Abstract. Constitutive laws of rock salt are required for the prediction of long-term deformation of solution mined caverns and radioactive waste repositories in rock salt, which are used for energy storage and play an important role in the energy transition. Much of this deformation is at differential stresses of a few MPa, while the vast majority of laboratory salt creep measurements are at much higher differential stress and require extrapolation over many orders of magnitude. This extrapolation can be made more reliable by including microphysical information on the deformation mechanisms in the laboratory samples, integrated with microstructural analysis data of samples deformed in natural laboratories at low differential stress. Rock deformation of rock salt can deform at widely different rates at the same temperature and deviatoric stress, depending on state variables such as grain size, solid solution- and second phase-impurities, crystallographic preferred orientation, water content and grain boundary structure. Both occur by dislocation creep and grain-size-dependent dissolution-precipitation creep processes are common, but dissolution-precipitation creep is not commonly included in current engineering predictions.

Here we show evidence for large grain size-dependent differences in halite rheology based on microstructural observations from Zechstein rock salt cores of the Northern Netherlands that experienced different degrees of tectonic deformation. We studied the relatively undeformed horizontal-layered Z2 salt (Stassfurt Formation) from Barradeel, and compared it with much stronger deformed equivalent in diapirc salt from Winschoten, Zuidwending, and Pieterburen. We used optical microscopy of g-irradiated thin sections for microtectonic analysis, recrystallized grain size measurements and subgrain size piezometry, electron microscopy with energy dispersive X-ray spectroscopy SEM-EDX and X-ray diffraction analysis XRD for second phase mineralogy. Subgrain size piezometry shows that this deformation took place at differential stress between 0.5 and 2 MPa, providing a natural laboratory.
In the undeformed, layered salt from Barradeel we find cm-thick layers of single crystalline halite (Kristalllagen or megacrystals) alternating with fine-grained halite and thin anhydrite layers. The domal salt samples are typical of the well-known "Kristallbrocken" salt, and consist of cm-size tectonically disrupted megacrystals surrounded by fine-grained halite with a grain size of a few mm. We infer high strains in the fine-grained halite as shown by folding and boudinage of thin anhydrite layers, which are internally much less deformed and develop subgrains during dislocation creep. Subgrain size shows comparable differential stresses in Kristallbrocken than in matrix salt. The fine-grained matrix salt is dynamically recrystallized to some extent, has few subgrains and microstructures indicating deformation by solution-precipitation processes. We infer that the finer grained halite deformed dominantly via pressure solution and the megacrystals dominantly by dislocation creep. 

This provides evidence that the fine-grained matrix salt is much weaker than Kristallbrocken because of different dominant deformation mechanisms. This is in agreement with microphysical models of pressure solution creep in which grain size has a significant effect on strain rate at these low differential stress. Our results on the operation of pressure solution creep in rock salt at differential stress of a few MPa point to the importance of pressure solution creep at low differential stresses around engineered structures but also in most salt tectonic settings. We suggest that including results of microstructural analysis can strongly improve engineering models of rock salt deformation. We recommend that this mechanism of grain size dependent rheology is included more consistently in the constitutive laws describing the deformation of engineered structures in rock salt.

1 Introduction

1.1 Salt rheology, deformation processes and associated microstructures - relevance of natural laboratories

Salt - unlike most sedimentary rocks - is very weak and deforms like a viscous fluid, even at low temperatures and shallow depths, and its presence in sedimentary basins fundamentally changes their evolution by salt tectonic processes (Jackson et al., 1994; Urai et al., 2008; Jackson and Hudec, 2017). This has long been recognized for salt diapirs, (Trusheim, 1957; Schultz-Ela et al., 1993; Kakla et al., 2019), salt glaciers (Wenkert, 1979; Talbot, 1979; Talbot and Aftabi, 2004; Závada et al., 2012), salt decoupling (Peel, 2014; Rowan and Krzywiec, 2014; Tămaș et al., 2021), and at a smaller scale for internal salt flow creating folding or boudinage (van Gent et al., 2011; Fiduk and Rowan, 2012; Strozyk et al., 2014; Dooley et al., 2015; Rowan et al., 2019; Adamuszek et al., 2021).

Rock salt is the host of many large engineering constructions like salt caverns and radioactive waste repositories and the long-term operation and abandonment of these structures requires predictions of deformation up to thousands of years (Brouard et al., 2004; Chemia et al., 2009; Brüuer et al., 2011; Baumann et al., 2018). This deformation takes place at differential stresses of below a few MPa, however the measurement of salt rheology in the laboratory is problematic because of the long duration of the required experiments (Brouard et al., 2004; Bérest et al., 2010). Because laboratory experiments are limited in time, they are commonly conducted at relatively high deviatoric stresses and strain rates at which dislocation creep processes are expected.
and inferred to be the dominant deformation mechanism (Wawersik and Zeuch, 1986; Carter et al., 1993; Hunsche and Hampel, 1999; Hampel et al., 2007; Urai and Spiers, 2007; Urai et al., 2008; Hampel, 2016). Therefore, most of the long term predictions of salt deformation have been made based on extrapolation of such experimentally derived power-law creep rheology to low differential stress (Albrecht et al., 1993; Bräuer et al., 2011), although some predictions include both mechanisms (Buijze et al., 2022). However, it has been documented in the geological and materials science literature that below a certain differential stress in rock salt there can be a grain size-dependent dramatic change in deformation mechanism from dislocation creep to pressure solution creep and this can change the creep rate by many orders of magnitude (Urai et al., 1986b; Spiers et al., 1990; van Keken et al., 1993; Spiers and Carter, 1998).

In recent years, the validity of dislocation creep-based extrapolations was extensively discussed in the engineering community, and very slow creep tests were carried out that indeed show much faster deformation than power law creep rates would predict (Popp and Hansen, 2018; Bérest et al., 2019). An important contribution to this discussion comes from materials science, where microphysical processes are related to constitutive laws by state variables such as water content (at grain boundaries), solid solution and second phase impurities and grain size (Carter and Hansen, 1983; Heard and Ryerson, 1986; Urai et al., 1986b; Hunsche et al., 2003; Bérest et al., 2019; Spiers et al., 1990). Recent experiments show that the presence of secondary minerals such as phyllosilicates adds further complexity in the dissolution-precipitation process with potential influence on pressure solution creep rates (Macente et al., 2018; Schwichtenberg et al., 2022).

For steady state and non-dilatant deformation the microphysics-based deformation rate of rock salt is given by following Eq. (1):

\[ \dot{\epsilon}_{DC} = A e^{\frac{Q_{DC}}{RT}} (\sigma_1 - \sigma_3)^n, \]  

(1)

for dislocation creep, and Eq. (2):

\[ \dot{\epsilon}_{PS} = B e^{\frac{Q_{PS}}{RT}} (\sigma_1 - \sigma_3)^m, \]  

(2)

for solution-precipitation creep, with the sum of both being the total strain rate Eq. (3):

\[ \dot{\epsilon} = \dot{\epsilon}_{PS} + \dot{\epsilon}_{DC}. \]

(Wawersik and Zeuch, 1986; Spiers et al., 1990; Carter et al., 1993; van Keken et al., 1993; Hunsche and Hampel, 1999; Urai et al., 2008). Thereby A and B are material constants, \( Q_{DC} \) and \( Q_{PS} \) are apparent activation energies for dislocation creep and pressure-solution creep, \( R \) is the gas constant, \( T \) is absolute temperature, \( \sigma_1 - \sigma_3 \) is the differential stress, \( D_p \) is the grain size and \( n \) and \( m \) are stress and grain size exponents. For a compilation of parameters for the two mechanisms, we refer to Urai et al., 2008 and references therein (e.g. Spiers et al., 1990; van Keken et al., 1993; Brouard and Bérest, 1998; Hunsche and Hampel, 1999; Hunsche et al., 2003).
Because of the large differences in the stress and grain size exponents of the two mechanisms, pressure solution creep will dominate deformation at low differential stress and small grain size and dislocation creep will dominate deformation at high differential stress and large grain size. Key parameters in the evolution of grain size are the structure and mobility of brine-filled grain boundaries, which can change as a function of differential stress (Drury and Urai, 1990; van Noort et al., 2008); and the migration of grain boundaries, which can change the grain size (Urai et al., 1986a; Peach et al., 2001; Schenk and Urai, 2004; Schenk et al., 2006; Schmatz et al., 2011).

Because of the extremely long experiments (several years) required to measure pressure solution creep rates in rock salt at low differential stress (Bérest et al., 2019) and the very small strains reached in these experiments, it is useful to compare these results with naturally deformed samples. The differential stresses during natural deformation can be measured using subgrain size piezometry and are commonly found to be between 0.5 and 5 MPa (Carter et al., 1982; Schléder and Urai, 2005; Leitner et al., 2011; Rowan et al., 2019), but to much higher strains than can be achieved in low stress laboratory experiments. In addition, relative differences in rheology can be measured in layered salt (Talbot, 1979; Carter et al., 1982; Schmalholz and Podladchikov, 2001; Schléder and Urai, 2005; Hudleston and Treagus, 2010; Leitner et al., 2011; Komoróczii et al., 2013; Zulauf et al., 2014; Závada et al., 2015; Schmalholz and Mancktelow, 2016; Adamszuck et al., 2021; Schléder and Urai, 2007).

Microstructural observations of naturally deformed samples show that dislocation creep, dynamic recrystallization and pressure solution creep can be readily distinguished, indicated by plastic crystal deformation forming slip bands and subgrains (dislocation creep), grain boundary migration recrystallization, crystal overgrowth (dynamic recrystallization) as well as growth bands and crystal elongation (pressure solution creep) (Desbois et al., 2010, 2012; Závada et al., 2012, 2015).

1.2 Kristallbrocken-salt

The Kristallbrocken salt in the Zechstein II (Stassfurt Formation in Germany) is a well-known tectonite in the Permian Basin. Richter-Bernburg (1953) described Trümmersalze (German: ‘Trümmersalze’ = debris salt) with Kristallbrocken (German: ‘Kristallbrocken’ = crystal fragments) salt as large, sharp-edged crystals porphyroblasts/porphyroclasts inside a fine recrystallized matrix (Küster et al., 2008). Vintage mine photographs from Northern Germany show layer-parallel boudins of Kristallbrocken, large rotations of fragments and regular boudinage in multiple 20 cm thick layers (Richter-Bernburg, 1953; Simon, 1972). It is interpreted to have formed out of a layer cake by sedimentation of fine-grained matrix salt layers of single crystalline halite (German: ‘Kristalllagen’ = crystal layer (Seidl, 1914)), and thin anhydrite layers. Although the genesis of extraordinary large Kristalllagen is not clear, different models have been proposed that suggest post-sedimentary diagenetic grain growth or coalescence of fine grained halite (Küster et al., 2011), by deformation resulting of the formation resulted in an augen-like structure, with the Kristallbrocken decreasing in size with tectonic strain (Küster et al., 2008, 2009; Urai et al., 2019). Pape et al., (2002) presented samples from the Gorleben salt dome and showed that the depositional setting of ‘Kristalllagen’ halite was shallow marine based on the occurrence of abundant fluid inclusion trails in chevron patterns.

Another argument for Kristallbrocken being fragments from a primary layering is based on observations of internal laminations of fluid and solid inclusions (Richter-Bernburg, 1953; Simon, 1972; Pape et al., 2002). Following earlier interpretations,
(Richter-Bernburg, 1953; Simon, 1972), Pape et al. (2002) hypothesized that rupturing of halite crystal layers is attributable to early diagenetic destruction of layers from subaquatic gliding. This is in contrast to other interpretations (Löffler, 1962) were the so-called Augensalz (another name for Kristallbrockensalz) is interpreted to have formed from rupturing of halite crystal layers during tectonic flow, with clear halite crystallizing in the boudin necks. Extensive studies of distribution of bromide content, Kristallbrocken texture and microstructure, abundant sulphate and fluid inclusions in Kristallbrocken and interpretation of their formation and deformation mechanisms were presented by Küster et al. (2008, 2009, 2011; Küster, 2011). The structural characteristics of the Kristallbrocken salt were attributed to brittle deformation, dislocation glide and a strong competence contrast between porphyroclastic Kristallbrocken salt and fine-grained mylonitic matrix halite (Küster et al., 2010). Küster et al. (2009) described the matrix halite and inferred a secondary and dynamically recrystallized microstructure of sub-structured and sub-structure free grains. Lobate grain boundaries were interpreted to have formed by grain boundary migration recrystallization and it was later stated that due to the lack of crystallographic preferred orientation and high water contents fluid assisted solution-precipitation creep or grain boundary migration might have been controlling factors for the dominant deformation mechanisms (pg. 139 in Küster, 2011). It was hypothesized that second phase inclusions, large grain size and the monocristallinity of Kristallbrocken contribute to the observed rheology contrasts (Küster et al., 2008). In a more recent report from the KEM-17 study (Urai et al., 2019) boudinaged and folded anhydrite layers as well as boudinaged Kristallbrocken surrounded by recrystallized halite and original fine-grained halite were described in Zuidwending and Winschoten samples.

1.3 Aim of the study

In this study we build on the observations briefly reviewed above, and add our new observations on samples with Kristalllagen and Kristallbrocken from the Zechstein of the Netherlands (Fig. 1), and hypothesize that the large competence contrast and different deformation styles between Kristallbrocken and fine-grained matrix is caused by the different microphysical deformation mechanisms, with dislocation creep and ductile rupturing (boudinage) being dominant in the Kristallbrocken, and grain size dependent pressure solution creep being dominant in the fine-grained matrix. If this hypothesis is supported by our data, it provides further evidence for the operation of grain size-dependent creep in rock salt at the conditions relevant for the operation of engineered structures in rock salt.

2 Materials and Methods

We studied 21 samples from drill cores from the areas of Barradeel (BAS), Pieterburen (PBN), Zuidwending (ZW) and Winschoten (WSN, near Heiligerlee) Zechstein salt structures (Fig. 1). We use the term domal salt to refer to the subsurface diapirs in the Zechstein basin. BAS, ZW and WSN samples were collected and prepared for the KEM-17 study without gamma irradiating them (Urai et al., 2019). The samples were selected in the TNO central core storage facility in Zeist and core shed.
of the mining company (BAS). They were cut perpendicular to the bedding in a dry laboratory with a diamond saw cooled by a small amount of slightly undersaturated salt brine to reduce mechanical damage (Schléder and Urai, 2005).

To decorate crystal defect structures in NaCl, samples were irradiated in the research reactor FRM-II at the TU Munich in Garching with varying dose rates between 6 and 11kGyh⁻¹ to a total dose of 4MGy at a constant temperature of 100 °C (Urai et al., 1986b; Garcia Celma et al., 1988; Schléder and Urai, 2005, 2007). Thin sections of un-irradiated samples were dry-polished to a thickness of approximately 1 mm, and gamma-irradiated thin sections were dry-polished to a thickness of approximately 50 μm to reach optical transparency. To decorate grain boundaries and subgrain boundaries, the samples were chemically etched with slightly undersaturated brine which was removed with a jet of n-hexane using the technique described in (Spiers et al., 1986; Urai et al., 1987). The thin sections were imaged in reflected and transmitted light using a Zeiss optical microscope (Axioscope) with the stitching panorama function of the ZEN imaging software. Reflected light panoramas with 25x magnification were used for grain boundary digitization (Fig. 3) after making sure that the grain size distribution is sufficiently well captured.

Halite grain and subgrain boundaries were manually traced with a touch pen and tablet for statistical analysis. Grain and subgrain sizes for piezometry were analyzed with Fiji (Schindelin et al., 2012) and calculated as equivalent circular diameter (Schléder and Urai, 2005; Lopez-Sanchez and Llana-Fúnez, 2015) and differential stresses σ were calculated as follows according to (Carter et al., 1993; Schléder and Urai, 2005)

\[ \sigma = 107 \cdot D_{SG}^{-0.87}, \]

Electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDS) mapping has been used to identify the chemical composition and distribution of second phase impurities in halite. We used an Oxford Instruments X-Max 150 EDS system at the Institute of Structural Geology, Tectonics and Geomechanics (RWTH Aachen University) at 15 kV acceleration voltage. The samples were sputter-coated with approximately 7 nm of tungsten for conductivity.

Crystallographic orientations were measured by means of Electron Backscatter Diffraction on one thin section using a Symmetry EBSD camera by Oxford Instruments attached to a GeminiSEM 300 SEM by Carl Zeiss Microscopy. The measurement was performed at an acceleration voltage of 20 kV and a probe current of approximately 10nA. To avoid charging of the uncoated specimen, the analysis was performed in variable pressure mode using Nitrogen at a pressure of 30 Pa in the sample chamber. In a first measurement series, approximately half of the entire thin section was scanned by 30 small measurement areas with a step size of 20 μm, which afterwards were manually merged to a large dataset, finally covering an area of approx. 1.8 cm x 3 cm. The central Kristallbrockensalz region was subsequently measured again with higher spatial resolution by four measurements using a step size of 5 μm, which after merging covered an area of approximately 0.7 cm x 1.4 cm. All EBSD data were collected and indexed in “refined accuracy” mode with AZtec V 5.1 by Oxford Instruments. The final indexed datasets were further evaluated with OIM Analysis V 8.0 by Ametek-EDAX.
Prior to the electron microscopical investigations, the samples were freshly polished and etched again using the method described above, and coated with tungsten (in the case of the EDX measurements) or left uncoated (in the case of the EBSD measurements).

Qualitative X-ray diffraction analysis (XRD) measurements to identify impurity content were performed on a Bruker D8 equipped with a graphite monochromator and a scintillation counter. Scans were measured with Cu–Kα radiation.

3 Results

3.1 Relatively undeformed Barradeel samples

The Zechstein salt at Barradeel is sub-horizontally layered as seen on seismic (Strozyk et al., 2014; Barabasch et al., 2019) and has a total thickness of 800 m with a 580 m thick Z2 salt at a depth of up to 3 km based on well data (BAS-01, Kaart boringen | NLOG, 2022). Salt cores have mostly sub-horizontal layering except for sample KS-15 where layering is vertical, indicating local folding, which is common in these settings (Fig. 2a, b).

The salt is layered with cm-scale milky to honey-colored halite layers interbedded with mm thick anhydrite bands (Fig. 2a). There are large variations in grain size of halite, with 1 to 5 cm thick single megacrystal layers (Kristalllagen) alternating with layers of fine-grained (about 3 mm) and very fine-grained (about 0.2 mm) halite layers (Fig. 2a, c).

Kristalllagen are clear or milky with internal laminae (Fig. 2a, b) due to variable content of fluid and solid inclusions of sulphate minerals (Fig. 2e) as previously described (Simon, 1972; Küster et al., 2011). The Kristalllagen have bedding perpendicular or inclined cleavage cracks without displacement of layering, the cracks presumably caused by drilling (Fig. 2a, c). However, in sample KS-15 the Kristalllage is displaced by a few mm along cracks next to small folds in anhydrite bands (Fig. 2b, d) which points to tectonic origin. Gamma decoration in Kristalllagen is mostly homogenous blue (Fig. 2c, d), except for a few dark laminae which are interpreted as healed cracks in sample KS-07 that show the same orientation as an open crack in the same crystal. A Kristalllage in sample KS-07 has abundant slip bands oriented at 45 degrees to the cleavage crack, consistent with slip on the [110] system (Fig. 2c). Kristalllagen are subgrain-free as seen in reflected light on etched surfaces (Fig. 2c). In sample KS-16 (Fig. 2d) microstructures are very similar, with thicker anhydrite laminae. Cellular structures formed by dark blue gamma decoration (Fig. 2e) locally coincide with barely visible subgrain boundaries on etched surface (Supplement 1), but do not correspond to the abundant inclusions. Some megacrystals have single 1 mm large subgrains with small angle misorientation of slip bands and hopper crystal cores indicated by arrays of cubic fluid inclusions with fluid and gas bubbles (Supplement 1). The fine- and very fine-grained halite grains are equigranular, in layers of two distinct grain sizes classes of fine-grained (about 3 mm) and very fine-grained (about 0.2 mm) (Fig. 2c, g, h, Supplements 1). Grain boundaries are slightly curved forming 120° angles at triple junctions (Fig. 2f, h). In reflected light, etched surfaces show that the only porosity in the salt is that of isolated fluid inclusions in grain boundaries (Supplement 1). Fine-grained Halite grains have white cores and blue growth structures.
bands visible through gamma decoration (Fig. 2c, g). Most grains have bright crystal cores with characteristic arrangement of cubic and chevron shaped fluid inclusion trails and abundant impurities (Fig. 2g).

The layers with very fine grain sizes are rich in dispersed anhydrite and polyhalite (0.1 to 1 mm) located usually at grain boundaries (Fig. 2c, f, g, h).

Anhydrite layers of up to 5 mm thickness consist of µm to mm-sized anhydrite and polyhalite grains and occasionally include 0.1 to 1 mm sized halite crystals (Fig. 2c, d, g, h). These layers are straight or locally folded and continuous.

3.2 Diapiric salt samples from Pieterburen, Winschoten and Zuidwending

The studied Z2 rock salt comes from cores of 3 different salt diapirs (Winschoten (WSN), Zuidwending (ZW) and Pieterburen (PBN) (Juez-Larré et al., 2019). Base salt reaches a depth of 3000 m and the salt pierces the overburden up to depths of 100 m as in the case of Zuidwending diapir (Geluk et al., 2007). The bedding as seen in core is mostly vertical, strongly deformed with the older Z2 salt in the center of the sampled diapirs, except for Pieterburen structure, where the younger salt is in the center (Geluk et al., 2007). The samples come from 260 m to 1800 m depth.

The deformed diapiric salt consists of Kristallbrocken, surrounded by fine-grained and very fine-grained matrix halite and folded or boudinaged anhydrite bands (Fig. 3a) together with dispersed anhydrite and polyhalite inclusions, also confirmed by XRD measurements (Supplement 5). These inclusions locally have a lighter blue-colored halite rim but in the majority of cases the inclusions are not associated with color changes in the surrounding halite crystal. The rock salt has a typical gneissic appearance consistent with earlier descriptions of Kristallbrockensalz (Küster et al., 2008, 2011 and references in these).

The Kristallbrocken megacrystals are between 5 mm and 3 cm thick (comparable to the thickness of Kristalllagen in Barradeel) with a strongly elongated shape up to decimeters long (possibly longer but this could not be confirmed due to limitations of core dimensions (Fig. 4a-d). Kristallbrocken grains can be correlated to adjacent ones by thickness, inclusion content and crystallographic orientation (EBSD data, see below and Fig. 3a, Fig. 4, Fig. 5). In a number of cases, Kristallbrocken can be seen to contain a fracture along which the two megacrystals are displaced, and in other cases the two megacrystals are boudinaged with the boudin necks filled with inclusion-free overgrowth on the megacrystals, or with fine-grained matrix halite in the boudin-neck (Fig. 3a, Fig. 4).

A good example is presented in Figure 4d (BS-A), where two 1 cm thick Kristallbrocken parts can be correlated by thickness, enrichment of inclusions in the upper part and adjacent anhydrite bands. The 2 cm boudin neck contain epitaxially grown (see EBSD below), inclusion free halite from both crystals and fine-grained halite matrix (Fig. 4d). Both inclusion free overgrowths also have lighter blue gamma irradiation color. Two adjacent thin Anhydrite layers are also discontinuous, in coherence with the boudinaged Kristallbrocken. A 3 cm thick Kristallbrocken below is also displaced and has a small inclusion free overgrowth. Both inclusion free parts of the crystal also have lighter blue gamma irradiation color.

Gamma-decorated slip bands and subgrains are present in all Kristallbrocken, visible as white or dark blue subgrain boundaries and in reflected light on etched surfaces (Fig. 5a, Supplements 2). Subgrain sizes are on average 100 to 200 µm (Table 1 and...
subgrains can be either rounded or elongated with preferred orientation of subgrain boundaries forming a subgrain boundary network. Figure 5d shows one of the interpreted subgrain networks together and Table 1 shows the subgrain size statistics of all samples. Images of all other samples are included in the Supplement 2, together with their interpretation and subgrain size distribution. An interesting aspect of the subgrain boundary network is the locally fibrous morphology in the overgrowths in boudin necks, these are interpreted as grown in subgrains ([Fig. 5](Means and Fee, 1988). Planar arrays of fluid inclusions are present in some Kristallbrocken (Fig. 5a). These are interpreted to be healed microcracks (Supplement 1). All Kristallbrocken contain dispersed inclusions of anhydrite and/or polyhalite and/or brine (Fig. 5a-f, Fig. 6), very similar to those observed and discussed by [Küster et al., 2011].

The fine-grained matrix halite has a grain size of approximately 1 mm (Fig. 7). Halite grains are mostly elongated (KS-06, Kbx1, BS-B, Fig. 3]). The fine-grained matrix halite grains commonly have white cores and blue rims (BS-A, KS-13A, KS-05, kbx2, Fig. 3, Fig. 4b, d, Fig. 5g). An interesting observation is that in some of these grains (Fig. 5g), which are elongated, the white core has the blue overgrowth only in the direction of elongation (eg. pg. 36 in Supplement 1). Very fine-grained matrix halite grains are equiaxed with similar white core and blue mantle as the fine-grained matrix halite, and are associated to high fraction of impurities which have grain sizes of approximately 0.2 mm (KS-13A and B, Fig. 4b).

While in the Barradeel samples the boundary between the Kristalllagen and the fine-grained halite is sharp, in the [domal salt this boundary is less sharp, and the fine grains (without subgrains) are locally also present in the Kristallbrocken around their edges. (KS-02, KS-11, KS-08, Fig. 3]). These are interpreted to have formed by fluid-assisted grain boundary migration recrystallization, following the interpretation of [Küster et al., (Küster et al., 2008, 2011). The recrystallizing halite grains are free of fluid inclusions, with occasional second phase inclusions at grain boundaries (BS-A, KS-13A, KS-13B, KS-05 and KS-02, Fig. 4b, d, Fig. 5b, e, f). Such recrystallized parts and the presumed primary fine-grained matrix halite cannot clearly be distinguished and results grain size measurements regarding fine-grained matrix halite in Figure 7 comprise both classes, referring to the halite-labelled grains in Figure 3. The grain boundaries in halite in all samples are rich in fluid inclusions and occasional second phase inclusions. In contrast to the observations of [Küster et al., 2008], subgrains are infrequent in fine-grained salt in the samples studied, making up less than 1 % of total matrix halite volume. When possible, subgrains were digitized (Fig. 3, Supplement1) and piezometry results are presented in Table 1.

Thin anhydrite layers, when enclosed in fine-grained or very fine-grained matrix halite, are strongly deformed by folding and boudinage, together with the enclosing fine-grained or very fine-grained matrix halite. The concentric folding in sample KS-13A (Fig. 4b) indicates that the viscosity of the Anhydrite is much higher than that of the surrounding halite (Adamuszek et al., 2011, 2021). These structures indicate that the matrix halite was clearly much stronger (more strongly) deformed than the Kristallbrocken. Anhydrite layers directly adjacent to Kristallbrocken are much less deformed but are ruptured together with the Kristallbrocken to form coherent boudins.
3.3 EBSD results

EBSD data from sample BS-A are presented in Figure 8. Figure 8a shows Inverse Pole Figure Maps for the points indexed as halite with respect to the horizontal direction and the direction perpendicular to the image plane, respectively. The large Kristallbrocken grains are labelled with 1-5. The two parts of the halite boudin show different crystallographic orientation with a deviation of approximately 60° in the horizontal plane. Further each Kristallbrocken (1-5) has different crystallographic orientation (Fig. 8a). Figure 8b shows pole figures of the matrix halite after excluding these 5 Kristallbrocken grains from the calculation. The small orientation distribution densities (< 1.8 times random) show that the fine-grained matrix halite has no significant crystallographic preferred orientation (CPO), especially considering the fact that with approximately 60° in the horizontal plane (315-305-300-295-290-285), the matrix can be similar or quite different, despite showing the same microstructure.

3.4 Comparison to previous studies

Our observations of the Kristallbrockensalz samples correspond closely with those of earlier studies, the most extensive of which is the work of Löffler (1962) on samples from the same stratigraphic unit, but several hundred km further towards the basin interior. The key shared observations of both studies are: internally deformed megacrystals with solid (polyhalite and anhydrite) and fluid inclusions, subgrains between 0.05 and 0.5 mm, and ruptured in extension to form boudins with dissolution-precipitation in the boudin necks. These megacrystals are surrounded by finer grained halite, with a grain size around 1 mm, with some grains containing subgrains and others being subgrain-free. Solid solution content of Bromide in Kristallbrocken and matrix can be similar or quite different, despite showing the same microstructure. Grain boundaries contain fluid inclusion arrays, and the matrix contains boudinaged and strongly folded thin anhydrite layers indicating high strain in the matrix. Following the interpretation of Löffler (1962) we interpret rupturing of boudins to be tectonic and in fass
tresses that cannot be generated close to the surface, not before the onset of salt tectonic deformation, and not stallinity (large grain size) and the abundant inclusions in Kristallbrocken by restricting dislocation mobility occurring phenomenon in the Zechstein basin. However, our observations have added to the data of Küster et al. (2008, 2011), by providing high resolution microstructures of Gamma-irradiated samples, and crystallographic orientation data by EBSD. In reflected light micrograph we measured subgrain and grain size distributions (Supplement 2, Table 1, Figure 7). The measured grain sizes were comparable, but slightly smaller than grain sizes measured on similar samples from the KEM-17 report (Urai et al., 2019) and stresses from piezometry between 0.8 MPa and 1.5 MPa (Urai et al., 2019) also fit to our observations. We have also shown that subgrains in fine-grained halite are slightly smaller than subgrains in the associated Kristallbrocken (Figure 10). Based on results of both studies we also conclude that Kristallbrocken deformed by dislocation creep and that there is a large rheology contrast between Kristallbrocken and matrix, a widely occurring phenomenon in the Zechstein basin. However, our results of the Barradeel samples (which we interpret as an undeformed equivalent of the diapirc salt samples) clearly show that much of the fine- and very fine-grained halite was already present before the onset of salt tectonic deformation, and not only formed by recrystallization of the Kristallbrocken. Because Küster et al. (2008, 2011) did not investigate undeformed equivalents, she did not have access to this information. The original hypothesis by Küster et al. (2008, 2011) implies that the matrix salt is dynamically recrystallized equivalent of the Kristallbrocken, and deforms by equal contributions of dislocation creep and pressure solution creep (De Bresser et al., 1998; de Bresser et al., 2001; Ter Heege et al., 2005a, b). If this is the case, the predicted weakening would be relatively small (a factor of 2 in strain rate at the same differential stress) and could not explain the large differences in strain between Kristallbrocken and matrix. Additionally, if one would take the mean grain sizes from the matrix (Figure 7), assume that these are recrystallized grain sizes, and then apply the recrystallized grain size piezometer from Ter Heege et al., (2005a), one would get unrealistically high stresses between 5 and 10 MPa for the deformation. This effect large differences in strain could not formed diagenetically diagenetic from subaquatic gliding, although we cannot completely exclude fractures during diagenesis, the presence of abundant subgrains in Kristallbrocken require differential stresses that cannot be generated close to the surface, and this deformation is consistent with formation of boudins.

The interpretation of these observations by Küster et al. (2008, 2011) was that Kristallbrockensalz resemble porphyroclasts in gneissic or mylonitic rocks with a strong rheology contrast between Kristallbrocken and matrix. Kristallbrocken formed from Kristalllagen (of diagenetic origin) by plastic deformation with active [110] slip accompanied by subgrain formation, and by rupturing in extension, while the matrix salt was weaker and more strongly deformed than the Kristallbrocken and deformed by dislocation creep and dynamic recrystallization. We measured subgrain size in the studied micrographs and found comparable average subgrain sizes of 188 µm (n=68) in Kristallbrocken (Fig 2.10 in Küster, 2011) and 234 µm (n=22) in matrix halite (Fig. 7f in Küster et al., 2008), both from Teutschenthal, that indicate similar differential stresses. stress values of a few MPa found is when compared to our samples (Table 1, Figure 10). The same studies also suggest that matrix halite was secondary, replacing Kristallbrocken by recrystallization. The inferred strong rheology contrast was suggested to be related to ‘monocrystallinity’ (large grain size) and the abundant inclusions in Kristallbrocken by restricting dislocation mobility (Küster et al., 2008).

Our observations have added to the data of Küster et al. (2008, 2011), by providing high resolution microstructures of Gamma-irradiated samples, and crystallographic orientation data by EBSD. In reflected light micrograph we measured subgrain and grain size distributions (Supplement 2, Table 1, Figure 7). The measured grain sizes were comparable, but slightly smaller than grain sizes measured on similar samples from the KEM-17 report (Urai et al., 2019) and stresses from piezometry between 0.8 MPa and 1.5 MPa (Urai et al., 2019) also fit to our observations. We have also shown that subgrains in fine-grained halite are slightly smaller than subgrains in the associated Kristallbrocken (Figure 10). Based on results of both studies we also conclude that Kristallbrocken deformed by dislocation creep and that there is a large rheology contrast between Kristallbrocken and matrix, a widely occurring phenomenon in the Zechstein basin. However, our results of the Barradeel samples (which we interpret as an undeformed equivalent of the diapirc salt samples) clearly show that much of the fine- and very fine-grained halite was already present before the onset of salt tectonic deformation, and not only formed by recrystallization of the Kristallbrocken. Because Küster et al. (2008, 2011) did not investigate undeformed equivalents, she did not have access to this information. The original hypothesis by Küster et al. (2008, 2011) implies that the matrix salt is dynamically recrystallized equivalent of the Kristallbrocken, and deforms by equal contributions of dislocation creep and pressure solution creep (De Bresser et al., 1998; de Bresser et al., 2001; Ter Heege et al., 2005a, b). If this is the case, the predicted weakening would be relatively small (a factor of 2 in strain rate at the same differential stress) and could not explain the large differences in strain between Kristallbrocken and matrix. Additionally, if one would take the mean grain sizes from the matrix (Figure 7), assume that these are recrystallized grain sizes, and then apply the recrystallized grain size piezometer from Ter Heege et al., (2005a), one would get unrealistically high stresses between 5 and 10 MPa for the deformation. This effect large differences in strain could
also be enhanced by the presence of solid inclusions in the Kristallbrocken as proposed by Küster et al. (2008, 2011), however this would lead to larger density of dislocation around the inclusions with corresponding darker color after Gamma-irradiation (Garcia Celma et al., 1988) which was not observed. Finally, solid solution impurities could make the Kristallbrocken more competent (Heard and Ryerson, 1986). The most common solid solution impurity in halite is Bromide (Küster, 2011) but the Kristallbrocken in a previous study have a comparable structure in samples where Bromide concentration in Kristallbrocken is the same as in the matrix, and in samples where the Bromide concentrations are different (Küster, 2011), again not supporting this hypothesis. However, we note that a more extensive analysis of solid solution impurity in these samples would help to further test this hypothesis. Another effect that may make the Kristallbrocken stronger is the presence of adjacent thin anhydrite layers which can form a stronger sandwich - however microstructures with or without sandwiched Anhydrite layers are very similar so this effect cannot be major either (samples BS-A, KS-13A in Fig. 32).

4.2 Grain size dependent dominant deformation mechanism and rheology contrast

Here we present an alternative hypothesis to explain the rheology contrast: we propose that the matrix deformed by dominant pressure solution creep while the Kristallbrocken deformed by dislocation creep. Because pressure solution creep is strongly grain size-dependent (see eq. 2), this difference is caused by the large difference in grain size between Kristallbrocken and matrix, that we interpret to be sedimentary or early diagenetic, somewhat modified by dynamic recrystallization. Evidence for dominant pressure solution creep in the fine-grained and very fine-grained matrix is provided by the oriented overgrowth structures-bands (Poirier, 1985) (Fig. 5g), the epitaxial overgrowths in boudin necks (Fig. 4d) and the absence of crystallographic preferred orientation as shown by EBSD (Fig. 8). Examples of rock salt microstructures indicating pressure solution creep were presented by (Desbois et al., 2010; Závada et al., 2012), our microstructures are very similar to these. The presence of abundant fluid inclusions on grain boundaries and the evidence for fluid-assisted grain boundary migration recrystallization in both studies show that the required fluid is widely available in this stratigraphic unit. The studied diapiric samples have comparable mean grain sizes in the fine-grained salt around 1 or 2 mm (Fig. 7), while folding of anhydrite layers was best observed in Zuidwending samples and overgrowth in boudin necks is especially pronounced in Pieterburen samples (Fig. 3, 4).

To quantify the stress-strain rate conditions corresponding to this hypothesis, in Figure 9 we plotted the data from this study in a differential stress vs strain rate diagram, for a reference temperature of 60 °C. For dislocation creep, we used the BGR-recommended values (Liu, W. et al., 2017; Eickemeier et al., 2021; Popp, 2022) for Kristallbrockensalz, together with a small selection of characteristic values for rock salts from the Kriecklassen (German: ‘Krieckklasse’ = ‘creep classes’), and plotted our samples for the values of differential stress obtained from subgrain size piezometry, using the grain sizes of Kristallbrocken and matrix to estimate the expected strain rates. It can be seen that the corresponding strain rates differ by four orders of magnitude, in agreement with the inferred large differences in strain between Kristallbrocken and matrix.
4.3 Dynamic recrystallization and grain boundary mobility

The dynamic recrystallization of Kristallbrocken is also recognized in our samples, mainly grains directly next to Kristallbrocken (Fig. 4b, d, Fig. 5b, e, f), with a very interesting change of the solid inclusions present in the Kristallbrocken - these are completely reworked by grain boundary migration (Figure 5e) and not present in the same configuration in the new grains. However, in our interpretation the fraction of newly recrystallized grains in the matrix is relatively minor, and grain size is similar to the ones already present in the undeformed samples: providing the small grains for pressure solution creep. The small grain size in the matrix is interpreted to be pre-deformational as in relatively undeformed Barradeel samples; hardly influenced by dynamic recrystallization as seen by rare abundance of only minor subgrains and a small grain size which would indicate unrealistic high differential stresses when plotted in the (Ter Heege et al., 2005a) recrystallized grain size piezometer (cp. 4.1 Comparison to previous studies). Recrystallization reduces the grain size of large Kristallbrocken single crystals and increases the relative content of finer grained salt. Overgrowth of large Kristallbrocken crystals (increasing their size) has been observed in boudin necks. Hopper crystals indicating primary grains (Pape et al., 2002) were preserved in some BAS samples, but not found in highly deformed domal salt. The relatively minor amount of newly recrystallized grain fraction in the strongly deformed diapirc salt samples is interesting, and suggests that grain boundary mobility in nature is lower than in the models of (Peach et al., 2001; Schléder and Urai, 2005) and that recrystallization and grain growth in salt is more sluggish than previously thought.

The relatively minor newly recrystallized fraction in the strongly deformed diapirc salt samples is interesting, and suggests that grain boundary mobility in nature is lower than in the models of (Peach et al., 2001; Schléder and Urai, 2005) and that recrystallization and grain growth in salt is more sluggish. Our data do not provide sufficient information to investigate this quantitatively, but we suggest that further work along these lines is interesting.

4.4 Kristallbrockensalt bulk rheology

It is interesting to speculate on the deformation of initial layered salt with the very long Kristalllagen. In simple shear during shearing, this rock must have had an extremely anisotropic rheology due to the weak fine-grained and very fine-grained salt depending on the orientation of the original layering with respect to the shortening direction. However, in coaxial deformation the Kristalllagen could have carried most of the stress in the salt rock and deformed accordingly by dislocation creep (Bons and Urai, 1994). Once the Kristalllagen were sufficiently fragmented, the rheology of the Kristallbrockensalt becomes a mixture rheology (Bons and Urai, 1994) such that when the Kristallbrocken can form a load-bearing framework, the rock salt deforms by power law creep dominated by dislocation creep in the Kristallbrocken, but when there is sufficient matrix present, the rock salt deforms by Newtonian viscous creep dominated by pressure solution (Jessell et al., 2009). Based on subgrain size analysis we inferred similar differential paleostresses in Kristallbrocken and matrix halite (Fig. 1044, even though we had limited number of measurements in matrix halite) which suggest that in our samples the second model was dominant.

Commented [336]: Zavada: No! Really? Where is this described? I need to look myself where these features might be shown. The reader would not be able to see this in the figures referenced at a first glance the undeformed and deformed inclusions are not shown near to each other (e.g. Fig. 5a next to 5e). Provide accurate description in the text and figure captions (e.g. 5e solid inclusions are stretched).

Answer: done in Figure caption 5e.

Commented [337]: Bress101: See my main comment. I propose that the authors are more clear on the observations regarding recr in the matrix and underpin their interpretation that the small grain size in the matrix is pre-deformation, hardly influenced by dynamic recr and implying pressure solution creep (and no disloc creep).

Answer: We have elaborated to be more clear.

Commented [338]: Zavada: I suggest that this sentence is not needed, append the previous sentence to the previous paragraph.

Answer: ok.

Commented [339]: Zavada: You mean simple shear, where the layering of salt is parallel to the shear plane, right? I quite do not agree with the statement in this sentence. You say the rock salt formation is layered and therefore mechanical anisotropic, but it will be anisotropic in both, the simple shear and pure shear in the same way. These deformation modes are equivalent, the type (normal shear zones or folds) and shape of deformation structures depends on orientation of the original layering with respect to the shortening direction.

I also do not think that the load bearing framework would form during compression perpendicular to the layering. The boudins will never touch each other to form such framework. You will always get an interconnected weak layer.

Answer: We agree that the anisotropy will effect in both types of shearing, we have modified the text accordingly.

Commented [340]: Zavada: I guess that this part of the discussion is far-fetched from the main results. It is hard to evaluate on these speculations, because this larger scale aspect was not studied.

In contrast, the comparison of the microstructures from the different diapirs studied is completely missing - you sample Winschoten, Zuidwending, and Pieterburen. How the difference in the microstructures from cores taken in these diapirs inform you about the rheology of these layered rock salt sequences???
The different crystallographic orientation of individual Kristallbrocken with respect to the bedding (Fig. 8a) has not been studied previously and might contribute to the understanding of Kristalllagen formation (Küster, 2011). The absence of a crystallographic preferred orientation of individual Kristallbrocken neither promotes nor prevents the activation of different slip systems and hence would not significantly influence the bulk rheology (Linckens et al., 2016). However, to substantiate this observation and hypothesis more studies of Kristallbrocken crystallographic orientation with respect to bedding on different samples are required.

4.5 Implication of halite grain size of our results to engineering predictions

In current constitutive models of salt engineering (Albrecht et al., 1993; Hunsche et al., 2003; Bräuer et al., 2011; Kukla et al., 2011; Liu, W. et al., 2017; Popp, 2022) it was long recognized that the creep strain rate of rock salt (as measured at relatively high differential stress) can show several orders of magnitude differences, at the same differential stress and temperature. Based on an extensive dataset, such observations provided the basis for the definition of Kriechklassen which were used to model the evolution of engineered structures (Liu, W. et al., 2017) and are still used to describe a non-Newtonian rheology in salt tectonics numerical modeling (Granado et al., 2021). However, as has been reviewed above, extrapolation of these data to low differential stress predicts orders of magnitude lower creep rates than measured in experiments (Brouard and Bérest, 1998; Bérest et al., 2019) and predicted by microphysical models of pressure solution creep (Spiers et al., 1986; Urai et al., 1986b; Spiers et al., 1990). Integration of these mechanisms into engineering constitutive equations is sometimes conducted (e.g. Zill et al., 2022; Buijze et al., 2022). However, because it requires data on the grain size of the rock salt to be modelled, is usually not available, these could still be improved considerably together with microstructural characterization, and we recommend to include grain sizes in engineering predictions and create based on grain size-dependent pressure solution-creep classes.

5 Conclusion

In this study, we present examples of flat-lying and diapiric Zechstein salt from the same formation (Z2), which was naturally deformed under low differential stresses between 1 and 2 MPa, providing a natural laboratory to study salt rheology under conditions which are difficult to study in the laboratory but relevant for predicting the evolution of engineered structures over long time scales. The gneissic Kristallbrocken salt deforms by dislocation creep and pressure solution processes depending on the grain size. The fine-grained matrix halite is weaker and deforms with a higher strain rate by pressure solution and dynamic recrystallization while the Kristallbrocken mega grains tectonically boudinage and deform by dislocation creep. We infer that this large rheology contrasts in halite deformation at low differential stresses is caused by grain size-dependent dissolution-precipitation creep.
At present, grain size measurements are not available for most of the Zechstein salts used in salt engineering, and we recommend the creation of a salt microstructure knowledge base which will help predict creep rates at low differential stress.

Further studies to better define solid solution impurity contents, the role of mineral impurities and the contribution of dynamic recrystallization with grain boundary migration to solution precipitation processes will help to test the operating deformation mechanisms in more detail.

Supplements

1. Additional Micrographs
2. High resolution sample overview scans, piezometry images and results
3. EBSD material
4. BIB-SEM material
5. XRD analysis results

Data availability statement

The supplementary material has been uploaded to Zenodo repository and is available at https://doi.org/10.5281/zenodo.6839080

Author contribution

JB carried out the study and designed figures. JLU and JS designed the study. JK and JLU selected samples. AS did EBSD measurements and Figure 8. JB and JLU prepared the manuscript with contributions from all co-authors, which were also all involved in scientific discussions.

Competing interests

The authors declare that they have no conflict of interest.
Acknowledgements

We would like to acknowledge support of Nedmag Industries and RWTH Aachen University funding for completion of this study. Sample preparation of Werner Kraus was much appreciated. We further thank Marc Sadler for use of images in Figure 4c and Figure 5h from his MSc Thesis (Sadler, 2012). We thank Prokop Závada and Hans de Bresser for reviews, which helped improve the manuscript.

Figure 3: Overview of gamma decorated samples from Barradeel, Pieterburen, Zuidwending and Winschoten, together with maps of the interpreted microstructures. Reflected light images that were used for interpretation of grain boundaries are presented in Supplements 2. Anhydrite, polyhalite and gypsum layers were all mapped, but dispersed particles were mapped only partly as practicable.
Figure 4: a) Transmitted light salt core slab (Zuidwending) showing Kristallbrocken (KB), folded 3 mm thick anhydrite band in fine-grained halite matrix and unfolded, but boudinaged 3 mm thick anhydrite band next to Kristallbrocken. b) gamma irradiated transmitted light scans (samples KS-13A and B) location indicated in Fig. 4b) showing white cores and blue growth rims in fine-grained halite. c) Salt core slab photograph of Pieterburen slab and photo halite on Krmontaged transmitted light image of thick section showing Kristallbrocken (KB) with clear halite on the grain edges of Kristallbrocken grains (modified after Sadler, 2012). d) Transmitted light scan of gamma irradiated sample BS-A showing lighter blue cores and dark blue growth rims of fine-grained halite matrix.
Figure 5: a) Transmitted light micrograph of gamma irradiated KS-08 (Winschoten) sample showing abundant dark inclusions in Kristallbrocken, slip bands and gamma decorated white subgrain boundaries. b) Transmitted light micrograph of gamma irradiated KS-05 (Winschoten) sample showing abundant dark inclusions, slip bands and gamma decorated white subgrain boundaries in Kristallbrocken next to anhydrite band and inclusion poor light halite in-between. c) Reflected light image of sample KS-08 (Winschoten) Kristallbrocken with abundant subgrains and mineral inclusions used for piezometry. Exact location indicated in Fig. 3, KS-08, s2. d) Digitized subgrain boundaries are an example of the data used for piezometry. e) Transmitted light micrograph of gamma irradiated sample KS-13B (Zuidwending) showing Kristallbrocken (KB) grain with gamma decorated subgrains and abundant primary dark solid inclusions (white arrows). Clear halite grain shows array of reworked elongated clear anhydrite minerals parallel to grain boundary (white arrow) as well as abundant fluid inclusions at grain boundaries. f) Transmitted light micrograph of gamma irradiated Zuidwending sample KS-02 showing subgrain structures, abundant dark inclusions as well as clear elongated halite grains next to it. g) Transmitted light micrograph of gamma decorated halite grains showing light cores and directional overgrowth of elongated fine-grained halite in sample BS-B (Pieterburen). h) Transmitted light micrograph of thick section showing abundant fluid inclusions at fine-grained halite grain boundary of Pieterburen sample (digital appendix, Sadler, 2012).
Figure 5 continued
Figure 6: a) EDS map of KS-05 (Winschoten) showing anhydrite-polyhalite band, as well as Kristallbrocken with smaller anhydrite and polyhalite inclusions. b) SEM micrograph of polyhalite and anhydrite inclusions in fine-grained halite. c) SEM micrograph of Kristallbrocken broken along grain boundary showing fluid inclusion imprints and abundant Mg/K-sulfate inclusions.
Figure 7: a) grain size histograms of fine-grained matrix halite for each sample presented in Figure 3, including statistical parameters. Grains smaller than 0.117 mm were not mapped due to image resolution. b) fractions of matrix halite, Kristallbrocken and anhydrite/polyhalite and gypsum for each sample.
Figure 8: a) Inverse Pole Figure Maps for halite grains with large Kristallbrocken grains labelled 1-5. b) Pole figures of fine-grained matrix halite excluding 5 Kristallbrocken grains show no significant crystallographic preferred orientation (CPO). c) Kernel Average Misorientation (KAM) Map overlaid white low- and high-angle grain boundaries (misorientation > 5°). KAM map was calculated over a distance of 40µm (second neighbor) with a threshold of 3° in order to enhance the small angle subgrain boundaries. KAM shows subgrain-free matrix halite with few exceptions in large matrix halite grains, Kristallbrocken 1 and 5 with subgrains,
and subgrains in boudin necks of Kristallbrocken 3 and 4. d) Cumulative reference orientation deviation map over the areas of Kristallbrocken 3 and 4, based on higher resolved EBSD measurements. Reference points for each of the two grains are indicated. Images a) and b) consist of 30 individual measurements, which due to image distortion under 70° tilt cannot be stitched perfectly. Therefore, in some cases an artificial separation of areas belonging to the same grain is visible.

Figure 9: Differential stress vs strain rate diagram plotting selected flow laws at 60°C. For dislocation creep, BGRa KK="Kriechklassen" 5, 4 and 3 calculated with Eq. 1, $A = 2.083 \times 10^{-6} \, s^{-1}, Q_{DC} = 54 \, \frac{kJ}{mol}$ and $n = 5$. (Liu, W. et al., 2017) as well as Avery Island samples calculated with Eq. 1, $A = 1.6 \times 10^{-4} \, s^{-1}, Q_{DC} = 68 \, \frac{kJ}{mol}$ and $n = 5.3$ from (Carter et al., 1993) are included for dislocation creep. Dotted lines show combined pressure solution (Spiers et al., 1990) and dislocation creep flow laws for different halite grain sizes calculated with Eq. 2, previous values for dislocation creep and $B = 4.7 \times 10^{-4} \, s^{-1}, Q_{DC} = 24.53 \, \frac{kJ}{mol}$ and $m = 3$ (Spiers et al., 1990). Results from this study are plotted based on measured median fine-grained halite grain sizes (Fig. 7) and differential stresses from subgrain size piezometry of Kristallbrocken for each sample (Supplement 2 and Table 1).
Figure 10: Comparison of differential stresses measured in Kristallbrocken and matrix halite, for samples were both were available ($\sigma = 107^{*} (D^{-0.87})$, $D =$ subgrain size, (Carter et al., 1993; Schléder and Urai, 2005)), with 95% confidence intervals based on all measured subgrains per sample. Measurements indicate comparable differential stresses for both halite types, but slightly lower values for differential stress in Kristallbrocken of this study. Differential stresses from Teutschenthal were measured based on micrographs presented in Küster et al. (2008) for matrix halite and Küster (2011) for Kristallbrocken and show comparable, slightly lower differential stresses.
Table 1 Differential stresses from subgrain size piezometry calculated with $\sigma=10^7D^{-0.87}$ (Supplement 2) after (Carter et al., 1993; Schléder and Urai, 2005). Halite types KB=Kristallbrocken
