13 **Abstract**

14 While landscapes are broadly sculpted by tectonics and climate, on a catchment scale, the
15 density of bedrock fractures can influence hillslope denudation rates and dictate the location of
16 topographic highs and valleys. In this work, we used ¹⁰Be cosmogenic radionuclide analysis to
17 measure the denudation rates of bedrock, boulders, and soil, in three granitic landscapes with
18 different climates in Chile, with the hypothesis that high fracture density reduces grain size and
19 increases denudation rates. Denudation rates range from 10 to 15 m Myr⁻¹ for bedrock and
20 boulders and from 15 to 20 m Myr⁻¹ for soil in the humid and semi-arid climates, and are higher
21 in the mediterranean climate (~40-140 m Myr⁻¹), likely due to steeper slopes. We found that
22 hillslope bedrock and boulders erode more slowly than the surrounding soil in the diffusively-

eroding study sites. Furthermore, across a bedrock ridge in the humid site, bedrock denudation rates increase with fracture density. These findings are consistent with the observation that streams in our field sites follow the orientation of at least one major fault orientation. Our results suggest that tectonically-induced fractures and faults dictate landscape evolution through reducing grain size and thus enhancing differential denudation rates.

1 Introduction

Landscapes on earth are shaped by tectonic uplift and climate, which dictate erosional and weathering regimes over geologic timescales. When uplift and climate are held constant sufficiently long, fluvial landscapes reach a steady state, in which the slopes of hills and stream channels adjust so that denudation rates match tectonic uplift rates (e.g. Burbank et al., 1996; Kirby and Whipple, 2012). Variations in bedrock strength and the grain size of hillslope sediment, however, exert additional control on the morphology of hills and valleys (e.g. Attal et al., 2015; Glade et al., 2017). Initially, hillslope sediment size is set by lithology and the density of fractures, which are formed due to tectonic and topographic stresses (e.g. Molnar et al., 2007; Roy et al., 2016; St. Claire et al., 2015; Sklar et al., 2017). Near the earth surface, water, often carrying biotic acids, infiltrates bedrock fractures and promotes chemical weathering that further reduces sediment size and converts bedrock to regolith (Lebedeva and Brantley, 2017; Hayes et al., 2020). Therefore, long residence times of sediment in the weathering zone, being the consequence of slow erosion, may result in complete disintegration of bedrock and the formation of saprolite and soil, whereas rapid erosion and short residence times can lead to hillslope sediment size limited by fracture spacing (e.g. Sklar et al., 2017; Attal et al., 2015; Roda-Boluda et al., 2018; van Dongen et al., 2019).

46 Soil-mantled hillslopes are typically considered to be dominated by diffusive processes,
47 for which conceptual models and geomorphic transport laws are relatively well-established (e.g.,
48 Dietrich et al., 2003; Perron, 2011). However, these models generally assume uniform hillslope
49 material and do not account for the exhumation of larger boulders through the critical zone (we
50 refer to large hillslope sediment as boulders, but they could also be considered corestones or tors).
51 Neely et al. (2019) addressed erosion and soil transport on mixed bedrock and soil-covered
52 hillslopes using a nonlinear diffusion model, assuming the same denudation rate for bedrock and
53 soil. Often, however, bedrock and large boulders protrude above the surrounding soil, indicating
54 that they are eroding more slowly than the soil, and that denudation rates of boulders are lower
55 than soil transport rates (Oberlander, 1972; Bierman, 1994; Portenga and Bierman, 2011). Once
56 exposed, larger boulders require greater forces to be moved, which can be achieved by steepening
57 slopes (Granger et al., 2001; DiBiase et al., 2018; Neely and DiBiase, 2020), or by lengthening
58 residence until subaerial weathering has decreased their size sufficiently to be transported
59 downslope. During this prolonged residence time, boulders can shield hillslopes from erosion
60 (Glade et al., 2017), and stream channels from incision (Shobe et al., 2016). In terrain where
61 spatial gradients in bedrock fracture spacing result in spatial gradients of hillslope sediment size,
62 it is thus reasonable to expect that the resistance of surface boulders to weathering and transport
63 ought to retard erosion locally, resulting in spatially differential erosion. Moreover, because
64 smaller blocks are easier to move (Shobe et al., 2016), we would expect that rivers preferentially
65 incise in zones of intensely fractured rocks that align with the orientation of faults (Molnar et al.,
66 2007; Roy et al., 2016).

67 In this study, we examined the roles of fractures and hillslope boulders on landscape
68 evolution by quantifying bedrock, boulder, and soil denudation rates along the granitic Coastal
69 Cordillera of Chile, using *in situ* cosmogenic ^{10}Be . By developing a simple model to convert ^{10}Be

70 concentrations from boulders into soil and boulder denudation rates and by examining our field
 71 sites for signs of fracture control on landscape morphology, we tested the following hypotheses:
 72 a) on a hillslope, boulders affect differential erosion by eroding more slowly than the surrounding
 73 soil, and b) more highly fractured bedrock is more susceptible to erosion and stream incision than
 74 intact bedrock.

75 **2 Field sites**

76 The Chilean Coastal Cordillera, a series of batholiths in the forearc of the Andean
 77 subduction zone, lies along a marked climate gradient with humid conditions in the south and
 78 hyper-arid conditions in the north (Fig. 1). The Andean subduction zone, in which the Nazca
 79 Plate subducts under the South American Plate, has been active since at least Jurassic times (e.g.,
 80 Coira et al., 1982). In this study we investigated three field sites along the Coastal Cordillera from
 81 south to north: Nahuelbuta National Park, (NA), with a humid-temperate climate, La Campana
 82 National Park (LC), with a mediterranean climate, and Private Reserve Santa Gracia (SG), with a
 83 semi-arid climate (Fig. 1). All three sites are underlain by granitoid bedrock (Oeser et al., 2018),
 84 none show any signs of former glaciation, and all are located on protected land, away from major
 85 human influence, such as mines, dams, and large infrastructure. In all three sites, denudation rates
 86 from ^{10}Be cosmogenic radionuclide analysis have been reported by van Dongen et al. (2019)
 87 (catchment average rates), and Schaller et al. (2018) (soil pits).

88 NA is located on an uplifted, fault-bounded block (plateau), an unusually high part of the
 89 Coastal Cordillera with a mean elevation of ~1300 m above sea level. All of the measurements in
 90 this work are from the plateau (~9° mean slope). Tectonic uplift rates in NA increased from 0.03–
 91 0.04 to >0.2 mm year⁻¹ at 4±1.2 Ma (Glodny et al., 2008), a shift that is also recorded by
 92 knickpoints in streams that drain the plateau. ^{10}Be -derived denudation rates are around 30 m Myr⁻¹

¹ (Schaller et al., 2018; van Dongen et al., 2019). The main catchment in LC has a mean elevation of 1323 m with a mean slope of 23°, and regional uplift rates are estimated to be <0.1 mm yr⁻¹ (Melnick, 2016). Van Dongen et al. (2019) reported a catchment average denudation rate of ~200 m Myr⁻¹ for a sub-catchment in LC, and Schaller et al. (2018) reported soil denudation rates of 40-55 m Myr⁻¹. In SG, the mean elevation is 773 m above sea level, the mean slope is 17.2°, and uplift rates are <0.1 mm year⁻¹ (Melnick, 2016). Previously reported ¹⁰Be-derived denudation rates are ~9-16 m Myr⁻¹ (Schaller et al., 2018; van Dongen et al., 2019).

3 Methods

3.1 In situ ¹⁰Be analysis

3.1.1 Sample collection

We collected samples for cosmogenic ¹⁰Be analysis from bedrock, boulders, and soil to estimate denudation rates from our field sites, targeting hillslopes near previously-collected catchment average and soil pit samples from van Dongen et al (2019) and Schaller et al. (2020). Bedrock samples were taken from an area of up to ~20 m × 20 m (on ridge tops or hillslopes) and consist of an amalgamation of at least ten chips (~25 cm² and <2 cm thick), with which we aim to obtain representative mean values of denudation rates that are potentially variable due to episodic erosion by spalling rock chips (Small et al., 1997). Similarly, for boulder samples, one chip was taken from the top of each of at least ten similarly-sized boulders and amalgamated for an area of up to ~40 m × 40 m, depending on boulder abundance. We targeted boulders that appear to be in situ, based on the observation that they are tightly imbedded in the ground. In places with many various-sized boulders, we collected samples from different protrusion heights (~1-m tall boulders, ~0.5-m tall boulders, etc.). Each sampled boulder was measured along the a, b, and c

115 axes, and the protrusion height was noted (see Table 1). Topsoil samples were also collected by
 116 amalgamation in the area surrounding the sampled boulders.

117 In NA, we collected five bedrock samples from an area called “Piedra de Aguila” from
 118 outcrops with different fracture densities, and measured fracture spacing by stringing a measuring
 119 tape along the bedrock surface and measuring the distance between fractures that were at least 1
 120 mm wide (Fig. 2A and 2B). We further collected six boulder samples and three soil samples from
 121 the ridge and hillslope of “Cerro Anay” (Fig. 1 and 2C), an area called “Casa de Piedras”, and a
 122 hillslope near the soil pits that were sampled by Schaller et al. (2018). In LC and SG, we were not
 123 able to directly measure fracture density due to rarely exposed bedrock. In LC, we took one
 124 bedrock sample, two boulder samples and two soil samples from the ridge and slope of “Cerro
 125 Cabra” (Fig. 1 and 2D), and three boulder samples and three soil samples from the ridge, upper
 126 slope, and lower slope of “Cerro Guanaco” (Fig. 1 and 2F). In SG, we took four bulder samples
 127 and three soil samples from the ridge and slope of a hill we termed “Santa Gracia Hill,” which
 128 also hosts the soil pits of Schaller et al. (2018) (Fig. 1, 2H, and 2I).

129

130 **3.1.2 Analytical methods**

131 We dried, crushed, and sieved amalgamated bedrock and boulder samples for quartz
 132 mineral separation, and dried and sieved soils, each to 250-500 micrometer particle size, or to
 133 250-1000 micrometers if the 250-500 micrometer sample amount wasn’t sufficient. We used
 134 standard physical and chemical separation methods to isolate ~20 g of pure quartz from each
 135 sample. After spiking each sample with 150 µg of ^9Be carrier and dissolving the quartz in
 136 concentrated hydrofluoric acid, we extracted Be following protocols adapted from von
 137 Blanckenburg et al. (2004). $^{10}\text{Be}/^9\text{Be}_{(\text{carrier})}$ ratios were measured by accelerator mass
 138 spectrometry at the University of Cologne, Germany (Dewald et al., 2013). Sample ratios were

139 normalized to standards KN01-6-2 and KN01-5-3 with ratios of 5.35×10^{-13} and 6.320×10^{-12} ,
 140 respectively. Final ^{10}Be concentrations were corrected by process blanks with an average
 141 $\text{Be}^{10}/\text{Be}^9$ ratio of $(2.21 \pm 0.25) \times 10^{-14}$.

142 **3.1.3 Denudation rate calculations**

143 In order to calculate denudation rates from the measured ^{10}Be concentrations, we
 144 evaluated bedrock, boulder, and soil samples differently. Bedrock samples present the simplest
 145 case, in which we assumed steady state erosion and calculated bedrock denudation rates (ϵ_{br})
 146 using the CRONUS online calculator v2.3 (Balco et al., 2008). The steady state assumption is
 147 based on our amalgamated sampling, and follows the results of Small et al. (1997), who showed
 148 that an amalgamation of several individual bedrock samples is a reasonable approximation of the
 149 long-term average denudation rate in episodically eroding settings.

150 Boulder and soil samples require a more nuanced assessment. Boulders protrude above
 151 the ground surface, which implies that the lowering of the ground surface (i.e., the soil
 152 denudation rate, ϵ_s) is faster than the lowering of the boulder's surfaces (i.e., the boulder
 153 denudation rate, ϵ_b) (Fig. 3). Thus, even while they are buried and covered by soil, boulders are
 154 exposed to cosmic rays for a significant amount of time prior to breaching the surface (Fig. 3A).
 155 We refer to this time span as phase 1. When boulders breach the surface, they should have a
 156 concentration similar to that of the surrounding soil (Fig. 3B). As boulders are exposed during
 157 phase 2, nuclide production and decay continues, but it takes time for the boulder surfaces to
 158 attain a ^{10}Be concentration that is in equilibrium with the slower boulder denudation rate. Thus,
 159 we expect that the measured concentrations from the tops of boulders are combinations of the two
 160 different phases in which ^{10}Be is accumulated at different rates. Converting the ^{10}Be
 161 concentrations of soil samples collected from around the boulders to a denudation rate also

requires a special approach, as these samples include an unknown number of grains eroded off boulders, which ought to increase the ^{10}Be concentration, due to the slower denudation rate of boulders, as compared to soil.

Because of the above complications, we used an approach to estimate the soil and boulder denudation rates that considers the measured boulder protrusion heights and their measured ^{10}Be concentrations. We first calculated the modelled ^{10}Be concentrations (N , in atoms g^{-1}) by approximating the production rate profile with a combination of several exponential functions (e.g., Braucher et al., 2011) during the two different phases:

$$N = \sum_i \frac{P_i(0)}{\lambda + \frac{\epsilon_s \rho}{\Lambda_i}} e^{-t_2 \lambda} + \sum_i \frac{P_i(0)}{\lambda + \frac{\epsilon_b \rho}{\Lambda_i}} \left[1 - e^{-t_2 (\lambda + \frac{\epsilon_b \rho}{\Lambda_i})} \right] \quad (1),$$

where i indicates different terms for the production by spallation, fast muons, and negative muons; $P_i(0)$ are the site-specific ^{10}Be surface production rates in atoms $\text{g}^{-1} \text{yr}^{-1}$ for the different production pathways (Table 1); λ is the ^{10}Be decay constant (4.9975×10^{-7}); ϵ_b is the boulder denudation rate (cm yr^{-1}); ρ is the boulder density (here we use a value of 2.6 g cm^{-3} for all samples); and Λ_i is the attenuation length scale (160 g cm^{-2} for spallation, 4320 g cm^{-2} for fast muons, and 1500 g cm^{-2} for negative muons, respectively (Braucher et al., 2011). Surface production rates by spallation are based on a SLHL (sea level high latitude) reference production rate of $4.01 \text{ atoms g}^{-1} \text{yr}^{-1}$ (Borchers et al., 2016) and the time constant spallation production rate scaling scheme of Lal (1991) and Stone (2000) ('St' in Balco et al., 2008). Surface production rates by muons were obtained using the MATLAB-function 'P_mu_total.m' of Balco et al. (2008). Topographic shielding at each sampling site was calculated with the function 'toposhielding.m' of the TopoToolbox v2 (Schwanghart and Scherler, 2014) and 12.5-meter resolution ALOS PALSAR-derived digital elevation models (DEMs) from the Alaska Satellite Facility. In equation 1, the first term represents phase 1 and the second term represents phase 2,

with t_2 being the exposure time of the boulder, calculated from the height of the boulder (z)
 divided by the difference between the soil denudation rate and the boulder denudation rate:

$$t_2 = \frac{z}{(\epsilon_s - \epsilon_b)} \quad (2)$$

For each sample and associated average boulder protrusion height, we modelled ^{10}Be
 concentrations with equation 1 for different combinations of soil and boulder denudation rates
 that we allowed to vary between 5 and 50 m Myr⁻¹ (NA and SG), and between 10 and 300 m Myr⁻¹
 (LC), guided by previously published denudation rate estimates (Schaller et al., 2018; van
 Dongen et al., 2019). We consider permissible denudation rates as those for which the difference
 between the modelled and observed ^{10}Be concentrations is less than the measured 2σ
 concentration uncertainty.

3.2 Topographic analysis

To test if stream orientations in our field sites follow fault orientations, we analyzed the
 orientations of streams using one-meter resolution LiDAR DEMs (Kügler et al., 2022). Within
 each DEM, we first calculated stream networks based on flow accumulation area thresholds of
 10⁴, 10⁵ and 10⁶ m². The lowest threshold was determined based on the occurrence of incised
 channels visible in the DEMs. We then used the TopoToolbox function ‘orientation’ with a
 default smoothing factor (K) of 100, to obtain the orientation of each node in the stream network.
 To obtain the orientation of mapped faults, we extracted faults within ~50 km of each sampling
 site from a 1:1,000,000-scale geological map from Chile’s National Geology and Mining Service
 in ArcGIS (SERNAGEOMIN, 2003). Fault orientations were measured for straight fault
 segments with a length of 100 m. Because we are only interested in the strike of streams and
 faults, all orientations lie between 0° and 180°. For displaying purposes in rose diagrams, we
 mirrored these values around the diagram origin by duplicating values and adding 180°.

206 4 Results

207 4.1 ^{10}Be concentrations

208 Measured ^{10}Be concentrations span a wide range of values, and are generally lowest in LC
 209 and higher in NA and SG (Table 1). Within NA, we observe the lowest averaged ^{10}Be
 210 concentrations (normalized to SLHL) for soil samples ($\mu \pm 1\sigma = 1.41 \times 10^5 \pm 0.031 \times 10^5$ atoms g^{-1}),
 211 followed by bedrock samples ($2.19 \times 10^5 \pm 0.036 \times 10^5$ atoms g^{-1}) and boulder samples
 212 ($2.82 \times 10^5 \pm 0.041 \times 10^5$ atoms g^{-1}) (Fig. 4). In NA at Piedra de Aguila, where we were able to
 213 measure fracture spacing in areas with exposed bedrock, the ^{10}Be concentrations of samples from
 214 fractured bedrock decrease with increasing fracture density (Fig. 4A). One boulder sample from
 215 the slope of Soil Pit Hill stands out with a concentration that is lower than most soil samples.
 216 Similar average values as in NA are attained in SG, with soil samples ($1.70 \times 10^5 \pm 0.039 \times 10^5$
 217 atoms g^{-1}) being lower than boulder samples ($3.23 \times 10^5 \pm 0.059 \times 10^5$ atoms g^{-1}) (Fig. 4C). Only in
 218 LC are the averaged differences between soil ($0.82 \times 10^5 \pm 0.022 \times 10^5$ atoms g^{-1}) and boulder
 219 samples ($0.74 \times 10^5 \pm 0.025 \times 10^5$ atoms g^{-1}) small (Fig. 4B). In addition, at 3 out of 5 sampling
 220 locations in LC, boulders have lower concentrations than adjacent soil samples, inconsistent with
 221 the assumption that $\epsilon_s < \epsilon_b$ (see section 3.1.3). However, our single bedrock sample from LC has
 222 a higher concentration of $1.38 \times 10^5 \pm 0.082 \times 10^5$ atoms g^{-1} . Finally, in all three field sites, boulder
 223 samples from slope locations have usually lower ^{10}Be concentrations compared to boulder
 224 samples from ridge locations, when accounting for their protrusion height as a relative indicator
 225 for exposure time. An exception is again found in LC, at Cerro Cabra.
 226

227 **4.2 Bedrock, boulder, and soil denudation rates**

228 Bedrock denudation rates in NA range from $8.53 \pm 0.6 \text{ m Myr}^{-1}$ to $18.64 \pm 1.4 \text{ m Myr}^{-1}$, and
 229 the LC bedrock sample yielded a denudation rate of $22.28 \pm 2.62 \text{ m Myr}^{-1}$. We modelled boulder
 230 (ϵ_s) and soil denudation rates (ϵ_s) using the approach described in section 3.1.3 for all boulder
 231 samples that have higher concentrations than the adjacent soil concentrations. We address
 232 locations where ^{10}Be concentrations are higher in soil compared to boulder samples in the
 233 discussion (three locations in LC and one in NA). In contrast to the bedrock denudation rates,
 234 modelled boulder and soil denudation rates have no unique solution, and their range of possible
 235 denudation rates is more complex (Fig. 5). However, not every combination within the range
 236 plotted in Fig. 5 is likely. For example, the part of the colored bands in Fig. 5 that is close to the
 237 1:1-line (edge of the gray area) exists because at very low differential denudation rates
 238 (differences between soil and boulder denudation rates), phase 2 gets very long so that the
 239 boulder denudation rate dominates the resulting concentration and approaches the value one
 240 would obtain when neglecting the first term on the right side in Eq. 1. We argue that differential
 241 denudation rates of less than $\sim 1 \text{ m Myr}^{-1}$ are highly unlikely, as it would take $\sim 1 \text{ Myr}$ to exhume a
 242 boulder of only 1 m in height above the soil, while simultaneously eroding many times more soil
 243 and boulder material.

244 In NA, modelled soil denudation rates range from ~ 13 to 37 m Myr^{-1} and modelled
 245 boulder denudation rates range from ~ 5 to 20 m Myr^{-1} (Fig. 5A). Three samples that were taken
 246 from the same ridge at Cerro Anay (Fig. 2C and 4A) all overlap in denudation rate despite
 247 varying protrusion heights. These samples also overlap with a sample from Casa de Piedras, and
 248 together indicate a rather narrow range of soil and boulder denudation rates of $\sim 15\text{-}20 \text{ m Myr}^{-1}$
 249 and $\sim 10\text{-}15 \text{ m Myr}^{-1}$, respectively. Only the mid-slope sample from Cerro Anay has higher
 250 modelled soil and boulder denudation rates. In LC, modelled boulder and soil denudation rates

that are consistent with the measured ^{10}Be concentrations extend to much higher values compared to the other field sites (40-140 m Myr^{-1}) and the two solutions do not overlap. In SG, modelled denudation rates are similar in magnitude to results from NA (Fig. 5C); soil denudation rates range from ~10 to 28 m Myr^{-1} and boulder denudation rates range from ~5 to 23 m Myr^{-1} . Samples taken from the ridge of Santa Gracia Hill (Fig. 2I and 4C) have modelled soil and boulder denudation rates that overlap at values of ~12-15 m Myr^{-1} and ~10-12 m Myr^{-1} , respectively. Samples from the slope of Santa Gracia Hill have higher modelled soil denudation rates, when considering very low differential denudation rates unlikely.

4.3 Fault and stream orientations

Fault orientations in our field sites, based on straight segments of 100 m (8,731 segments for SG, 6,572 segments for LC, and 6,214 segments for NA), generally have at least one dominant orientation that aligns with stream orientations (Fig. 6). Stream orientations depend on the flow accumulation threshold: at smaller thresholds (10^4 m^2), many small streams are selected, giving a large distribution of orientations that reflects the shape of the catchment as a whole. At a high flow accumulation threshold (10^6 m^2), the derived stream networks comprise only the largest channels and their orientation is strongly controlled by the orientation and tilt of the drainage basin. This can be seen clearly in NA, where the east-west oriented trunk stream is weighted heavily. In SG, faults and stream orientations match each other well, both trending north-south. In LC and NA, one of two regional fault orientations matches stream orientations, and faults closest to the field sites more closely match dominant stream orientations (red faults in Fig. 6). Specifically, in LC, the dominant orientations for the regional faults are roughly northeast and secondarily northwest, whereas streams are generally oriented northwest. In NA, faults generally

273 have east-west and northwest-southeast orientations, and streams with an accumulation threshold
 274 above 10^4 follow an east-west orientation.

275 **5 Discussion**

276 **5.1 Deciphering the true denudation rates of boulders and soil**

277 Our model results show that there exist no unique combination of soil and boulder
 278 denudation rates for any particular site (Fig. 5). Which, then, are the most likely combinations of
 279 boulder and soil denudation rates? The answer depends on the characteristic exhumation histories
 280 of the boulders, and events that could have influenced the accumulation of ^{10}Be during the course
 281 of exhumation. In order to narrow down the ranges of denudation rates for boulders and soils
 282 investigated in this study, we address several complicating factors, such as shielding and toppling
 283 of boulders, and compare measured and modelled ^{10}Be concentrations of soils to each other.

284 **5.1.1 Shielding and toppling of boulders**

285 When sampling, two ways to inadvertently introduce bias include: 1) sampling material
 286 that remains in situ, but has been previously shielded by a boulder, or 2) sampling a boulder that
 287 has toppled or rolled downhill, and is no longer in situ. In both cases, the actual production rate
 288 for the sample could be lower than assumed, leading to an artificially high denudation rate
 289 estimate. The first scenario is more likely in areas where there are tall, densely-clustered
 290 boulders, or at protruding bedrock outcrops such as Piedra de Aguila, where we measured a very
 291 low ^{10}Be concentration in sample NB-BR4 (Table 1; Fig. 4A). This sample was taken from a
 292 bedrock knob close to a cliff in an area accessed by tourists; it is possible that the low
 293 concentration of our sample is due to shielding by boulders or bedrock blocks that toppled from
 294 the sampled area.

295 The second scenario is more likely in areas with steep slopes. In LC, where slopes are
 296 generally steeper than the other field sites, it is possible that some boulders were not in situ when
 297 we sampled them: they could have rolled or been overturned on the steep slopes, uncovering a
 298 side that was previously shielded. Indeed, three boulder samples from LC (LC2, LC4, and LC18;
 299 Table 1) have measured ^{10}Be concentrations that are lower than the surrounding soil, violating
 300 our model assumptions, and suggesting that the boulders were shielded. Two of these samples
 301 (LC4 and LC18) were collected from slopes with rather high angles of 27° and 18° , respectively,
 302 and therefore could have toppled downslope, but LC2 was collected on a ridge with a relatively
 303 lower slope of 9° (Table 1). For LC2, the low concentration could stem from shielding by stacked
 304 boulders (scenario 1). In NA, one boulder sample (NA15; Table 1) also has a very low ^{10}Be
 305 concentration and was not included in the model. We did not collect a soil sample near the
 306 boulder sample NA15, and instead compared its concentration to the adjacent surficial soil pit
 307 sample of Schaller et al. (2018). Because these samples were not taken exactly next to each other,
 308 there exists some ambiguity in this comparison. However, the relatively low ^{10}Be concentrations
 309 of sample NA15 when compared to other boulder samples in NA suggest issues that could be
 310 related to shielding or toppling of boulders.

311 **5.1.2 Most likely ranges for modelled denudation rates**

312 Most of our soil samples have measured ^{10}Be concentrations that are similar to ^{10}Be
 313 concentrations calculated using our modelled denudation rates (Table 2), supporting the
 314 reliability of the model results. Positive or negative deviations are expected, however, because (1)
 315 soil samples we collected in the field are most likely a mixture between lower concentrations in
 316 soil that is directly exhumed from below, and higher concentration grains eroded from the
 317 surrounding boulders, and (2) we did not account for shielding of soil by the surrounding

318 boulders, which would lower production rates. In one case (Casa de Piedras in NA), the measured
319 soil ^{10}Be concentration is significantly lower than the modelled soil ^{10}Be concentration (Table 2).
320 If the soil was eroding as fast as our measured soil samples indicate, the boulders should be
321 protruding higher. However, Casa de Piedras has a high density of tall boulders. The observed
322 discrepancy could be caused by boulders shielding the soil directly surrounding it from cosmic
323 rays, or by eroding chips with low ^{10}Be concentrations of shielded parts of the boulders, perhaps
324 from the base, that erode directly into the soil.

325 Next, we identify the most likely range of denudation rates for each sample type and
326 location for all modelled denudation rates. Specifically, we chose denudation rate ranges for
327 samples on Cerro Anay ridge and Casa de Piedras based on their overlap with each other, for
328 samples on Cerro Anay slope based on their overlap with sample NA9 on Cerro Anay ridge, and
329 ranges for Santa Gracia hill ridge and slope based on the overlap of modelled rates for each
330 respectively (Fig. 5). For LC we chose denudation rates near the center of the modelled curves in
331 Figure 5, based on realistic expectations of differential erosion (section 4.2), and considering
332 possible issues with shielding and toppling (section 5.1). These ranges are listed in Table 2 along
333 with measured and modelled ^{10}Be concentrations of soil samples, and are displayed in Fig. 7
334 along with previously published soil (Schaller et al., 2018) and catchment-average denudation
335 rates (van Dongen et al., 2019). In the following section, we discuss the erosional processes that
336 may account for the differences and similarities in denudation rates from bedrock, boulders, soil
337 (this study and Schaller et al., 2018), and stream sediment (van Dongen et al., 2019) within each
338 field site.

339 **5.2 Processes controlling differential erosion**

340 In NA, the slowest denudation rates occur on bedrock and boulders, likely because
341 precipitation runs off quickly, limiting chemical alteration (Eppes and Keanini, 2017) and
342 weathering (Hayes et al., 2020), whereas soils erode faster. However, denudation rates for soil
343 surrounding the sampled boulders are lower than denudation rates from the soil pit and the
344 catchment average denudation rates. It is possible that boulders physically block soil from being
345 transported downslope: where a dense clustering of exhumed boulders exists, the regolith will be
346 thinner, and the boulders likely retard soil erosion throughout the area in which they are clustered
347 (Glade et al, 2017). Where soil is thicker, if slopes are steep enough, shallow landsliding can
348 occur, as observed in NA by Terweh et al. (2021). In accordance with these observations, van
349 Dongen et al (2019) found that smaller grains in stream sediment were likely derived from the
350 upper mixed soil layer, and the largest grains were likely excavated from depth, perhaps by
351 shallow landsliding. The smaller grains have denudation rates similar to those presented in this
352 study (Fig. 7), while larger grains have denudation rates similar to deeper soil pit samples from
353 Schaller et al. (2018).

354 Finally, in NA, where bedrock fracture density is higher, denudation rates are also higher
355 (Fig. 7), likely because precipitation infiltrates into fractures, accelerating chemical weathering,
356 regolith formation (St. Claire et al., 2015; Lebedeva and Brantley, 2017), and subsequent
357 vegetation growth, which introduces biotic acids that further accelerate chemical weathering
358 (Amundson et al., 2007). We further speculate that large exhumed boulders in NA are also sites
359 of less-fractured bedrock at depth, as boulders can only be as large as the local fracture spacing
360 allows (e.g. Sklar et al., 2017). Based on the observed differences in soil, boulder, and fractured
361 bedrock denudation rates in NA, and on previous studies that have correlated higher fracture
362 density with more rapid erosion (e.g., Dühnforth et al., 2010; Dibiase, 2018; Neely et al., 2019),

363 we suggest that bedrock fractures have an effect on NA's morphology through grain size
364 reduction and differential erosion. Further, the thicker soil cover and shallow landsliding on NA
365 slopes may increase the discrepancy between slowly-eroding, less-fractured bedrock and boulders
366 versus more rapidly-eroding, vegetation-covered hillslopes, eventually causing bedrock and
367 boulders to sit at topographic highs, as we observed in the field.

368 In the semi-arid landscape of SG, as in humid-temperate NA, boulders are eroding more
369 slowly than the surrounding soil, but the differences in boulder and soil denudation rates are
370 subtle. In addition, denudation rate differences between ridge and slope samples – possibly
371 related to slope angle – are larger than the differences between boulders and soil. Furthermore,
372 unlike in NA, our boulder and soil denudation rates are similar to the soil pit and catchment
373 average denudation rates (Fig. 7), suggesting that erosional efficiencies are similar across
374 different sediment sizes. Uniform ^{10}Be concentrations across grain sizes is in accordance with
375 absent landsliding (Terweh et al., 2021). Van Dongen et al. (2019) also measured relatively
376 constant catchment average ^{10}Be concentrations over seven grain size classes in SG (Fig. 7),
377 which suggests that all grain sizes must have been transported from the upper mixed layer of
378 hillslope soil, and that deep-seated erosion processes are unlikely. Thus, our results agree with
379 previous findings that erosion in SG is likely limited to grain-by grain exfoliation of boulders and
380 the slow diffusive creep of the relatively thin soil cover on hillslopes (Schaller et al., 2018). When
381 bedrock is exhumed, its long residence time on hillslopes allows it to weather slowly in place and
382 reduce in size, with minimal transportation of weathered material by runoff and a low degree of
383 chemical weathering and soil production (Schaller and Ehlers, 2022).

384 Such a narrow range of relatively low denudation rates indicates that very long time
385 periods are necessary to produce relief between hilltops and valleys. Note, however, despite low
386 uplift rates in SG, the total mean basin slope in SG is 17° compared to 9° in NA (van Dongen et

al., 2019). This could be due to low MAP resulting in a low erosional efficiency in SG; in order to achieve denudation rates that match uplift rates, slopes in arid climates must be steeper (Carretier et al., 2018). Although the differences in denudation rates between grain sizes is subtle in SG, soils have higher denudation rates than the boulders they directly surround, suggesting that, if the boulders are delineated by fractures at depth as we infer for NA, fractures could also have an effect on landscape morphology in SG. Additionally, Krone et al (2021) noted that the fractures in a drill core in SG were rimmed by halos of weathered material depleted in soluble elements, and concluded that the fractures act as pathways for fluid transport into the subsurface, which enhances chemical weathering. In summary, we suggest that fractures likely accelerate chemical weathering and erosion in SG, but the resultant differential denudation rates are subtle due to low MAP and low tectonic uplift rates.

In LC we observe the largest range of denudation rates between bedrock, boulders, soil, and stream sediment, and also the highest overall denudation rates of the three field sites. We suspect that both of these characteristics are related to slope angles, which are on average nearly twice as steep as in NA and SG (Table 1; van Dongen et al., 2019). It should be noted that the stream sediment samples were taken from an adjacent catchment that does not drain the hillslopes sampled in this study, and the generally low and wide-ranging ^{10}Be concentrations in the stream sediment have been related to relatively recent landslides observed in the upper headwaters (van Dongen et al., 2019; Terweh et al., 2021). However, steep slopes are pervasive throughout LC and lead us to suggest that shallow landslides are important erosional processes in this field site too.

In LC we frequently observed boulder samples with lower ^{10}Be concentrations than adjacent soil samples (Table 1, section 5.1), which is inconsistent with our simple model of boulder exhumation (Fig. 3), and is possibly because the sampled boulders were not exhumed in

411 situ (section 5.1.1). Landslides as observed in LC can bring down boulders in the processes of
 412 downhill movement, and may cause the excavation of larger blocks from greater depth before
 413 their size is reduced in the weathering zone. More vigorous mass wasting is consistent with larger
 414 average hillslope grain sizes for LC, as compared to NA and SG (Terweh et al., 2021). In general,
 415 the high relief, steep slopes, and high denudation rates in LC suggest that tectonic uplift rates
 416 could be higher than assumed for the nearby coast (Melnick et al., 2016). Finally, although the
 417 role that fracturing plays in LC is difficult to assess, note that our bedrock sample has a
 418 significantly lower denudation rate than boulders and soils (Fig. 7), despite being on a steep slope
 419 (Table 1). If we assume that the bedrock patch has a lower fracture density than the boulders
 420 based on previous studies that correlate fracture spacing with grain size (e.g. Sklar et al., 2017;
 421 Dibiase et al., 2018; Neely et al., 2019), then the slower denudation rate of the bedrock patch
 422 could be an effect of fracture spacing in LC.

423 Overall, each field site presents a different pattern of denudation rates between bedrock,
 424 boulders, soil, stream sediment, and soil pits. The patterns of differential erosion between the
 425 field sites are likely dictated by a combination of tectonics (differences in uplift and fracture
 426 spacing) and the local climate regime.

427 **5.3 Fracture control on larger-scale landscape evolution**

428 In NA, we were able to measure fracture density in several bedrock outcrops and found
 429 that higher fracture density is correlated with higher denudation rates (Fig. 7), and we suggest that
 430 patterns in fracture density affect the landscape morphology. We were not able to measure
 431 fracture density in the other two field sites due to the scarcity of bedrock exposure. However, we
 432 suspect that fractures may also play a role in their landscape morphology, and this may be visible
 433 on a larger scale, through similarity of fault and stream orientations.

434 As tectonically-induced faults and fractures are products of the same regional stresses, we
 435 assume that regional faults have orientations consistent with fractures in our field sites (c.f.,
 436 Krone et al., 2021). We observe that stream channels in our field sites ($A_{\min} \geq 10^5 \text{ m}^2$) generally
 437 follow fault orientations (Fig. 6), presumably because faults and fractures reduce grain size and
 438 allow easier transport of hillslope material and directing stream incision (Roy et al., 2016). This is
 439 especially clear in SG, where the north-south striking Atacama Fault System is reflected in the
 440 orientation of faults, streams, and also fractures measured in a nearby drill core (Krone et al.,
 441 2021; Fig. 6). In LC and NA, despite more variety in fault and stream orientations, faults closest
 442 to the field sites tend to align with stream orientations (Fig. 6). Especially in NA, the larger
 443 streams are often nearly perpendicular to each other, similar to rectangular drainage networks,
 444 which are often indicative of structural control on drainage patterns (e.g., Zernitz, 1932). We
 445 speculate that over geologic time scales, smaller streams are more transient features, whereas the
 446 larger ones are more persistent. These results suggest that within the same rock type, local
 447 fracture patterns induced by regional faults can induce differential denudation in landscapes.
 448 Further, such differential denudation rates have the ability to shift the landscape from steady
 449 state. If faults are inclined, the location of fractured bedrock will shift over time as bedrock is
 450 exhumed and erodes, thus also shifting the locations of streams, valleys, and topographic highs
 451 over time, and introducing topographic disequilibrium to the landscape (Roy et al., 2016).

452 In summary, we argue that in NA, and likely also in SG and LC, bedrock fracturing
 453 influences landscape morphology by setting grain size and thus dictating patterns of denudation
 454 rates on hillslopes and in streams. We therefore offer the following conceptual model: in a
 455 landscape with fractured bedrock (Fig. 8A), areas with higher fracture density should be sites of
 456 smaller sediment sizes (e.g. Sklar et al., 2017; Neely and Dibiase, 2020), where rainfall can easily
 457 infiltrate, conversion of bedrock to regolith is easiest (St. Claire et al., 2015; Lebedeva and

458 Brantley, 2017), and denudation rates are highest. Over time, precipitation will divergently run
 459 off topographic highs and starve bedrock and boulders on high points while infiltrating into
 460 topographic lows, where streams eventually incise (Bierman, 1994; Hayes et al., 2020; Fig. 8B).
 461 Regolith also promotes vegetation growth, which slows runoff, raises rates of infiltration, and
 462 enhances chemical weathering (Amundson et al., 2007), creating a positive feedback between
 463 precipitation and fracture density (Fig. 8B). Additional fractures due to topographic stresses from
 464 exhumation may also form at topographic highs as the topography emerges (St. Claire et al.,
 465 2015), countering this positive feedback loop (Fig. 8C). Over longer timescales, bedrock with
 466 different patterns of fracture density may be exhumed, which can invert landscapes to reflect the
 467 new fracture patterns exposed at the surface (Roy et al., 2016). In this way, fracturing, climate,
 468 and residence time can operate in conjunction to set the sediment size and morphology of
 469 hillslopes and streams within landscapes.

470 **6 Conclusions**

471 In this study, we tested the ability of bedrock patches and large boulders to retard
 472 denudation and influence landscape morphology, in relatively slowly-eroding landscapes along a
 473 climate gradient in the Chilean Coastal Cordillera. Based on in-situ cosmogenic ^{10}Be -derived
 474 denudation rates of bedrock, boulders and soil, we find that (1) in almost all cases across the three
 475 sites studied, soil denudation rates are higher than the denudation rates of the boulders that they
 476 surround; (2) hillslope denudation rates increase with fracture density in NA; and (3) streams tend
 477 to follow the orientation of larger faults. These results suggest that large hillslope boulders affect
 478 landscape morphology through differential denudation rates: soil erodes from around bedrock
 479 patches and boulders, exposing these features over time. Eventually, the largest boulders and
 480 bedrock patches in a landscape should become topographic highs due to their overall lower

481 denudation rates than soil; therefore, we predict that current bedrock patches on hillslopes are
482 nuclei for future peaks and ridges.

483 Our results also support the concept that bedrock patches and boulders represent locations
484 where fracture density is lower, and thus weathering, erosion, and soil formation are suppressed.
485 Precipitation runs off topographic highs where intact bedrock is exposed, and infiltrates into soils
486 on hillslopes and in valleys, promoting chemical weathering below. Bedrock fracture density
487 affects denudation rates by damaging bedrock, reducing grain size, and making it easier to be
488 removed by erosional processes. On a larger scale, our results imply that tectonic preconditioning
489 in the form of bedrock faulting and fracturing influences landscape evolution by impacting the
490 pathway of streams, as well as the migration of ridges, drainage divides and knickpoints, as
491 landscapes erode through layers of bedrock preconditioned by tectonic fracturing over time, and
492 encounter varying levels of resistance depending on the fracture density.

^aOpen access metadata: <http://gsn.org/insertIGSNnumberhere>

^bSample locations: SGH: Santa Gracia Hill, CC: Cerro Cabra, CG: Cerro Guanaco, PdA: Piedra de Aguilas, CdP: Casa de Piedas, CA: Cerro Anay, SPH: Soil Pit Hill.

^cSample type abbreviations: BR: bedrock, B: boulders, S: soil.

^dConcentrations were normalized to SLHL (sea level high latitude) using a SLHL production rate of 4.01 atoms g⁻¹ yr⁻¹ (Borchers et al., 2016) and the site's scaling factor.

^eTime constant spallation production rate scaling scheme of Lal (1991) and Stone (2000) ('St' in Balco et al., 2008).

^fLocal hillslope angles were calculated using a 12.5m DEM and an 8-connected neighbourhood method.

^gFracture density for bedrock (in meters) and width and protrusion measurements (in meters) for boulders. Values are averages of >10 measurements per sample site.

Table 2. Modelled denudation rates for soil and boulder samples using the first term of Eq. 1, and comparison of modelled and measured ^{10}Be concentrations for soil samples. Sample location abbreviations are described in the caption for Table 1.

Sample location	Soil sample ID	Best-fitting modelled soil denudation rate range (ϵ_s) (m Myr ⁻¹)	Corresp. modelled range of ^{10}Be conc. ($\times 10^5$) (atoms g ⁻¹) for soil (N_m)	Measured ^{10}Be conc. $\pm 1\sigma$ ($\times 10^5$) (atoms g ⁻¹)	Boulder sample IDs	Best-fitting modelled boulder denudation rate range (ϵ_b) (m Myr ⁻¹)

11 Figures

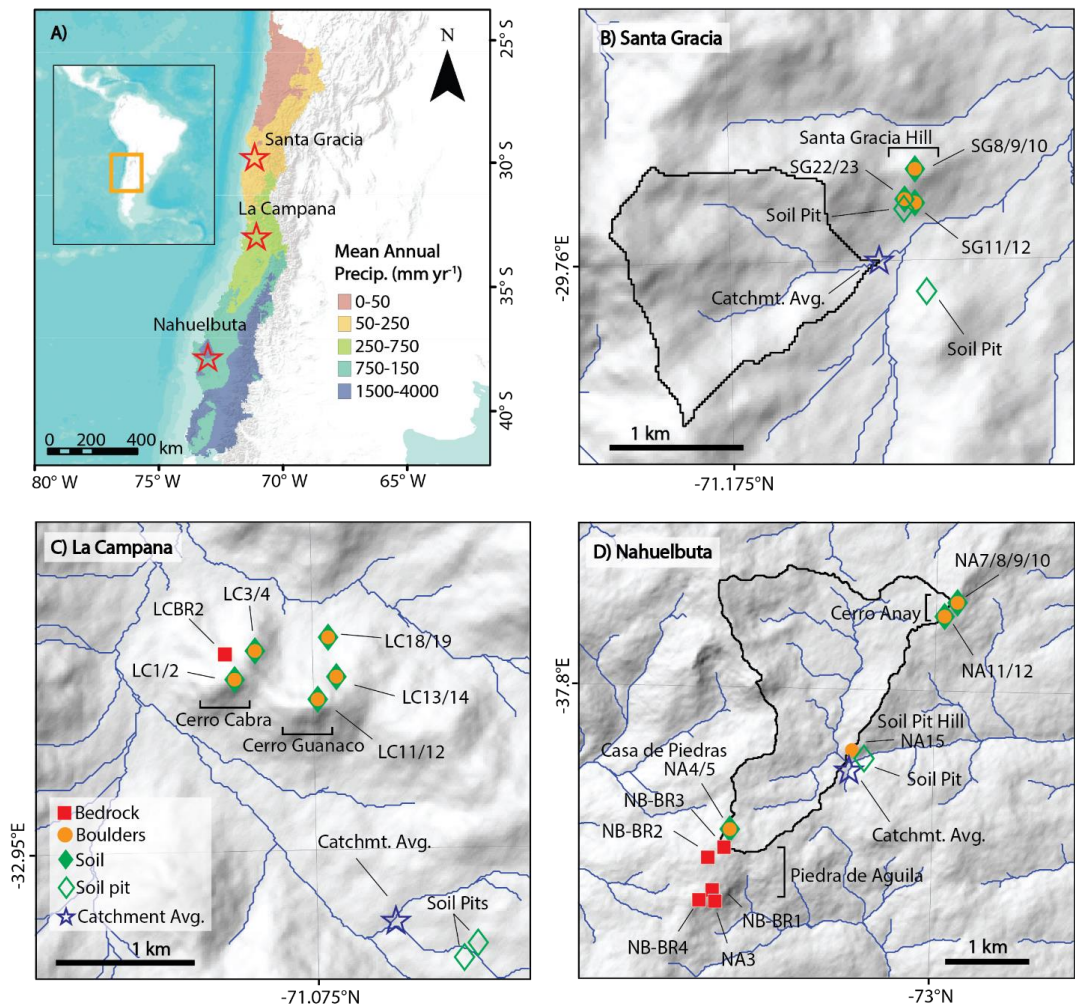

Figure 1. Field site locations and features. A) Map of mean annual precipitation in central Chile, with field sites marked by red stars. Precipitation data from the CR2MET dataset, by the Center for Climate and Resilience Research (CR²) (Boisier et al., 2018), provides an average for the time period 1979-2019. World Terrain Base map sources are Esri, USGS, NOAA. B-D: Hillshade images from 12.5-m ALOS PALSAR digital elevation models, of B) Santa Gracia (SG), C) La Campana (LC), and D) Nahuelbuta (NA). Sample locations and sample names are shown, with symbol shape and color indicating the sample type (see legend in lower left panel). Black outlines delineate the catchments from which the catchment average sample (star) was taken (the catchment from La Campana does not fit within the bounds of the map and therefore is not shown). Blue lines indicate streams. Soil pit sample data are from Schaller et al. (2018), and catchment average sample data are from van Dongen et al. (2019).

Figure 2. Field photos showing the various surfaces sampled, including bedrock, boulders and soil. A: Nahuelbuta, A1) Bedrock (sample NB-BR1). A2) Fractured bedrock, in transition between unfractured bedrock and boulders (sample NB-BR2). A3) Smaller boulders surrounded by soil (sample NA7). B: La Campana, B1) Bedrock (sample LC-BR2). B2) Bedrock transitioning to large boulders and soil. B3) Boulders and soil on a hillside (samples LC13 and LC14). C: Santa Gracia, C1) Boulders on a hillside delineated by fractures. C2) Large boulders on the ridge of Santa Gracia Hill (sample SG8). C3) Soil with minimal boulders on the slope of Santa Gracia Hill (samples SG22 and SG23).

Figure 3. Schematic image showing the process of boulder exhumation. A) During phase 1, the boulder is buried, and accumulates nuclides at a rate governed by the soil denudation rate, ϵ_s . B) Phase 1 ends when the boulder breaches the soil surface. C) During phase 2, the boulder itself is eroding at a rate of ϵ_b , and the surrounding soil continues to erode at a rate of ϵ_s . Phase 2 lasts for a time period t_2 that ends with our sampling.

Figure 4. Measured ^{10}Be concentrations normalized to reference production rate at sea-level high latitude. A) Nahuelbuta, B) La Campana, and C) Santa Gracia; note different scales of y-axes. X-axes show the sample size (cm) of bedrock, boulder and soil samples. For bedrock samples, the sample size indicates the fracture density at the sample site. For boulder samples, the sample size indicates the average width (b-axis) of boulders from which we collected chips for an amalgamated sample. Soils are labeled <0.1 cm. Labels next to data points provide sample IDs, also reported in Table 1.

Figure 5. Range of best fitting combinations of modelled soil and boulder denudation rates in A) Nahuelbuta, B) La Campana, and C) Santa Gracia according to Eq. 1. Each color band corresponds to an amalgamated boulder sample, listed in the legend along with the average protrusion height of the boulders. Areas where best fitting denudation rates overlap for samples from the same location are highlighted by a black outline. The gray areas are forbidden fields, as by assumption, boulder denudation rates have to be lower than soil denudation rates, otherwise there would be no boulder protruding above the soil surface.

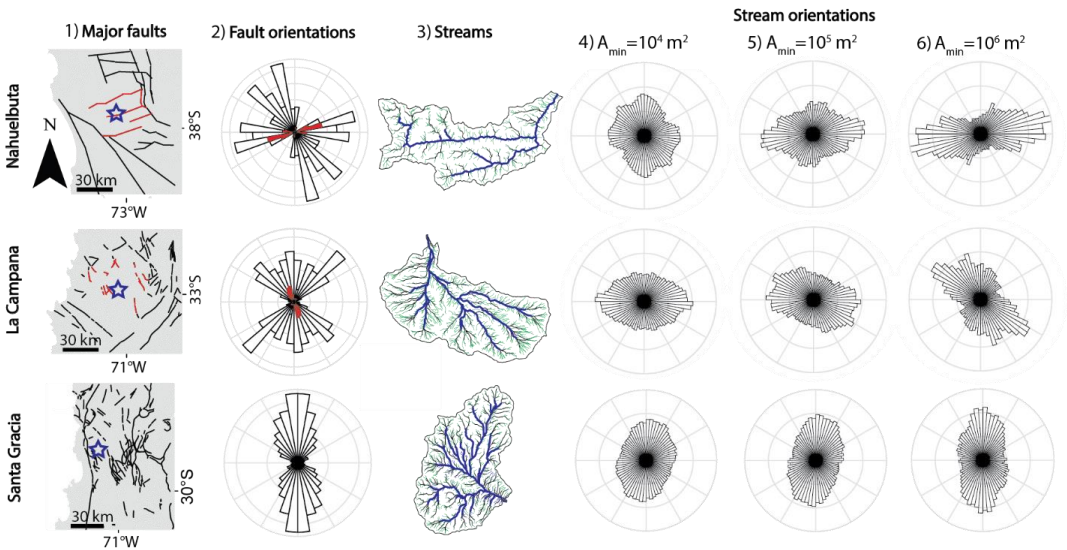

Figure 6. Rose diagram plots and maps showing fault and stream orientations for Nahuelbuta (top row), La Campana (middle row), and Santa Gracia (bottom row). For each field site, the columns show from left to right: (1) major faults digitized from geological map (SERNAGEOMIN, 2003), within ~50 km (black) and ~25 km (red, NA and LC only) of the sampling site (blue star); (2) rose diagram of fault orientations from the maps in column 1, constructed using 100 m long, straight fault segments and 36 bins, with orientations of faults <25 km from NA and LC in red;

(3) a map of the studied catchments and the drainage network, with green, black, and blue streams indicating minimum upstream areas (A_{\min}) of 10^4 , 10^5 , and 10^6 m², respectively, derived from one-meter resolution LiDAR DEMs (Kügler et al., 2022).; (4-6) rose diagrams (72 bins) of stream orientations for different A_{\min} . All maps and rose diagrams are oriented with the top being north.

Figure 7. Overview of new and previously published denudation rates. Soil pit data from Schaller et al. (2018), and catchment average data from van Dongen et al. (2019). Catchment average denudation rates from various sediment grain sizes (from left to right for each field site: 0.5-1, 1-2, 2-4, 4-8, 8-16, 16-32, and 32-64 mm). Bedrock denudation rates are calculated using the CRONUS online calculator v2.3 (Balco et al., 2008). Boulder and soil denudation rates are estimated using our model and reflect the most likely denudation rates as described in section 5.1.2. Denudation rates for each location within a field site are separated by thin gray bars, and locations are labeled at the top of the chart. Samples that were not included in the model (one sample from Nahuelbuta and 3 samples from La Campana) are also not included here. Data from this study is shown by solid symbols and previously-published data is shown by hollow symbols.

752

753 Figure 8: Schematic illustration showing influence of bedrock fractures on landscape evolution.
754 (A) Bedrock with different fracture densities is to different degrees infiltrated by rain and ground
755 water, which leads to differences in chemical weathering, soil formation and vegetation growth,
756 resulting in different hillslope sediment sizes. (B) Differential denudation between highly
757 fractured and less fractured areas induce relief growth, which further promotes spatial gradients
758 in chemical weathering, hillslope sediment size, and denudation. (C) Growing relief increases
759 topographic stresses and formation of new fractures (red) at topographically high positions (e.g.,
760 St. Clair et al., 2015).
