate constants as implemented in the MCM, which would make ozone loss reactions relevant for atmospheric conditions, are not applicable (Table 2).

In the FZJ-NO<sub>3</sub> mechanism, reaction rate constants of organic nitrates with OH radicals (Reaction R27, R30, R33, R36) are taken from the Caltech mechanism, but rate constants with ozone and NO<sub>3</sub> are optimized to best describe the temporal behaviour of the signals observed by the VOCUS PTR-MS instrument at the respective mass (Table 2). Reaction rate constants of loss reactions that lead to loss rates much lower than the dilution rate of the chamber, are set to upper limit values that equal the loss rate due to dilution in the experiments ( $k_{dil} = 1.5 \times 10^{-5}$  s<sup>-1</sup>). Reaction rate constants are likely even lower because

**Table 2.** Reaction rate constants for the reaction of first generation major organic products from the reaction of isoprene with NO<sub>3</sub> with OH, O<sub>3</sub> and NO<sub>3</sub> implemented in the MCM, Caltech and FZJ-NO<sub>3</sub> mechanisms. For simplicity rate constants are given for a temperature of  $T = 298$  K and only for the organic nitrate that is produced from the most abundant  $\beta$ -1,2-RO<sub>2</sub> radical, except for the MCM, where the  $\delta$ -1,4-RO<sub>2</sub> is solely present. For the nitrate carbonyl (NC<sub>4</sub>CHO). For the nitrate carbonyl (NC<sub>4</sub>CHO), which cannot be produced from this RO<sub>2</sub> isomer, the value for the  $E$ - $\delta$ -1,4-RO<sub>2</sub> isomer is given instead. In the FZJ-NO<sub>3</sub> mechanism, loss rates due to reactions that lead to loss rates much lower than the dilution rate of the chamber, were set to upper limit values that equal the loss rate due to dilution. Chemical lifetimes ( $\tau$ ) are calculated for the presence of  $1 \times 10^6 \text{ cm}^{-3}$  OH, 100 ppbv O<sub>3</sub> and 50 pptv NO<sub>3</sub>, which can be regarded as upper limit concentrations for typical night-time conditions. The code of the Caltech mechanism (Bates and Wennberg, 2017) includes less loss reactions implemented as described in (Wennberg et al., 2018). Chemical loss of nitrate epoxides are not implemented in the chemical mechanisms.

doubling the loss rate from dilution would already worsen the model-measurement agreement of the temporal behaviour of products.

Chemical loss of NISOPOOH by reactions with NO<sub>3</sub> (Reaction R29) and O<sub>3</sub> (Reaction R28) are expected not to be relevant for atmospheric conditions in all mechanisms. This is consistent with the slow decay of the total signal for C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub> observed by the VOCUS PTR-MS instrument in the experiment on 09 August 2018 (Experiment #1), when OH oxidation was suppressed by the presence of an OH scavenger (Fig. 4, Panel (a)). In this case, the loss rate is consistent with the dilution rate in the experiment.

In the MCM, the rate of the reaction of OH with hydroperoxides, NISOPOOH, is assumed to be fast with a rate coefficient of  $10^{-10} \text{ s}^{-1} \text{ cm}^3$ . In contrast, the Caltech and FZJ-NO<sub>3</sub> mechanisms assume a smaller rate coefficient for this reaction, by a factor of 3, which can account for the faster decay of NISOPOOH in the MCM mechanism than in the Caltech and FZJ-NO<sub>3</sub> mechanisms.

In the MCM, products of the NISOPOOH + OH reaction (Reaction R27) are a nitrate alkoxy radical together with an OH radical leading to a zero net loss of OH. In addition, the alkoxy radical produces a nitrate carbonyl (NC<sub>4</sub>CHO) together with an HO<sub>2</sub> (Section 5.3). In contrast, in the Caltech and FZJ-NO<sub>3</sub> mechanisms, a large fraction of the predicted products are epoxide products (yield: 0.37 to 1.0 depending on the precursor RO<sub>2</sub> isomer, Schwantes et al. (2015)) together with OH analogous to the formation of epoxides in the OH oxidation of isoprene (Paulot et al., 2009). The implementation in these mechanisms is based on the observation of epoxides in chamber experiments in Schwantes et al. (2015).

Nitrate epoxides have the same sum formula as NISOPOOH (C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub>), so that the VOCUS PTR-MS instrument cannot distinguish between both compounds. The reaction of OH radicals with nitrate epoxides is expected to be much slower than their reaction with NISOPOOH due to the lack of C=C double bonds. Therefore, the time series of the sum of both compounds is affected by their different temporal behaviour in the Caltech and FZJ-NO<sub>3</sub> mechanisms. The loss rate of C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub> compounds in the MCM is only determined by the fast loss of NISOPOOH because no epoxides are formed.

For the experiment on 13 August 2018 (Experiment #4) (Fig. 5, Panel (a)), the temporal behaviour of the total ion signal corresponding to C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub> species observed by the VOCUS PTR-MS instrument fits best the modelled trace of the FZJ-NO<sub>3</sub> mechanism with the low OH reaction rate of NISOPOOH. In addition, the low chemical loss rate of epoxides contributes to the slow decay of the ion signal at that mass improving the model-measurement agreement. This demonstrates that OH reaction rate constants measured in Lee et al. (2014b) for nitrate alcohols can be applied to NISOPOOH as implemented in the Caltech and FZJ-NO<sub>3</sub> mechanisms. In contrast, the fast OH reaction rate constant for NISOPOOH implemented in the MCM cannot describe the observations.

If the MCM mechanism is used, a significant fraction of nitrate carbonyls, NC<sub>4</sub>CHO, that are produced from nitrate RO<sub>2</sub> + RO<sub>2</sub> reactions and from the decomposition of specific nitrate alkoxy radicals is expected to be consumed on the time scale of the experiment for the experiment on 13 August 2018 (Experiment #4) (Fig. 5, Panel (d)). For conditions of this experiment, reactions of NC<sub>4</sub>CHO with OH (Reaction R30) but also with NO<sub>3</sub> (Reaction R32) for high NO<sub>3</sub> concentrations can be relevant if reaction rate constants of the MCM are applied (Table 2). The faster loss of NC<sub>4</sub>CHO calculated using the MCM is faster than calculated compared to using the Caltech and FZJ-NO<sub>3</sub> mechanisms can be partly explained by because of the fast chemOH reaction rate constants for some isomers of NC<sub>4</sub>CHO are up to a factor of 3 lower OH reaction rate constants for some isomers of NC<sub>4</sub>CHO. In addition, the MCM overestimates the loss of NC<sub>4</sub>CHO by the reaction with ozone as discussed above.

The temporal behaviour of the modelled NC<sub>4</sub>CHO concentrations are in good agreement with the corresponding signal observed by the VOCUS PTR-MS instrument for the Caltech and FZJ-NO<sub>3</sub> mechanisms. This confirms that only a small fraction of NC<sub>4</sub>CHO is expected to be chemically lost for typical night-time conditions. in contrast to results if reaction rate

constants implemented in the MCM are used leads to a loss rate that is too fast to be consistent with the observed ion mass signal.

In addition, a fast loss rate due to the reaction with  $\text{NO}_3$  (Reaction R32) as suggested in Wennberg et al. (2018) would lead to a chemical lifetime of  $\text{NC}_4\text{CHO}$  of less than 30 min in the last phase of the experiment on 13 August 2018 (Experiment #4), when  $\text{NO}_3$  mixing ratios increased to several 100 pptv (Fig. 2, Panel (b)), but this is not observed (Fig. 5, Panel (d)). Though not fully applicable, structure activity relationship in Kerdouci et al. (2014) gives reaction rate constants lower than  $10^{-16} \text{ s}^{-1} \text{ cm}^3$  due to the carbonyl group in the  $\beta$ -position of the  $\text{C}=\text{C}$  double bond supporting the low loss rate due the addition of  $\text{NO}_3$ . Overall, further oxidation of nitrate carbonyls from isoprene is of minor importance for typical night-time conditions as experienced in these experiments.

Similar differences between model predictions in the temporal behaviour such as like for  $\text{NC}_4\text{CHO}$  are seen for nitrate alcohols ( $\text{ISOPCNO}_3$ , Reaction R33, 34, 35): The MCM predicts a significant faster chemical loss than the Caltech and FZJ- $\text{NO}_3$  mechanisms. A large part of the discrepancy is explained by the fast loss due to the reaction with ozone implemented in the MCM that is not applicable as discussed above. In addition, the reaction rate constant of the reaction of  $\text{ISOPCNO}_3$  with OH (Reaction R33) is up to 3 times faster in the MCM than in the Caltech and FZJ- $\text{NO}_3$  mechanisms (Table 2). The good agreement of the temporal behaviour of The signal of the VOCUS PTR-MS instrument at the mass of  $\text{ISOPCNO}_3$  confirms also the low reaction rate constants with OH determined experimentally in Lee et al. (2014b).

HPALD formation from the reaction of isoprene with  $\text{NO}_3$  is only implemented in the FZJ- $\text{NO}_3$  mechanism. Wolfe et al. (2012) investigated the photo-oxidation of a closely-related compound of HPALD to constrain photolysis rates and reaction rate constants in the reaction with OH (Reaction R36) and  $\text{O}_3$  (Reaction R37). A fast OH-reaction rate constant  $5.1 \times 10^{-11} \text{ s}^{-1} \text{ cm}^3$  was found. This value is implemented in the MCM, Caltech and FZJ- $\text{NO}_3$  mechanisms (Table 2). The reaction rate constant of HPALD with ozone was determined in Wolfe et al. (2012) to be  $1.2 \times 10^{-18} \text{ s}^{-1} \text{ cm}^3$  making the ozone reaction irrelevant for typical atmospheric conditions. There are no experimental values for the reaction rate constant of HPALD with  $\text{NO}_3$ . Structure activity relationship (SAR) described in Kerdouci et al. (2014) cannot be applied because the effect of a  $\text{COOH}$  substituent in the  $\beta$ -position of the  $\text{C}=\text{C}$  double at which  $\text{NO}_3$  adds is not considered. Omitting this substituent results in a reaction rate constant similar to the value in the MCM, indicating that a  $\text{COOH}$  substituent further lowers the reaction rate constant.

In the MCM, a fast reaction rate constant of HPALD with ozone (Reaction R37) is implemented, which would lead to a short chemical lifetime of 4.6 h for conditions of the experiment in this work (100 ppbv  $\text{O}_3$ ). In addition, the MCM assumes that HPALD reacts with  $\text{NO}_3$  (Reaction R38) with a fast reaction rate constant of  $1.2 \times 10^{-14} \text{ s}^{-1} \text{ cm}^3$ , which would lead to a significant loss of HPALD in the last part of the experiment on 13 August 2018 (Experiment #4), when  $\text{NO}_3$  mixing ratios were up to several 100 pptv. These assumptions about the reaction rate constants of HPALD with  $\text{O}_3$  and  $\text{NO}_3$  are . This is inconsistent with the observed temporal behaviour of the signal at the mass of HPALD observed by the VOCUS PTR-MS instrument, which is explained by the loss of HPALD by only its reaction with OH (Fig. 5, Panel (c)). In the experiments on 09 August 2018 (Experiment #1), when OH reactions were suppressed by the presence of the OH scavenger, the temporal behaviour of the HPALD signal is fully consistent with only the loss due to dilution (Fig. 4, Panel (c)).

The reaction rate constant of HPALD with ozone was experimentally determined in Wolfe et al., (2012) to be  $1.2 \times 10^{-18} \text{ s}^{-1} \text{ cm}^3$  making the ozone reaction irrelevant for typical atmospheric conditions. Results in the experiments in this work confirm this low value. The temporal behaviour of HPALD implicates that also the reaction of HPALD with  $\text{NO}_3$  does not significantly contribute to its chemical loss for typical night-time conditions. There are no experimental values for the reaction rate constant of HPALD with  $\text{NO}_3$ . Structure activity relationship (SAR) described in Kerdouci et al., (2014) cannot be applied because the effect of a  $\text{COOH}$  substituent in the  $\beta$ -position of the  $\text{C}=\text{C}$  double at which  $\text{NO}_3$  adds is not considered. Omitting this substituent results in a reaction rate constant similar to the value in the MCM, indicating that a  $\text{COOH}$  substituent further lowers the reaction rate constant.

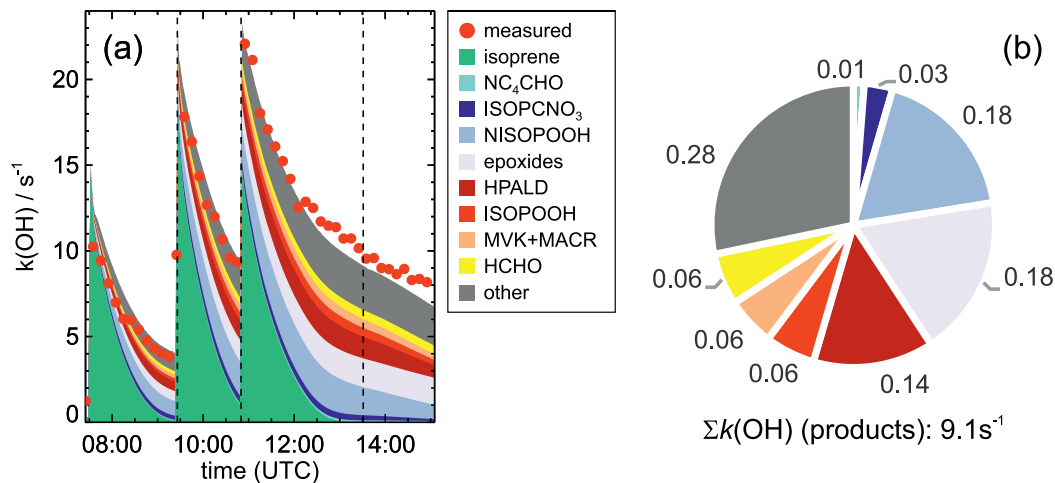

The further oxidation of epoxides produced from ring-closure reactions of nitrate alkoxy radicals calculated in Vereecken et al. (2021) have not been investigated so far. The temporal behaviour of signals measured by the VOCUS PTR-MS instrument suggests that their loss rate can be explained by only the dilution rate in the experiments indicating that chemical loss was not significant even in the presence of several 100 pptv  $\text{NO}_3$ , 100 ppbv  $\text{O}_3$  and presumably several  $10^5$  OH in the last period of the experiment on 13 August 2018 (Experiment #4) (Fig. 5, Panel (j)). An upper limit value of the reaction rate constant of the reaction of epoxides with OH of  $1.2 \times 10^{-11} \text{ s}^{-1} \text{ cm}^3$  ( $T = 298 \text{ K}$ ) can be assumed similar to the value found for epoxides produced from the reaction of OH reaction of hydroperoxides derived from isoprene (Bates et al., 2014) making chemical loss a minor loss pathway for typical conditions during night-time.

In the presence of aerosol surface, epoxides could be lost by particle uptake, but this was not relevant in the experiments analysed in this work due to the absence of seed aerosol. Loss to the Teflon surface of the chamber was not significant as demonstrated by the consistency of the loss rate with the dilution rate in the experiments.

## 5.8 OH and $\text{NO}_3$ reactivity from products

Overall, night-time oxidation of products from the reaction of isoprene with  $\text{NO}_3$  appear to be of minor importance. This is further supported by measurements of total OH and  $\text{NO}_3$  reactivity in the experiments in this work. In Figure 9, measured OH reactivity from organic compounds (Section 2.1) is compared to values calculated from modelled concentrations of products for the experiment on 13 August 2013 (Experiment #4), when the total consumption of isoprene by  $\text{NO}_3$  was highest. Reaction rate constants for the reactions of organic compounds with OH are applied from the FZJ- $\text{NO}_3$  mechanism.

OH reactivity is dominated by isoprene right after each injection (Fig. 9). After isoprene has reacted away, OH reactivity is only approximately 30 % of the initial reactivity demonstrating the much lower reactivity from products than from isoprene. The major organic nitrate and epoxides produced from the reaction of  $\text{NO}_3$  with isoprene explain approximately 50 % of the total reactivity of organic products. Hydroperoxy aldehydes (HPALD), which are partly also produced from the OH oxidation of isoprene, contribute approximately 15 % to the OH reactivity from products. A similar contribution is obtained from compounds that are formed from the oxidation of isoprene by OH and  $\text{O}_3$ , ISOPOOH, HCHO, MVK and MACR. At the end of the experiment, 25 % of the total reactivity is due to a high number of organic compounds that are produced from minor reaction pathways or secondary oxidation.

**Figure 9.** Comparison of measured OH reactivity from organic compounds and OH reactivity (left panel) calculated from concentrations of organic compounds modelled applying the FZJ-NO<sub>3</sub> chemical mechanism for the experiment on 13 August 2018 (Experiment #4). The reactivity from hydroperoxide compounds (NISOPOOH, ISOPOOH) is partly invisible for the LP-LIF instrument, because these species produce OH radicals after reacting with it. The OH yield is rather uncertain, but is expected to be less than 10 % for example in the Caltech mechanism. In addition, the relative distribution of OH reactivity from organic products is shown (right panel). OH reactivity from organic compounds is derived by subtracting the reactivity from NO<sub>2</sub> and O<sub>3</sub> calculated from measured concentrations from the measured total OH reactivity. “Other” compounds include a high number of organic compounds that are produced in the reaction of isoprene with OH, O<sub>3</sub> and NO<sub>3</sub> and for which loss by the reaction with OH is implemented in the FZJ-NO<sub>3</sub> mechanism. Dashed vertical lines indicate times, when isoprene, NO<sub>2</sub> and O<sub>3</sub> were re-injected. The last injection only included only NO<sub>2</sub> and O<sub>3</sub>.

700 The good agreement in the temporal behaviour of the observed and calculated OH reactivity is consistent with the low loss rate of products due to further oxidation reactions. In addition, measured OH reactivity values are consistent with OH reaction rate constants implemented in the FZJ-NO<sub>3</sub> mechanism, so that further OH oxidation of products is small for night-time conditions, when OH concentrations are typically maximum a few 10<sup>5</sup> cm<sup>3</sup> (Stone et al., 2012, 2014; Lu et al., 2014; Tan et al., 2017).

705 OH oxidation of nitrate hydroperoxides is most important due to their fast reaction rate constant and their high concentrations for typical night-time conditions, when HO<sub>2</sub> + RO<sub>2</sub> reactions can dominate the loss of RO<sub>2</sub>. However, part of the reactivity from hydroperoxides is invisible for the OH reactivity instrument, because OH is partly produced in their reactions with OH. Approximately 90 % of the reactivity is detected assuming an OH yield of 10 % as implemented in the Caltech and FZJ-NO<sub>3</sub> mechanisms. In contrast, an OH yield of 100 % is assumed for NISOPOOH in the MCM, which is likely too high as formation of epoxide products is expected to be a major reaction pathway.

710 OH oxidation of HPALD produced from unimolecular reactions of nitrate RO<sub>2</sub> can be significant because of the fast reaction of HPALD with OH.

In contrast the absolute values of OH reactivity as well as its temporal behaviour calculated from model calculations using the MCM with high OH reaction rate constants and high yields of NISOPOOH and NC<sub>4</sub>CHO leads to results that are inconsistent with the observed OH reactivity (Fig. A12). This confirms that the MCM does not reproduce the product distribution and loss rates of products.

Dewald et al. (2020) discussed the NO<sub>3</sub> reactivity measured in the experiments also investigated in this work. Consistent with conclusions above that the chemical loss of products by NO<sub>3</sub> was not relevant, the authors found that the NO<sub>3</sub> reactivity could be fully explained by the reactivity from isoprene and propene in these experiments. This confirms that loss of organic products from the reaction of isoprene with NO<sub>3</sub> due to further NO<sub>3</sub> oxidation is small compared to the dilution rate in the chamber experiments.

## 6 Comparison to previous experiments

The high yield of MVK and MACR from the decomposition of  $\beta$ -RO radicals in the Caltech mechanism was derived from chamber experiments in Schwantes et al. (2015). In their experiments, 54 to 74 % of the nitrate RO<sub>2</sub> reacted with HO<sub>2</sub>, so that the majority of alkoxy radicals was formed from this reaction. MVK and MACR concentrations, however, were only measured in 2 experiments in Schwantes et al. (2015), one of which was used to determine the MVK and MACR yields from the reaction of HO<sub>2</sub> + RO<sub>2</sub>. The overall yield of the sum of MVK and MACR was relatively low with a value of approximately 15 %. In order to determine the yield of MVK and MACR from the decomposition of alkoxy radicals from the RO<sub>2</sub> + HO<sub>2</sub> reactions, production from the isoprene oxidation by OH and O<sub>3</sub> and from the potential decomposition of alkoxy radicals produced from other reaction channels needed to be subtracted. The authors used model calculations to estimate the actual OH concentration. Uncertainties in this calculations may explain the high MVK and MACR yield in Schwantes et al. (2015).

MVK and MACR concentrations were also measured in an experiment in the SAPHIR chamber reported by Rollins et al. (2009), in which low reactant concentrations were present as in this work (10 ppbv isoprene, 20 to 30 ppbv NO<sub>2</sub>, 40 to 60 ppbv O<sub>3</sub>). According to model calculations in Rollins et al. (2009) using the MCM 3.2, the fate of nitrate RO<sub>2</sub> radicals from isoprene with NO<sub>3</sub> was dominated by their reactions with HO<sub>2</sub>. Measured MVK and MACR concentrations were consistent with the production of MVK and MACR mainly from the ozonolysis of isoprene. Therefore, this result supports that MVK and MACR are not produced from the decomposition of alkoxy radicals from  $\beta$ -RO<sub>2</sub> radicals. [This is further supported by other experiments investigating the reaction of isoprene with NO<sub>3</sub> at high reactant concentrations \(Barnes et al., 1990; Kwok et al., 1996; Perring et al., 2009\) and also](#) in chamber experiments of Kwan et al. (2012). ~~the fate of nitrate RO<sub>2</sub> was dominated by reactions with other RO<sub>2</sub> and with NO<sub>3</sub>, both of which also produce nitrate alkoxy radicals. The total yield for MVK and MACR determined in these experiments was 6 %. The authors state that all measured MVK and MACR could be explained by production from OH reactions because no ozone was present. The low yield of MVK and MACR appears to be inconsistent with the production of MVK and MACR from the decomposition of alkoxy radicals from  $\beta$ -RO<sub>2</sub> radicals as proposed in Schwantes et al. 2015).~~ This is further supported by other experiments investigating the reaction of isoprene with NO<sub>3</sub> at high

745 reactant concentrations (Barnes et al., 1990; Kwok et al., 1996; Perring et al., 2009), in all of which the yield of MVK and  
MACR was maximum in the range of a few percent.

Similar to the experiments in this work, products that have the sum formulas of nitrate epoxide products expected to be  
formed in the FZJ-NO<sub>3</sub> mechanism were observed in the experiments in Kwan et al. (2012) and Schwantes et al. (2015): (1)  
C<sub>5</sub>H<sub>9</sub>NO<sub>5</sub> compounds, which appear at the same mass as NISOPOOH, (2) C<sub>5</sub>H<sub>7</sub>NO<sub>5</sub> compounds from epoxy-RO<sub>2</sub> + RO<sub>2</sub>  
750 reactions, (3) C<sub>5</sub>H<sub>9</sub>NO<sub>6</sub> compounds from epoxy-RO<sub>2</sub> + HO<sub>2</sub> reactions.

In Kwan et al. (2012) and Schwantes et al. (2015) it is suggested that the product with the sum formula C<sub>5</sub>H<sub>9</sub>NO<sub>6</sub> is  
a hydroxy hydroperoxy nitrate and that the product with the sum formula C<sub>5</sub>H<sub>7</sub>NO<sub>5</sub> is a hydroxy carbonyl nitrate. Both  
compounds are suggested to be products from a 1,5-H-shift reaction of  $\delta$  nitrate alkoxy radicals from the bimolecular reactions  
of  $\delta$ -RO<sub>2</sub> radicals. The authors could not estimate a reaction rate constant for the 1,5-H-shift reaction from their experiments.  
755 Vereecken et al. (2021) calculated a reaction rate of  $2.2 \times 10^6 \text{ s}^{-1}$  ( $T = 298 \text{ K}$ ), which makes the 1,5-H-shift reaction too low to  
compete with the ring-closure reaction forming epoxy alkyl radicals ( $1.2 \times 10^8 \text{ s}^{-1}$ ,  $T = 298 \text{ K}$ ) and subsequent O<sub>2</sub> addition.  
It is worth noting that compounds suggested by Kwan et al. (2012) and Schwantes et al. (2015) would only be produced from  
nitrate  $\delta$ -RO<sub>2</sub> radicals that have small yields, whereas the nitrate epoxy products in the FZJ-NO<sub>3</sub> mechanism are also produced  
from the most abundant nitrate  $\beta$ -RO<sub>2</sub> radicals. This may also explain why compounds with these sum formulas were clearly  
760 detected in the experiments in all studies.

In the experiments in Kwan et al. (2012) and Schwantes et al. (2015), a C<sub>5</sub>H<sub>8</sub>O<sub>3</sub> compound without a nitrate functional  
group was observed, which is consistent with observations in this work. Because HPALD appears at the same mass and  
HPALD is also produced from OH oxidation, the authors concluded that C<sub>5</sub>H<sub>8</sub>O<sub>3</sub> is a product from the reaction of isoprene  
with OH. Nevertheless, their observations of C<sub>5</sub>H<sub>8</sub>O<sub>3</sub> compounds could also be partly due to the production of epoxy species  
765 from the oxidation of isoprene by NO<sub>3</sub> as described in the FZJ-NO<sub>3</sub> mechanism.

The other product without a nitrate group that is produced from the ring-closure pathway of nitrate alkoxy radicals in the  
FZJ-NO<sub>3</sub> mechanism, C<sub>5</sub>H<sub>8</sub>O<sub>4</sub>, was not observed in the experiments in Kwan et al. (2012) and Schwantes et al. (2015). The  
reason could be that the chemical lifetime of RO<sub>2</sub> radicals was too short in the experiments in Kwan et al. (2012), in which  
high concentrations of reactants were present, so that the 1,6-H-shift reaction of the epoxy-RO<sub>2</sub> radical producing the C<sub>5</sub>H<sub>8</sub>O<sub>4</sub>  
770 compound could not compete with bimolecular reactions. Similarly, RO<sub>2</sub> reactions with HO<sub>2</sub> were favoured in the experiments  
in Schwantes et al. (2015), so that the 1,6-H reaction may have not been competitive.

Interestingly, similar to the experiments in this work, no organic nitrate with the sum formula C<sub>4</sub>H<sub>5</sub>NO<sub>4</sub> that is expected to  
be formed from the ring-closure reactions of nitrate alkoxy radicals (Fig. 6) was observed in the experiments in Kwan et al.  
(2012) and Schwantes et al. (2015). This further suggests that there is no significant production of this compound.

775 NISOPOOH has been detected by mass spectrometer instruments in previous chamber studies by Ng et al. (2008), Kwan  
et al. (2012) and Schwantes et al. (2015). Similar to this work, the instruments were not calibrated for NISOPOOH, but the  
sensitivity of the instrument was calibrated for nitrate alcohols (ISOPCNO<sub>3</sub>). The sensitivity for other organic nitrates such  
as NISOPOOH was estimated from calculations of the dipole moment and polarisability (Ng et al., 2008; Kwan et al., 2012;  
Schwantes et al., 2015).

780 In the experiments of Schwantes et al. (2015), HO<sub>2</sub> concentrations were enhanced. NISOPOOH yields were between 0.32 and 0.41, when 54 and 76 % of the nitrate RO<sub>2</sub> were calculated to react with HO<sub>2</sub>. The authors calculated that these yields are consistent with a 50 % branching ratio of the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> (Reaction R2) to form alkoxy radicals. An uncertainty of ±20 % of the measured NISOPOOH concentration is stated. The uncertainty of the alkoxy radical yield, however, could be higher because the calculation also requires the knowledge of the fraction of isoprene that reacted with NO<sub>3</sub> and the fraction of RO<sub>2</sub> that reacted with HO<sub>2</sub>, both of which are uncertain because NO<sub>3</sub> and HO<sub>2</sub> concentrations were not measured. Therefore, a NISOPOOH yield of the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> higher than 50 % may also be consistent with the experimental results in Schwantes et al. (2015).

Ng et al. (2008) quantified NISOPOOH concentrations in their chamber experiment, which was performed at high concentrations of reactants (800 ppbv isoprene, 120 ppbv N<sub>2</sub>O<sub>5</sub>). They determined that 50 % of the reacted isoprene resulted in the formation of NISOPOOH, but the fraction of nitrate RO<sub>2</sub> that reacted with HO<sub>2</sub> could not be determined to calculate yields from specific reactions. Therefore, their experiments cannot be used to derive information about potential alkoxy radical formation from the reaction of RO<sub>2</sub> with HO<sub>2</sub>. HO<sub>2</sub> concentrations in experiments in Kwan et al. (2012) were presumably small because high reactant concentrations were used. This explains the relatively small overall NISOPOOH formation of 10 % from the reaction of isoprene with NO<sub>3</sub>.

795 Kwan et al. (2012) assumed that specific C<sub>5</sub> organic compounds (HPALD, ISOPOOH, C<sub>5</sub> hydroxy carbonyl C<sub>5</sub>H<sub>8</sub>O<sub>2</sub>) and MVK and MACR, all of which were quantified in their chamber experiments, were exclusively formed from OH radicals that are formed as co-product of alkoxy radicals. In this case, the yield of nitrate alkoxy radical formation competing with the formation of NISOPOOH in the reaction of nitrate RO<sub>2</sub> with HO<sub>2</sub> is 38 to 58 %. Although the experiments were performed in the absence of ozone, so that OH was not produced by ozonolysis reactions, this approach gives only an upper limit of the yield because OH as well as some of the organic products may not have been exclusively produced by this assigned reaction pathway. For example, HPALD can also be produced from the oxidation of isoprene by NO<sub>3</sub> from 1,6-H reactions of nitrate RO<sub>2</sub> (Vereecken et al. (2021), Fig. 3, Section 5.6).

HPALD was also observed in chamber experiments in Kwan et al. (2012) and Schwantes et al. (2015). The authors attributed the observations to the OH oxidation of isoprene, but their observations could also indicate HPALD formation from nitrate RO<sub>2</sub>. Specifically in the experiments in Schwantes et al. (2015) the total loss rate of nitrate RO<sub>2</sub> were calculated to be in the range of 0.03 to 0.13 s<sup>-1</sup>, so that 1,6-H shift reactions with rates 0.02 and 0.05 s<sup>-1</sup> (*T* = 298 K) calculated in Vereecken et al. (2021) can compete with bimolecular loss reactions.

Tsiligiannis et al. (2022) showed that a C<sub>4</sub> nitrate with the sum formula C<sub>4</sub>H<sub>7</sub>NO<sub>5</sub> was observed by the I<sup>-</sup> CIMS instrument in the experiments in this work and also in several field campaigns, in which isoprene oxidation by NO<sub>3</sub> was important. This compound was also detected in the chamber experiments by the Br<sup>-</sup> CIMS instrument (Wu et al., 2021), but signals observed by the VOCUS PTR-MS instrument at the respective mass were below the limit of detection. Yields of C<sub>4</sub>H<sub>7</sub>NO<sub>5</sub> determined in previous chamber experiments in Schwantes et al. (2015) were below 1 %.

Mayhew et al. (2022) applied the three chemical models investigated in this work to field observations in an urban location in Beijing in June 2017. Differences between model results were similar as calculated in this work. The comparison of modelled

815 data with measurements, however, is more complex for field experiments than for chamber experiments, because trace gas concentrations are not only impacted by chemical process, but also by ~~transportation~~ [transport](#). In the field campaign in Beijing, organic nitrates from isoprene were detected by an I<sup>-</sup> CIMS instrument. The instrument was not specifically calibrated for those compounds, but the same sensitivity as for isoprene epoxides (IEPOX) was assumed. In general, concentrations of measured isoprene-derived organic nitrates were lower than calculations for all three models in the night (Mayhew et al., 820 2022). As pointed out by the authors, the potential loss of epoxide nitrates due to particle uptake could not entirely explain the model-measurement discrepancies.

Overall, results in the experiments in this work appear to be consistent with results in previous experiments supporting the validity of the FZJ-NO<sub>3</sub> mechanism.

## 7 Conclusions

825 The oxidation of isoprene by the nitrate radical, NO<sub>3</sub>, was investigated in chamber experiments covering different atmospherically relevant chemical regimes. The chemical lifetimes of RO<sub>2</sub> radicals formed in the initial reaction of isoprene with NO<sub>3</sub> were in the range of atmospheric lifetimes with values between 30 s and several minutes due to atmospheric concentrations of reaction partners (RO<sub>2</sub>, HO<sub>2</sub> and NO<sub>3</sub>). In one experiment, RO<sub>2</sub> + HO<sub>2</sub> reactions were favoured by producing HO<sub>2</sub> and OH radicals in the ozonolysis of propene in the presence of excess CO for the conversion of OH to HO<sub>2</sub> radicals. Results from 830 calculations of three near-explicit chemical models (MCM, Caltech, FZJ-NO<sub>3</sub>) were compared to measurements.

A critical difference between the three chemical mechanisms is the fate of nitrate alkoxy radicals formed in the radical reaction chain which mainly undergo ring-closure reactions in the FZJ-NO<sub>3</sub> mechanisms, whereas decomposition to MVK and MACR is not competitive. Measured concentrations of MVK and MACR in the experiments in this work are consistent with their production from only O<sub>3</sub> and OH reactions with isoprene in agreement with results in previous chamber experiments 835 in Rollins et al. (2009) and Kwan et al. (2012).

Mass signals of most of the organic products expected from the ring-closure reactions of the nitrate alkoxy radicals were detected by the VOCUS PTR-MS instrument demonstrating that the reactions calculated in Vereecken et al. (2021) may indeed be relevant pathways. Signals at the same masses were observed by chemical ionization mass spectrometer in previous chamber experiments (Kwan et al., 2012; Schwantes et al., 2015). One product of the ring-closure reaction of nitrate alkoxy radicals, 840 which has the sum formula C<sub>4</sub>H<sub>5</sub>NO<sub>4</sub>, calculated by Vereecken et al. (2021) to be produced could not be detected by the VOCUS PTR-MS instrument in the experiments in this work and has also not been observed in experiments in Kwan et al. (2012) and Schwantes et al. (2015). Therefore, the reaction pathway leading to this product is likely less important than implemented in the FZJ-NO<sub>3</sub> mechanism, but this is within the uncertainty of the calculations in Vereecken et al. (2021).

The formation of hydroperoxy aldehydes (HPALD) from 1,6-H-shift reactions of nitrate Z-δ-RO<sub>2</sub> isomers is only implemented in the FZJ-NO<sub>3</sub> mechanism (Vereecken et al., 2021) ~~analogous to RO<sub>2</sub> from the reaction of isoprene with OH (Peeters et al., 2014). The calculated isomerization reaction rate constant would lead to a HPALD yield between 10 and 30 % for conditions of the experiments in this work. High yields of total organic nitrates of around 100 % were determined in~~ 845

Brownwood et al. (2021) for the same experiments, but the lowest total organic nitrate yield of  $(94 \pm 20)\%$  was found in the experiment with the longest RO<sub>2</sub> lifetime due to bimolecular reactions (10 August 2018, Experiment #2) consistent with the production from unimolecular H-shift reactions, which were most competitive in this reaction. Although total organic nitrate yields determined in Brownwood et al. (2021) have a large uncertainty of up to 25 %, the overall high values hint that reaction rate constants of 1,6-H-shift reactions are lower than calculated by Vereecken et al. (2021), which have an uncertainty of at least a factor of 2.

A clear signal at the mass of HPALD was detected by the VOCUS PTR-MS instrument in all experiments in this work. This was also the case in the experiment, when an OH scavenger was present (09 August 2018, Experiment #1), demonstrating that HPALD was formed from the reaction of isoprene with NO<sub>3</sub> and that the HPALD was not only formed from the small fraction of isoprene reacting with OH radicals and ozone in the experiments. This is also consistent with previous chamber experiments by Kwan et al. (2012) and Schwantes et al. (2015), in which HPALD formation was observed but attributed to the production from the reaction of OH with isoprene. Measurements of total organic nitrates in Brownwood et al. (2021) for the same experiments, however, give high yields of organic nitrates hinting that reaction rate constants of 1,6-H-shift reactions might be lower than calculated by Vereecken et al. (2021).

In the night, the fate of nitrate-RO<sub>2</sub> includes bimolecular reactions with HO<sub>2</sub> radicals, other RO<sub>2</sub> radicals and NO<sub>3</sub> radicals, all of which are significant for atmospheric conditions. This is in particular true if the reaction rate constants for the RO<sub>2</sub> + RO<sub>2</sub> reactions of the most abundant nitrate-RO<sub>2</sub> isomer from isoprene are rather low compared to other RO<sub>2</sub> radicals as concluded in Schwantes et al. (2015), and if the reaction rate constants for the nitrate-RO<sub>2</sub> + NO<sub>3</sub> reactions are a factor of 2 higher than previously assumed as concluded in Dewald et al. (2020). Nevertheless, the reaction with HO<sub>2</sub> is the dominant loss reaction of nitrate-RO<sub>2</sub> in the experiments in this work with a contribution of approximately 50 % to the total loss rate. This is also confirmed by the high signal in the mass spectrum of the VOCUS PTR-MS instrument at the mass of the nitrate hydroperoxides (NISOPOOH) produced from this reaction. The large model-measurement discrepancy of HO<sub>2</sub> concentrations hints that HO<sub>2</sub> production in the NO<sub>3</sub>-isoprene chemistry is still not well described by the FZJ-NO3 model (Vereecken et al., 2021). For atmospheric concentrations of radicals (Lu et al., 2014; Tan et al., 2017), it can also be expected that the loss of nitrate-RO<sub>2</sub> in the reaction with HO<sub>2</sub> has a large contribution to their overall loss.

None of the current chemical models can predict C<sub>4</sub>H<sub>7</sub>NO<sub>5</sub> yields estimated in Tsiligiannis et al. (2022). They could be formed from further oxidation of first-generation C<sub>5</sub> nitrates by OH (Wennberg et al., 2018), but the expected yields in the experiments in this work are small due to the low OH concentrations. In addition, C<sub>4</sub>H<sub>7</sub>NO<sub>5</sub> compounds were also detected in the experiment, when OH concentrations were suppressed by an OH scavenger demonstrating that they are also formed from other reaction pathways. Further investigations are required to quantify the importance of C<sub>4</sub>H<sub>7</sub>NO<sub>5</sub> in the NO<sub>3</sub> isoprene oxidation scheme.

In the nocturnal atmosphere, isoprene is not only oxidized by NO<sub>3</sub>, but also a significant fraction reacts with ozone depending on the availability of nitrogen oxides and ozone (Edwards et al., 2017). It is worth noting that due to the fast reaction rate constant of isoprene with OH, reaction with OH could also contribute to the overall loss of isoprene in the night. Part of the OH radicals can be produced in the subsequent reaction chain of the NO<sub>3</sub> oxidation of isoprene (Kwan et al., 2012; Vereecken

et al., 2021). In the Caltech and FZJ-NO<sub>3</sub> mechanisms, a large fraction is produced from the reaction of nitrate-RO<sub>2</sub> with HO<sub>2</sub>. This again emphasizes the need to quantify the branching ratio of the alkoxy radical formation of this reaction pathway.

885 Fast unimolecular reactions of RO<sub>2</sub> from the reaction of isoprene with OH (Peeters et al., 2014) can further gain in importance during the night compared to daytime (Novelli et al., 2020) because of the long chemical lifetime of RO<sub>2</sub> radicals in the range of minutes in the absence of NO, which is often the most important reaction partner for RO<sub>2</sub> radicals during the day. Therefore, the yield of HPALD produced from the OH reactions with isoprene can be high in the night despite low OH concentrations. HPALD photolysis could then contribute to OH production on the next day (Wolfe et al., 2012).

890 Only a small fraction of first-generation organic products are further oxidized for atmospheric night-time conditions **but are most likely chemically processed by photolysis and reaction with OH on the next day**. Reaction rate constants of the reactions of nitrate-carbonyl, nitrate-alcohol and epoxides with NO<sub>3</sub> and O<sub>3</sub> give chemical lifetimes which are longer than a night for typical concentrations of NO<sub>3</sub> and O<sub>3</sub>. Also HPALD does not react efficiently with NO<sub>3</sub> and O<sub>3</sub>. Reaction rate constants of these reactions as implemented in chemical models such as the MCM, which lead to short chemical lifetimes in the range of

895 hours, need to be revised.

~~Depending on the availability of OH radicals, first-generation products can partly be oxidized by OH in the night. Because OH concentrations are often very low, however, the majority of these compounds are most likely chemically processed by photolysis and reaction with OH on the next day. Oxidation of isoprene by the nitrate radical is most important in the residual layer, in which anthropogenic emissions including nitrogen oxides and biogenic emissions are present (Brown et al., 2009; Edwards et al., 2017). Oxidation products are therefore expected to be first further oxidized by OH radicals after sunrise within the residual layer, before the residual layer mixes with the convective boundary layer.~~

Overall, results from experiments in this work demonstrate that the FZJ-NO<sub>3</sub> mechanism for isoprene (Vereecken et al., 2021) **is valid and gives more complete and accurate description of the nocturnal oxidation of isoprene than** previous chemical mechanisms ~~are incomplete to describe the nocturnal oxidation of isoprene~~. New reaction pathways in Vereecken et al. (2021)

905 can have consequences for the nocturnal loss of reactive nitrogen and formation of secondary organic aerosol. However, large uncertainties still exist in the exact distribution of the different RO<sub>2</sub> isomers formed in the reaction of isoprene with NO<sub>3</sub> and their fate. Specifically, the yield of alkoxy radicals from the reaction of nitrate-RO<sub>2</sub> with HO<sub>2</sub> is uncertain. Calibration of instruments detecting organic nitrate products for specific reaction pathways is urgently needed in future experiments in order to determine the absolute importance of these reaction pathways for atmospheric conditions.

910 *Data availability.* Data from the experiments in the SAPHIR chamber used in this work are available on the EUROCHAMP database webpage (<https://data.eurochamp.org>). Experiment on 09 August 2018 (Experiment #1): Fuchs et al. (2018a), experiment on 10 August 2018 (Experiment #2): Fuchs et al. (2018b), experiment on 12 August 2018 (Experiment #3): Fuchs et al. (2018c), experiment on 13 August 2018 (Experiment #4): Fuchs et al. (2018d).

*Author contributions.* PC and HF wrote the manuscript, analysed the data and did model calculations of the experiments. SB, MH, JF, AN  
915 and HF designed and executed the experiments. LV provided insights into the chemical mechanisms. LH, TH, SK, TM, RT, DR, FR, RW,  
BB, JF, ET, JC, PD, NS, JF, JS, FB were responsible for measurements used in this work. All authors intensively discussed the manuscript  
and thereby contributed to the writing.

*Competing interests.* The authors declare no competing interests.

*Financial support.* This research has been supported by the European Research Council (ERC), (SARLEP grant agreement no. 681529),  
920 European Commission (EC) under the European Union's Horizon 2020 research and innovation program, (Eurochamp 2020 grant agree-  
ment no. 730997 and FORCeS grant agreement no. 821205), Vetenskapsrådet (VR, grant nos. 2014-05332 and 2018-04430), and Svenska  
Forskningsrådet Formas (grant nos. 2015-1537 and 2019-586).

**Table A1.** Organic products expected to be produced from the oxidation of isoprene in this work and the ion mass (m/z) at which they are detected by the mass spectrometry instruments, which measured in the experiments. Evaluation of the ion mass signals of the Br<sup>-</sup>-CIMS instrument includes both major isotopes of Br. Only the chemical structure of one isomer of the same compound is shown.

Organic product	Sum formula	molecular weight	ion mass (m/z) VOCUS PTR-MS	ion mass (m/z) Br <sup>-</sup> -CIMS	ion mass (m/z) I <sup>-</sup> -CIMS
	C <sub>5</sub> H <sub>8</sub> O <sub>3</sub>	116	117	195 / 197	370
					
	C <sub>4</sub> H <sub>5</sub> NO <sub>4</sub>	131	132	210 / 212	385
	C <sub>5</sub> H <sub>8</sub> O <sub>4</sub>	132	133	211 / 213	386
	C <sub>5</sub> H <sub>7</sub> NO <sub>4</sub>	145	146	224 / 226	399
	C <sub>5</sub> H <sub>9</sub> NO <sub>4</sub>	147	148	226 / 228	401
	C <sub>5</sub> H <sub>7</sub> NO <sub>5</sub>	161	162	240 / 242	415
	C <sub>5</sub> H <sub>9</sub> NO <sub>4</sub>	163	164	242 / 244	417
					
	C <sub>5</sub> H <sub>9</sub> NO <sub>5</sub>	179	180	258 / 260	433

**Figure A1.** Measurements of radical and trace gas concentrations and OH and NO<sub>3</sub> reactivity in the experiment on 10 August 2018 (Experiment #2) investigating the oxidation of isoprene by NO<sub>3</sub>. NO<sub>3</sub> reactivity does not include reactivity from organic radicals and NO<sub>2</sub>. OH and NO<sub>3</sub> reactivity from isoprene is calculated from measured isoprene concentrations and reaction rate constants recommended in literature (Mellouki et al., 2021). Observed RO<sub>2</sub> radicals only include a fraction of the total RO<sub>2</sub> because the LIF instrument cannot detect all RO<sub>2</sub> radicals formed in the reaction of isoprene with NO<sub>3</sub> (Vereecken et al., 2021).

**Figure A2.** Measurements of radical and trace gas concentrations and OH and NO<sub>3</sub> reactivity in the experiment on 12 August 2018 (Experiment #3) investigating the oxidation of isoprene by NO<sub>3</sub>. NO<sub>3</sub> reactivity does not include reactivity from organic radicals and NO<sub>2</sub>. OH and NO<sub>3</sub> reactivity from isoprene is calculated from measured isoprene concentrations and reaction rate constants recommended in literature (Mellouki et al., 2021). Observed RO<sub>2</sub> radicals only include a fraction of the total RO<sub>2</sub> because the LIF instrument cannot detect all RO<sub>2</sub> radicals formed in the reaction of isoprene with NO<sub>3</sub> (Vereecken et al., 2021).

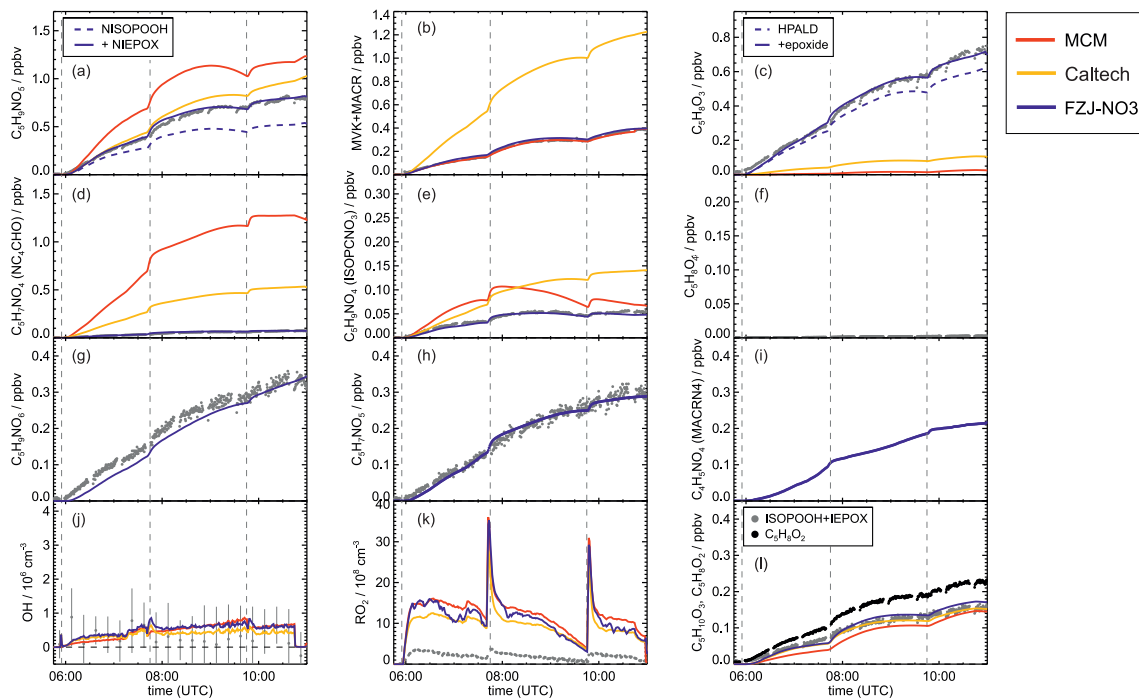

**Figure A3.** Relative distribution of loss rates of nitrate  $\text{RO}_2$  for the experiment on 10 August 2018 (Experiment #2) and on 12 August 2018 (Experiment #3). The total  $\text{RO}_2$  loss rate was  $0.005$  and  $0.008 \text{ s}^{-1}$  in the experiment on 10 August 2018 (Experiment #2) and 12 August 2018 (Experiment #3), respectively. Calculations of the loss rates of  $\text{RO}_2$  radicals in bimolecular reactions make use of measured  $\text{HO}_2$  and  $\text{NO}_3$  concentrations. Total  $\text{RO}_2$  concentrations and concentrations of speciated nitrate  $\text{RO}_2$  were taken from model calculations applying either the FZJ- $\text{NO}_3$ , Caltech or MCM mechanism. The chemical mechanisms differ with respect to the number of nitrate  $\text{RO}_2$  isomers that are considered, the type of  $\text{RO}_2$  loss reactions and products of loss reactions (Fig. 3 and 6). Therefore, the distributions of nitrate  $\text{RO}_2$  radicals and  $\text{RO}_2$  concentrations differ between the model runs.

**Figure A4.** Relative distribution of loss rates of nitrate  $\text{RO}_2$  for the experiment on 13 August 2018 (Experiment #3) if the FZJ- $\text{NO}_3$  mechanism is applied and  $\text{HO}_2$  is not constrained to measured values. Total  $\text{RO}_2$  concentrations and concentrations of speciated nitrate  $\text{RO}_2$  were taken from model calculations.

**Figure A5.** Comparison of results from model calculations applying the different isoprene  $\text{NO}_3$  chemistry mechanisms for the experiment on 10 August 2018 (Experiment #2). MVK, MACR, NISOPOOH, ISOPCNO<sub>3</sub> and NC<sub>4</sub>CHO are produced from all mechanisms, whereas the other compounds are only produced from either 1,6-H-shift reactions or ring-closure reactions of nitrate alkoxy radicals, which are only implemented in the FZJ-NO3 mechanism. Grey and black dots are measured values. Measured organic peroxy radical concentrations only include part of the total RO<sub>2</sub> because the LIF instrument cannot detect a fraction of nitrate RO<sub>2</sub> (Vereecken et al., 2021). Organic products were detected by the VOCUS PTR-MS instrument, which was only calibrated for MVK and MACR. All other traces are scaled to match best the results from the FZJ-NO3 mechanism.

**Figure A6.** Comparison of results from model calculations applying the different isoprene  $\text{NO}_3$  chemistry mechanisms for the experiment on 12 August 2018 (Experiment #3). MVK, MACR, NISOPOOH, ISOPCNO<sub>3</sub> and NC<sub>4</sub>CHO are produced from all mechanisms, whereas the other compounds are only produced from either 1,6-H-shift reactions or ring-closure reactions of nitrate alkoxy radicals, which are only implemented in the FZJ-NO3 mechanism. Grey and black dots are measured values. Measured organic peroxy radical concentrations only include part of the total RO<sub>2</sub> because the LIF instrument cannot detect a fraction of nitrate RO<sub>2</sub> (Vereecken et al., 2021). Organic products were detected by the VOCUS PTR-MS instrument, which was only calibrated for MVK and MACR. All other traces are scaled to match best the results from the FZJ-NO3 mechanism.

**Figure A7.** Comparison of reported signals from three mass spectrometer instruments applying different ionization methods (VOCUS PTR-MS,  $\text{Br}^-$ -CIMS,  $\text{I}^-$ -CIMS) measuring organic products in the experiment on 09 August 2018 (Experiment #1). All signals are scaled to match best the concentrations resulting from model calculations applying the FZJ-NO3 chemical mechanism.

**Figure A8.** Comparison of reported signals from three mass spectrometer instruments applying different ionization methods (VOCUS PTR-MS,  $\text{Br}^-$ -CIMS,  $\text{I}^-$ -CIMS) measuring organic products in the experiment on 10 August 2018 (Experiment #2). All signals are scaled to match best the concentrations resulting from model calculations applying the FZJ-NO3 chemical mechanism.

**Figure A9.** Comparison of reported signals from three mass spectrometer instruments applying different ionization methods (VOCUS PTR-MS,  $\text{Br}^-$ -CIMS,  $\text{I}^-$ -CIMS measuring organic products in the experiment on 12 August 2018 (Experiment #3). All signals are scaled to match best the concentrations resulting from model calculations applying the FZJ-NO3 chemical mechanism.

**Figure A10.** Comparison of reported signals from three mass spectrometer instruments applying different ionization methods (VOCUS PTR-MS,  $\text{Br}^-$ -CIMS,  $\text{I}^-$ -CIMS measuring organic products in the experiment on 13 August 2018 (Experiment #4). All signals are scaled to match best the concentrations resulting from model calculations applying the FZJ-NO3 chemical mechanism.

**Figure A11.** Ion mass signal of the VOCUS PTR-MS instrument scaled to the model results from the MCM, Caltech and FZJ-NO3 models in the experiment on 13 August 2018 (Experiment #4). Only species for which the instrument was not calibrated and which are produced in all models are shown.

**Figure A12.** Comparison of measured OH reactivity from organic compounds and OH reactivity calculated from concentrations of organic compounds modelled applying the MCM chemical mechanism. Up to 10 % of the reactivity from hydroperoxide compounds (NISOPOOH, ISOPOOH) is invisible for the LP-LIF instrument, because these species produce partly OH in their reaction with OH. The exact OH yield is uncertain. 100 % yield is assumed in the MCM. OH reactivity from organic compounds is derived by subtracting the reactivity from  $\text{NO}_2$  and  $\text{O}_3$  calculated from measured concentrations from the measured total OH reactivity. “Other” compounds include a high number of organic compounds that are produced in the reaction of isoprene with OH,  $\text{O}_3$  and  $\text{NO}_3$  and for which loss by the reaction with OH is implemented in the MCM mechanism.
