10 **Abstract.** The basal cavity of a rock block formed due to differential weathering is an important predisposing factor for rockfall
11 in hard-soft interbedded rocks, which induces eccentricity situation at the base of the rock block. Rock block falling due to the
12 non-uniform distribution with the failure modes of toppling or sliding is defined as biased rockfall in this study. Taking into
13 account the non-uniform stress distribution due to the eccentricity effect, a new analytical method is proposed for three-
14 dimensional stability analysis of biased rockfall. The development of non-uniform stress distribution stress calculated by this
15 analytical method was verified by numerical simulation. The biased rockfall progresses from partial damage of the soft
16 underlying layer, caused by non-uniform distributed stress, to toppling and sliding of overhanging hard rock block due to
17 overall unbalanced force. Therefore, a set of factors of safety (Fos) against partial damage (compressive and tensile damage
18 of the soft underlying layer) and overall failure (toppling and sliding of the hard rock block) are used to determine the rockfall
19 susceptibility level. The analytical method is applied and validated using biased rockfalls on the northeast edge of the Sichuan
20 Basin in Southwest China, where a significant number of rockfalls consisting of overhanging thick sandstone and underlying
21 mudstone occur. The evolution process of biased rockfalls is divided into four stages, initial state, basal cavity formation,
22 partial unstable and failure. The proposed method is validated by calculating Fos of the typical unstable rock blocks in the
23 study area. As the cavity continues to grow, the continuous retreat of mudstone causes stress redistribution between the hard
24 and soft rock layers. This results in damage to the underlying soft rock layer due to the development of the non-uniform
25 distribution, ultimately leading to the failure of the hard rock block. The critical retreat ratio is determined to be 0.33, which
26 is used to classify the low and moderate rockfall susceptibility in the eastern Sichuan Basin. The proposed analytical method
27 provides insights into the evolution of biased rockfall and a means for early identification and susceptibility assessment of
28 rockfall.

51	M_{bHx}	bending moment of H_x with respect to the x -axis on the mudstone foundation
52	M_{bWx}	bending moment of W with respect to the x -axis on the mudstone foundation
53	M_{Ex}	overturning moment provided by E_x along the x direction
54	M_{Hx}	overturning moment provided by H_x along the x direction
55	M_{px}	stabilizing moment of p_n along the x direction
56	$M_{W_{inx}}$	stabilizing moment provided by W along the x direction
57	$M_{W_{outx}}$	overturning moment provided by W along the x direction
58	N_z	total applied vertical load on the mudstone base
59	O	origin of the (x, y) coordinates
60	$p(x, y)$	pressure magnitude at point (x, y)
61	r_i	the basal mudstone retreat ratio equal to the ratio of basal cavity width to block width in a certain direction
62	W	weight of the block
63	x	distance to O along the x -axis
64	y	distance to O along the y -axis

65	α	true dip of the contact surface
66	γ_s	unit weight of sandstone
67	γ_w	unit weight of water
68	θ_1	apparent dip of α on plane J1
69	θ_2	apparent dip of α on plane J2
70	σ_{cmax}	ultimate compressive strength of the mudstone
71	σ_{tmax}	ultimate tensile strength of the mudstone
72	τ_{max}	ultimate shear strength of the mudstone
73	φ	friction angle of the mudstone
74	ω_1	angle between the trend of the contact surface and the x direction
75	ω_2	angle between the trend of the contact surface and the y direction

76 **1 Introduction**

77 Rockfall is defined as the detachment of a rock block from a steep slope along a surface, on which little or no shear
78 displacement takes place ([Cruden and Varnes, 1996](#)). Rockfalls frequently occur in mountainous ranges, cut slopes, and coastal
79 cliffs, and they may cause significant facility damage and casualties in residential areas and transport corridors ([Chau et al.,](#)
80 [2003](#); [Volkwein et al., 2011](#); [Corominas et al., 2018](#)). Stability analysis of rock blocks are crucial for risk management and
81 early warning of rockfall ([Kromer et al., 2017](#)).

82 Rockfalls are prone to occur in soft-hard rock formations, and the non-uniform stress distribution caused by differential
83 weathering of rock formations is the main reason for the failure of rockfall. In the eastern Sichuan Basin, Southwest China,
84 rockfall is widespread and poses high risk ([Chen et al., 2008](#); [Chen and Tang, 2010](#); [Zhang et al., 2016](#); [Zhou et al., 2017](#);
85 [Zhou et al., 2018](#)). The rockfall in this area is attributed to the tectonic setting of Jura-type folds and the stratum sequence,
86 which is characterized by the interbedding of hard and soft layers. An alternation of thick sandstone and thin mudstone layers
87 is formed in the wide and gentle-angle synclines ([Zhang et al., 2015](#); [Wu et al., 2018](#)). Weathering is known to be one of the
88 main predisposing factors for rockfall ([Jaboyedoff et al., 2021](#); [Zhan et al., 2022](#)). The cliff comprised of hard sandstone is the
89 source of rockfall, and the underlying mudstone is more susceptible to weathering. Along with the retreat of basal cavities in
90 the mudstone layer, the gravity centre of the overhanging sandstone block moves outward relative to the mudstone. In this
91 case, the stress distribution in the contact surface of sandstone and mudstone is non-uniform. The mudstone on the outer side
92 bears higher compressive stress than that on the inner side. This phenomenon can be defined as an eccentricity effect, which
93 leads to mudstone damage and failure of the overhanging sandstone by toppling or sliding. This type of rockfall is defined as
94 biased rockfall in this study (Fig. 1). Similar rockfall patterns have been widely reported in other regions, such as Joss Bay in
95 England ([Hutchinson, 1972](#)), Okinawa Island in Japan ([Kogure et al., 2006](#)), and the Colorado Plateau of the southwestern
96 United States ([Ward et al., 2011](#)). Retreat of the basal cavity is a main cause for the failure of the overhanging block. Therefore,

97 it is necessary to establish an analytical method, considering the development of the basal cavity, to analyse the stress
98 distribution and stability of rock blocks, which is fundamental to the susceptibility assessment and risk control of biased
99 rockfall.

100
101 **Figure 1** Potential unstable blocks and basal cavities caused by differential weathering.

102

103 Rockfall stability analysis methods include statistical analysis ([Frattini et al., 2008](#); [Santi et al., 2009](#)), empirical rating systems
104 ([Pierson et al., 1990](#); [Ferrari et al., 2016](#)), and mechanical analysis ([Lin and Fairhurst, 1988](#); [Jaboyedoff et al., 2004](#); [Derron](#)
105 [et al., 2005](#); [Matasci et al., 2018](#)). The statistical analysis and empirical rating systems are suitable for rockfall hazard
106 assessment at a regional scale. The accuracy of statistical analysis depends on the completeness of rockfall inventories ([Chau](#)
107 [et al., 2003](#); [Guzzetti et al., 2003](#); [D'amato et al., 2016](#)). However, its application to rockfall hazards is limited due to the lack
108 of complete inventory data ([Budetta and Nappi, 2013](#); [Malamud et al., 2004](#)). Empirical and semi-empirical rating systems are
109 used where site-specific rockfall inventories are either unavailable or unreliable. Therefore, rockfall susceptibility can be
110 assessed by heuristic ranking of selected predisposing factors ([Frattini et al., 2008](#); [Budetta, 2004](#)). Mechanical analysis based
111 on static equilibrium theory is the main method to analyse the stability of site-specific rockfall using the factor of safety (Fos).
112 [Ashby \(1971\)](#) conducted stability analysis with a parallelepiped block resting on an inclined plane (Fig. 2a), and the solution
113 was subsequently modified by [Bray and Goodman \(1981\)](#) and [Sagaseta \(1986\)](#). [Kogure et al. \(2006\)](#) utilized a cantilever beam
114 model to determine the critical state of limestone cliffs. [Frayssines and Hantz \(2009\)](#) proposed the limit equilibrium method
115 (LEM) to predict block stability against sliding and toppling in steep limestone cliffs (Fig. 2c). [Chen and Tang \(2010\)](#)
116 established a stability analysis method of three types of unstable rocks in the Three Gorges Reservoir area with the LEM.
117 [Alejano et al. \(2015\)](#) studied the influence of rounding of block corners on the block stability. [Zhang et al. \(2016\)](#) defined Fos
118 based on fracture mechanics and studied the progressive failure process by analysing crack propagation. [Alejano et al. \(2010\)](#)
119 and [Pérez-Rey et al. \(2021\)](#) deduced a formula for Fos of blocks with more complex geometry.

120

121 **Figure 2** Traditional force analysis diagrams of the rock block. (a) and (b) are stability analysis diagrams of rock blocks under dynamic
 122 conditions, resting on an inclined plane with a dip angle of α . The rock block is generalized as a cuboid with dimensions $b \times h$ and weight
 123 W (as modified from [Ashby \(1971\)](#), [Bray and Goodman \(1981\)](#) and [Sagasetta \(1986\)](#)). (c) Force description of the toppling model proposed
 124 by [Frayssines and Hantz \(2009\)](#). In the above assumptions, N , T , and W are regarded as forces applied at a point.

125

126 The supporting force on the contact surface is assumed to be applied at a point in the current LEM methods (i.e., N in Fig. 2 b
 127 and c). However, the supporting force is actually a distributed force. The external erosion generates an eccentricity situation
 128 on the overhanging rock block and results in a non-uniform distribution of the supporting force on the contact surface, which
 129 is not considered in the traditional LEM. The presence of non-uniform stress distribution plays a critical role in inducing
 130 localized damage within a rock mass. Damage is frequently considered as an indicator or a threshold for the onset of accelerated
 131 failure in rock masses (Zhang et al., 2016). Therefore, it is imperative to consider the non-uniform stress distribution for the
 132 rockfall stability analysis. Furthermore, most studies simplified the three-dimensional geometry of the rock block by one cross-
 133 section, which is used to represent the critical features of the slope structure. Nevertheless, for natural blocks with basal cavities,
 134 the cavities usually present different depths along different directions ([Pérez-Rey et al., 2021](#)). Therefore, a three-dimensional
 135 model is necessary to accurately calculate the stability. In addition, when a block has multiple free faces and a complex
 136 structure, its potential failure is dominated by different modes, including rock mass damage and overall block failure. Therefore,
 137 the probable failure modes should be determined prior to the calculation of FoS .

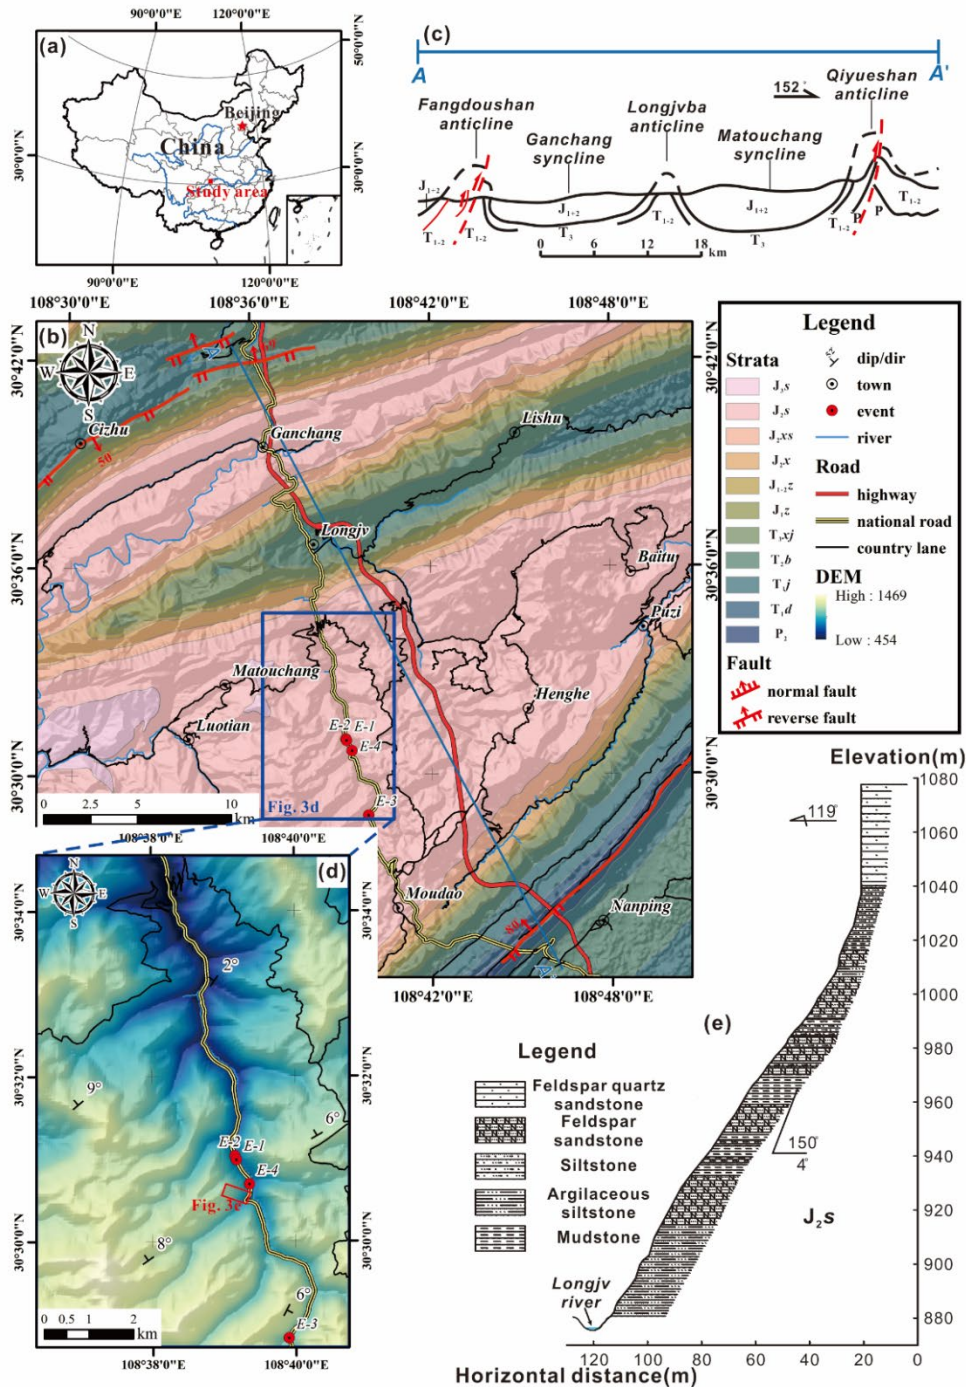

138 Based on rockfall investigation in the Eastern Sichuan Basin, China, the main objective of this study was to propose a new
 139 three-dimensional method for the determination of failure modes and FoS of biased rockfall, considering the non-uniform
 140 force distribution on the contact surfaces. Compared with the traditional LEM method, this study takes into account the partial
 141 damage of the underlying soft rock and the overall instability of the overhanging hard rock blocks, and can evaluate the stability
 142 of biased rockfall more comprehensively. FoS of the typical unstable rock blocks in the study area are calculated to validate

143 the proposed method. In addition, the critical mudstone retreat ratio in this area is analysed. This study is an extension of the
144 basic LEM for rockfall, which can promote the accuracy of rockfall stability analysis and facilitate rockfall prevention and
145 risk mitigation.

146 **2 Study area**

147 **2.1 Geological setting**

148 The study area is located on the northeastern edge of the Sichuan Basin, China (Fig. 3a). Continuous erosion processes generate
149 moderate-low mountain and valley landforms ([Yu et al., 2021](#)). The tectonic structure of this area is characterized by a series
150 of ENE anticlines and synclines (Fig. 3b, c). In the anticline area, the rock layers dip relatively steeply, where translational
151 rockslides are the main mode of slope failure. The syncline area is dominated by gently dipping strata and is prone to rockfall
152 ([Zhou et al., 2018](#)). The study area is located in the core of the Matouchang syncline, where the rock layers are sub-horizontal
153 (Fig. 3d, e). In this valley, due to the longstanding fluvial incision, the relative relief is approximately 500 m and the valley
154 flanks are extremely steep (Fig. 3e). In addition, the toes of the hill slopes are reshaped because of the construction of the
155 G318 national road, which is the main traffic line and is always threatened by rockfalls from steep rock slopes (shown in Fig.
156 3d and Table 1).

157

158 **Figure 3** (a) Location of the study area in China; (b) geological map of the study area; (c) tectonic sketch profile of A-A', whose location is

159 showed in Fig. 3b; (d) rockfall-prone segment and key investigation areas. The red dots are the positions of historical rockfall events,

160 corresponding to the numbers in Table 1; (e) Geological cross-section of the hillslope in the Jitougou section of G318 national road, which

161 is marked by a red rectangle in Fig. 3d.

162 **Table 1** Historical rockfall events along G318 national road in the study area

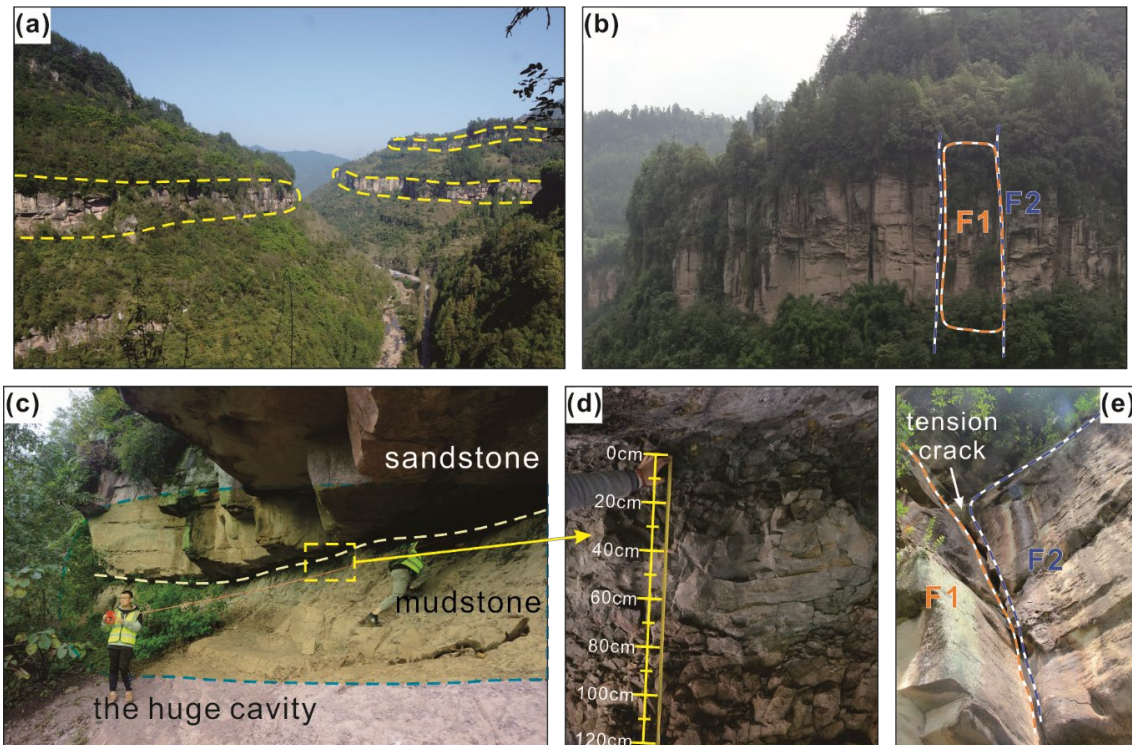

No	Location	Time of occurrence (GMT+8)	Volume [m ³]	Consequence
E-1	K1698+900	2014-05 to 06*	Unknown	The power transmission facilities outside the road were smashed.
E-2	K1699+000	2015-02-14 23:00	About 240	A passing truck was stuck and two people dead.
E-3	K1690+700	2015-06-16	Unknown	The road was interrupted for a day.
E-4	K1698+400	2015-06-18 09:00	About 200	A vehicle was crashed into a gully and four people dead.

163 *Note: The exact time is unknown.

164

165 **2.2 Rockfall characteristics**

166 The slopes in the study area consist of a sub-horizontally interbedded sandstone and mudstone layer. Therefore, there are
 167 multiple layers of potentially unstable rock blocks in the hill slopes (Fig 4a). The thick sandstone has two sets of sub-vertical
 168 joints (Fig. 5), which cut the rock mass into blocks as the potential rockfall source (Fig. 4b). Basal cavities have formed in the
 169 underlying mudstone layer (Fig. 4c, d). Joints and bedding planes (BP) constitute the detachment surfaces between the blocks
 170 and steep slope (Fig. 4e). The eccentricity effect produced by the mudstone external erosion plays an important role in the
 171 evolution process of rockfall. When the basal mudstone cannot provide adequate supporting force, the blocks detach from the
 172 steep slope, and biased rockfall occurs. Sliding and toppling are two possible failure modes of biased rockfall.

173

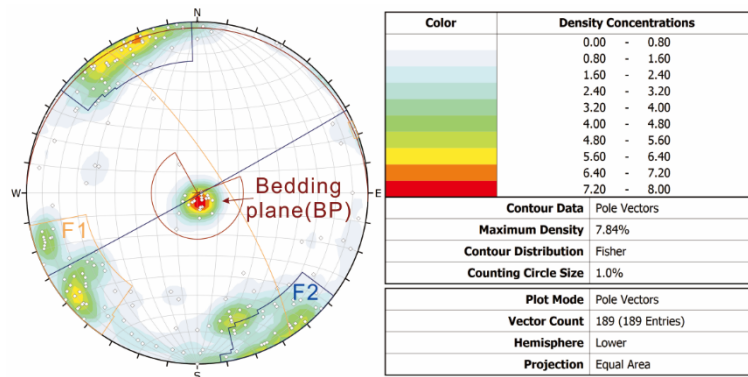

174 **Figure 4** Characteristics of biased rockfalls in the study area. (a) Multiple-layers of rockfall sources, which is consist of thick sandstone. (b)

175 Two sets of sub-vertical joints (F1 and F2) recognized by the UAV photos. (c) Large basal cavity developed in the underlying mudstone. (d)

176 Dense fractures on the mudstone surface generated by weathering and compression. (e) Vertical tension crack in the rear of the block, through
177 which precipitation can infiltrate.

178

179 According to the historical rockfall events in this area, precipitation is considered a triggering factor of rock instability. The
180 precipitation mainly infiltrates along the sub-vertical joints or cracks of the sandstone (Fig. 4e). However, the drainage of
181 fissure water is hysteretic due to the obstruction of basal mudstone. Therefore, transient steady flow exists in vertical cracks
182 during heavy rainfall, and the hydrostatic pressure triggers the detachment of rock blocks. Thus, typical scenarios (such as
183 rainfall intensity and earthquake) need to be considered in the stability analysis model.

184

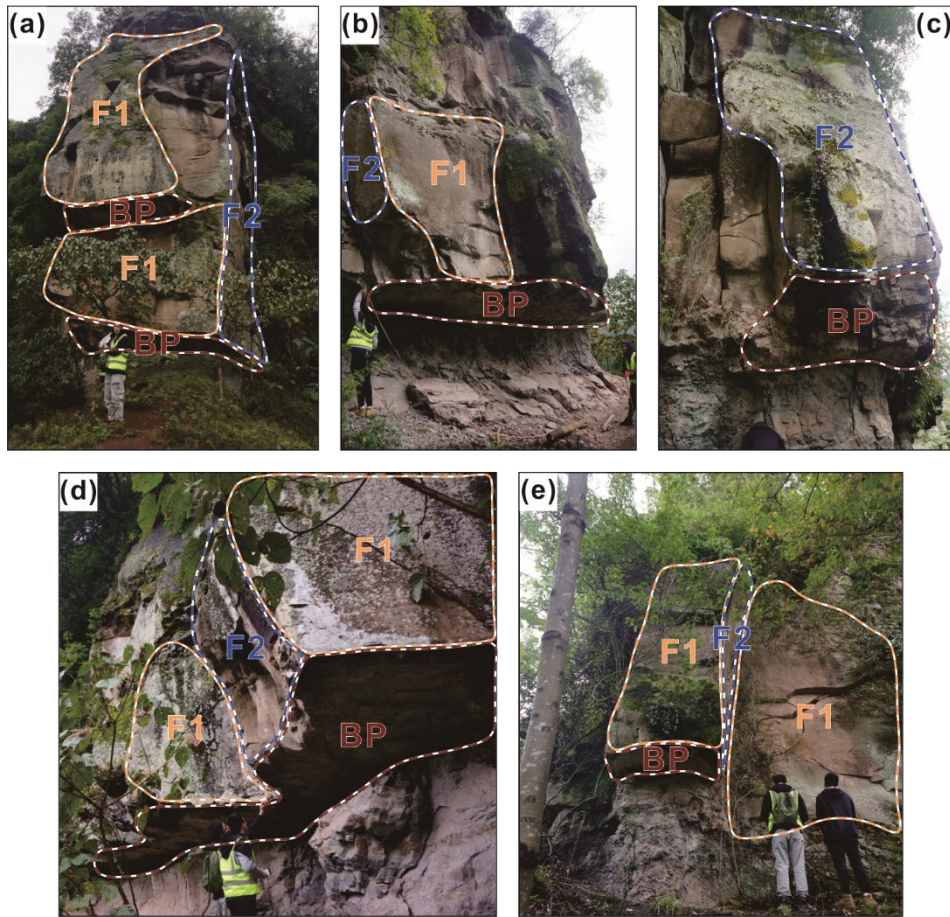

185 **Figure 5** Stereo net produced using compass-clinometer survey data, which shows the densities and orientations of five clusters. The data
186 were collected in the rockfall-prone area shown in Fig. 3d.

187 3 Calculation method

188 3.1 Geological models and assumptions

189 A detailed geological investigation of unstable rock blocks was carried out in the study area (Fig. 6). The geological model of
190 the rock block is mainly composed of the overhanging sandstone and the underlying mudstone. The sandstone block is assumed
191 to be a rigid body, which is divided by two sets of orthogonal vertical smooth joints without friction resistance. According to
192 the relatively persistent sub-vertical fractures observed in the field, the vertical joints are assumed to be fully persistent in the
193 geological model. The sandstone block is assumed to be a complete body without persistent discontinuity, and it will not
194 disintegrate before it falls. Due to the basal cavity in mudstone, the contact surface between sandstone and mudstone exhibits
195 an eccentricity situation where non-uniform stresses are distributed at different positions. Mudstone is mainly loaded by
196 compressive stress and tensile stress. When the compressive stress of mudstone exceeds its strength on the outer side, some
197 initial damage appears. The effective contact surface between mudstone and sandstone is reduced, which aggravates the non-
198 uniform distribution of stress. In this way, the ability of mudstone to resist the sliding and toppling of overhanging sandstone
199 is reduced. In the field, compression deformation of mudstone can be observed, which usually manifests as micro-fractures
200 and cleavages (Fig. 4d). The deformation is very slight and slow in the short term. In addition, the LEM is essentially a

201 force/stress approach that does not take into account the deformation. Therefore, in this study, it is assumed that the mudstone
202 is not subjected to deformation. The rock block remains in the state of static equilibrium prior to the final overall failure. Fig.
203 7 displays the four evolution stages of biased rockfall. In the initial stage, the base cavity has not yet formed, and the normal
204 force acting on the contact surface is uniform in different positions. The eccentricity effect leads to a non-uniform supporting
205 force as the basal cavity grows, and partial damage gradually develops when the non-uniform stress exceeds the compressive
206 or tensile strength of the mudstone. Under the triggering effects of rainfall or earthquakes, the rock blocks are separated by
207 sliding or toppling.

208

209 **Figure 6** The unstable blocks were labelled W02, W08, W18, W04, and W21, which are detached by the dominating discontinuities in Fig.

210 5. Basal cavities can be identified under the bedding planes of sandstone.

211

212
213 **Figure 7** The evolution process of rock blocks from stable state to failure.

214
215 Fig. 8 represents the mechanical model of the force equilibrium analysis of a rock block with two or three free faces. The rock
216 block (the overhanging sandstone) is generalized as a parallelepiped block. The underlying mudstone is impermeable, so
217 rainfall can fill the joints and transmit horizontal hydrostatic pressure. The shear strength of the underlying mudstone is
218 assumed to obey the Mohr–Coulomb criterion. Rainfall and earthquakes decrease *Fos* by generating hydrostatic pressure *H* in
219 the vertical crack and horizontal seismic force *E* on the block.

220 A Cartesian coordinate system is established in three-dimensional space for the force analysis. The origin *O* is located at the
221 centre of the contact surface between sandstone and mudstone. For the case with two free surfaces, the orientation of the free
222 surfaces is set to be the positive direction of the *x*-axis and *y*-axis. For the case with three free surfaces, the negative direction
223 of the *x*-axis is also a free surface. Joint J2 is perpendicular to the *x*-axis, and joint J1 is perpendicular to the *y*-axis.

224
225 **Figure 8** Diagram of the force equilibrium analysis of the rock block model. (a) and (b) represent the case of unstable rock blocks with
226 two or three free vertical surfaces, respectively.

227 3.2 Calculation processes

228 3.2.1 Stress distribution at the block base

229 The following formulas are used to calculate the apparent dip of α (θ_1 and θ_2):

$$230 \quad \theta_1 = \arctan(\tan \alpha \cdot \cos \omega_1) \quad (1)$$

$$231 \quad \theta_2 = \arctan(\tan \alpha \cdot \cos \omega_2) \quad (2)$$

232 where ω_1 and ω_2 are the angles between the trend of the contact surface and the x direction or y direction, respectively.

233 As shown in Fig. 8b, with respect to the x -axis, gravity, seismic forces, and hydrostatic pressure create a non-symmetrical
234 stress distribution on the foundation. The bending moment of gravity with respect to the x -axis (M_{bWx}) is

$$235 \quad M_{bWx} = W \cdot \frac{d_1 - d_3}{2} \cos \theta_1 \quad (3)$$

236 Assuming that the height of the water in the fracture is h_w , the hydrostatic pressure along the x direction (H_x) and its bending
237 moment (M_{bHx}) are respectively expressed as

$$238 \quad H_x = \frac{\gamma_w h_w^2}{2} (b - d_2) \quad (4)$$

$$239 \quad M_{bHx} = \int_{\frac{b-d_2}{2}}^{\frac{b-d_2}{2}} \int_0^{h_w \cos \theta_1} \gamma_w \left(h_w - \frac{z}{\cos \theta_1} \right) \left(\frac{z}{\cos \theta_1} + \frac{a - d_1 - d_3}{2} \cdot \sin \theta_1 \right) dz dy \quad (5)$$

240 The horizontal seismic force along x direction (E_x) and its bending moment (M_{bEx}) are respectively expressed as

$$241 \quad E_x = k_e W \quad (6)$$

$$242 \quad M_{bEx} = E_x \left(\frac{h}{2} - \frac{d_1 - d_3}{2} \sin \theta_1 \right) \quad (7)$$

243 The total applied vertical load (N_z) and the total bending moments along the x direction (M_{bx}) can be derived as

$$244 \quad N_z = W \cos \alpha - (H_x \cdot k_1 \cdot k_3 + E_x \cdot k_2) \sin \theta_1 - (H_y \cdot k_1 + E_y \cdot k_2) \sin \theta_1 \quad (8)$$

$$245 \quad M_{bx} = M_{bWx} + M_{bHx} \cdot k_1 \cdot k_3 + M_{bEx} \cdot k_2 \quad (9)$$

246 where k_1 , k_2 and k_3 are the coefficients set to make Eq. (8) and Eq. (9) compatible with different calculation scenarios.

247 Therefore, Eqs. (8) and (9) and the following formulas can be expressed in a unified form. In the natural scenario, k_1 and k_2

248 are both equal to 0. In the rainfall scenario, $k_1 = 1$. In the earthquake scenario, $k_2 = 1$. For the case of two free faces, $k_3 = 1$.

249 For the case of three free surfaces, $k_3 = 0$.

250 Based on bending theory ([Adrian, 2010](#)), the eccentricity distance along the x direction (e_x) can be expressed as

$$251 \quad e_x = \frac{M_{bx}}{N_z} = \frac{M_{bWx} + M_{bHx} \cdot k_1 \cdot k_3 + M_{bEx} \cdot k_2}{W \cos \alpha - (H_x \cdot k_1 \cdot k_3 + E_x \cdot k_2) \sin \theta_1 - (H_y \cdot k_1 + E_y \cdot k_2) \sin \theta_1} \quad (10)$$

252 The same method can be used to obtain e_y :

$$253 \quad e_y = \frac{M_{by}}{N_z} = \frac{M_{bWy} + M_{bHy} \cdot k_1 + M_{bEy} \cdot k_2}{W \cos \alpha - (H_x \cdot k_1 \cdot k_3 + E_x \cdot k_2) \sin \theta_1 - (H_y \cdot k_1 + E_y \cdot k_2) \sin \theta_1} \quad (11)$$

254 According to the stress distribution of a rectangular shaped foundation ([Adrian, 2010](#)), the stress in the (x, y) coordinates,
 255 $p(x, y)$, is

$$256 \quad p(x, y) = \frac{N}{A} + \frac{Ne_x}{I_y}x + \frac{Ne_y}{I_x}y \quad (12)$$

257 with the formulas

$$258 \quad I_x = \frac{(a - d_1)(b - d_2)^3}{12} \quad (13)$$

$$259 \quad I_y = \frac{(b - d_2)(a - d_1)^3}{12} \quad (14)$$

$$260 \quad A = (a - d_1 - d_3)(b - d_2) \quad (15)$$

261 By substituting Eq. (13-15) into Eq. (12), $p(x, y)$ can be derived as

$$262 \quad p(x, y) = \frac{N}{A} \left[1 + \frac{12e_x}{(a - d_1 - d_3)^2}x + \frac{12e_y}{(b - d_2)^2}y \right] \quad x \in \left[-\frac{a - d_1 - d_3}{2}, \frac{a - d_1 - d_3}{2} \right], y \in \left[-\frac{b - d_2}{2}, \frac{b - d_2}{2} \right] \quad (16)$$

263 p_{max} and p_{min} can be derived from Eq. (16) as

$$264 \quad p_{max} = p \left(\frac{a - d_1 - d_3}{2}, \frac{b - d_2}{2} \right) \quad (17)$$

$$265 \quad p_{min} = p \left(-\frac{a - d_1 - d_3}{2}, -\frac{b - d_2}{2} \right) \quad (18)$$

266 The mudstone foundation has both compressive strength and tensile strength, so the value of $p(x, y)$ is modified to obtain the
 267 two piecewise functions

$$268 \quad p_p(x, y) = \begin{cases} \sigma_{cmax}, & p(x, y) \geq \sigma_{cmax} \\ p(x, y), & 0 < p(x, y) \leq \sigma_{cmax} \\ 0, & p(x, y) < 0 \end{cases} \quad (19)$$

$$269 \quad p_n(x, y) = \begin{cases} 0, & p(x, y) < -\sigma_{tmax} \\ p(x, y), & -\sigma_{tmax} \leq p(x, y) < 0 \\ 0, & p(x, y) \geq 0 \end{cases} \quad (20)$$

270 Here, $p_p(x, y)$ provides support normal force for the overhanging sandstone, and $p_n(x, y)$ provides tension force.

271 3.2.2 Calculation of factors of safety

272 According to the Mohr-Coulomb criterion, the ultimate shear strength τ_{max} is

$$273 \quad \tau_{max} = \int_{-\frac{a-d_1-d_3}{2}}^{\frac{a-d_1-d_3}{2}} \int_{-\frac{b-d_2}{2}}^{\frac{b-d_2}{2}} [p_p(x, y) \tan \varphi + c] dy dx \quad (21)$$

274 Therefore, Fos against sliding, Fos_{sl} , can be defined as

$$275 \quad Fos_{sl} = \frac{S_{stabilizing}}{S_{sliding}} = \frac{\tau_{max}}{W|\sin \alpha_s| + H_x \cdot \cos \omega_s \cdot \cos \alpha_s \cdot k_1 \cdot k_3 + H_y \cdot |\sin \omega_s| \cdot \cos \alpha_s \cdot k_1 + E \cdot \cos \alpha_s \cdot k_2} \quad (22)$$

276 When the block can slide freely, $\alpha_s = \alpha$, $\omega_s = 0$; when the block is constrained to slide along a joint plane (e.g., J1), $\alpha_s =$
 277 θ_1 or θ_2 , $\omega_s = \omega_1$ or ω_2 . For the case of an anaclinal slope, the sliding direction is opposite to the free surface. Therefore, the
 278 rock block does not slide, and Fos_{sl} is not considered in the model.

279 With regard to stability against toppling, along the x direction, the part of the block above the mudstone base provides the
 280 stabilizing moment $M_{W_{inx}}$, and the part of the block above the basal cavity provides the overturning moment $M_{W_{outx}}$. When
 281 tension exists, there is an additional stabilizing moment. M_{px} , $M_{W_{inx}}$, $M_{W_{outx}}$ and M_{px} can be derived as

$$282 \quad M_{W_{inx}} = W \frac{a - d_1}{a} \cos \theta_1 \cdot \left(\frac{a - d_1}{2} \right) \quad (23)$$

$$283 \quad M_{W_{outx}} = W \frac{d_1}{a} \cos \theta_1 \cdot \frac{d_1}{2} \quad (24)$$

$$284 \quad M_{px} = - \int_{-\frac{b-d_2}{2}}^{\frac{b-d_2}{2}} \int_{\frac{a-d_1-d_3}{2}}^{\frac{a-d_1-d_3}{2}} p_n(x, y) \cdot \left(\frac{a}{2} - d_1 - x \right) dx dy \quad (25)$$

285 and M_{Hx} and M_{Ex} can be derived as

$$286 \quad M_{Hx} = \int_{-\frac{b-d_2}{2}}^{\frac{b-d_2}{2}} \int_0^{h_w \cos \theta_1} \gamma_w \left(h_w - \frac{z}{\cos \theta_1} \right) \left(\frac{z}{\cos \theta_1} + (a - d_1) \sin \theta_1 \right) dz dy \quad (26)$$

$$287 \quad M_{Ex} = E_x \left(\frac{h}{2} + \left(\frac{a}{2} - d_1 \right) \sin \theta_1 \right) \quad (27)$$

288 Therefore, the Fos against toppling along the x direction, Fos_{tox} , results in

$$289 \quad Fos_{tox} = \frac{M_{stabilizing}}{M_{overturning}} = \frac{M_{W_{inx}} + M_{px}}{M_{W_{outx}} + M_{Hx} \cdot k_1 \cdot k_3 + M_{Ex} \cdot k_2} \quad (28)$$

290 Similarly, Fos_{toy} can be obtained as

$$291 \quad Fos_{toy} = \frac{M_{stabilizing}}{M_{overturning}} = \frac{M_{W_{iny}} + M_{py}}{M_{W_{outy}} + M_{Hy} \cdot k_1 + M_{Ey} \cdot k_2} \quad (29)$$

292 The smaller value is selected as the Fos of the toppling failure mode Fos_{to} :

$$293 \quad Fos_{to} = \min(Fos_{tox}, Fos_{toy}) \quad (30)$$

294 When the stress on mudstone exceeds its strength, it causes partial damage and decreases the stability of the rock block.

295 Therefore, Fos with the consideration of compressive strength (Fos_{co}) and tensile strength (Fos_{te}) can be derived as

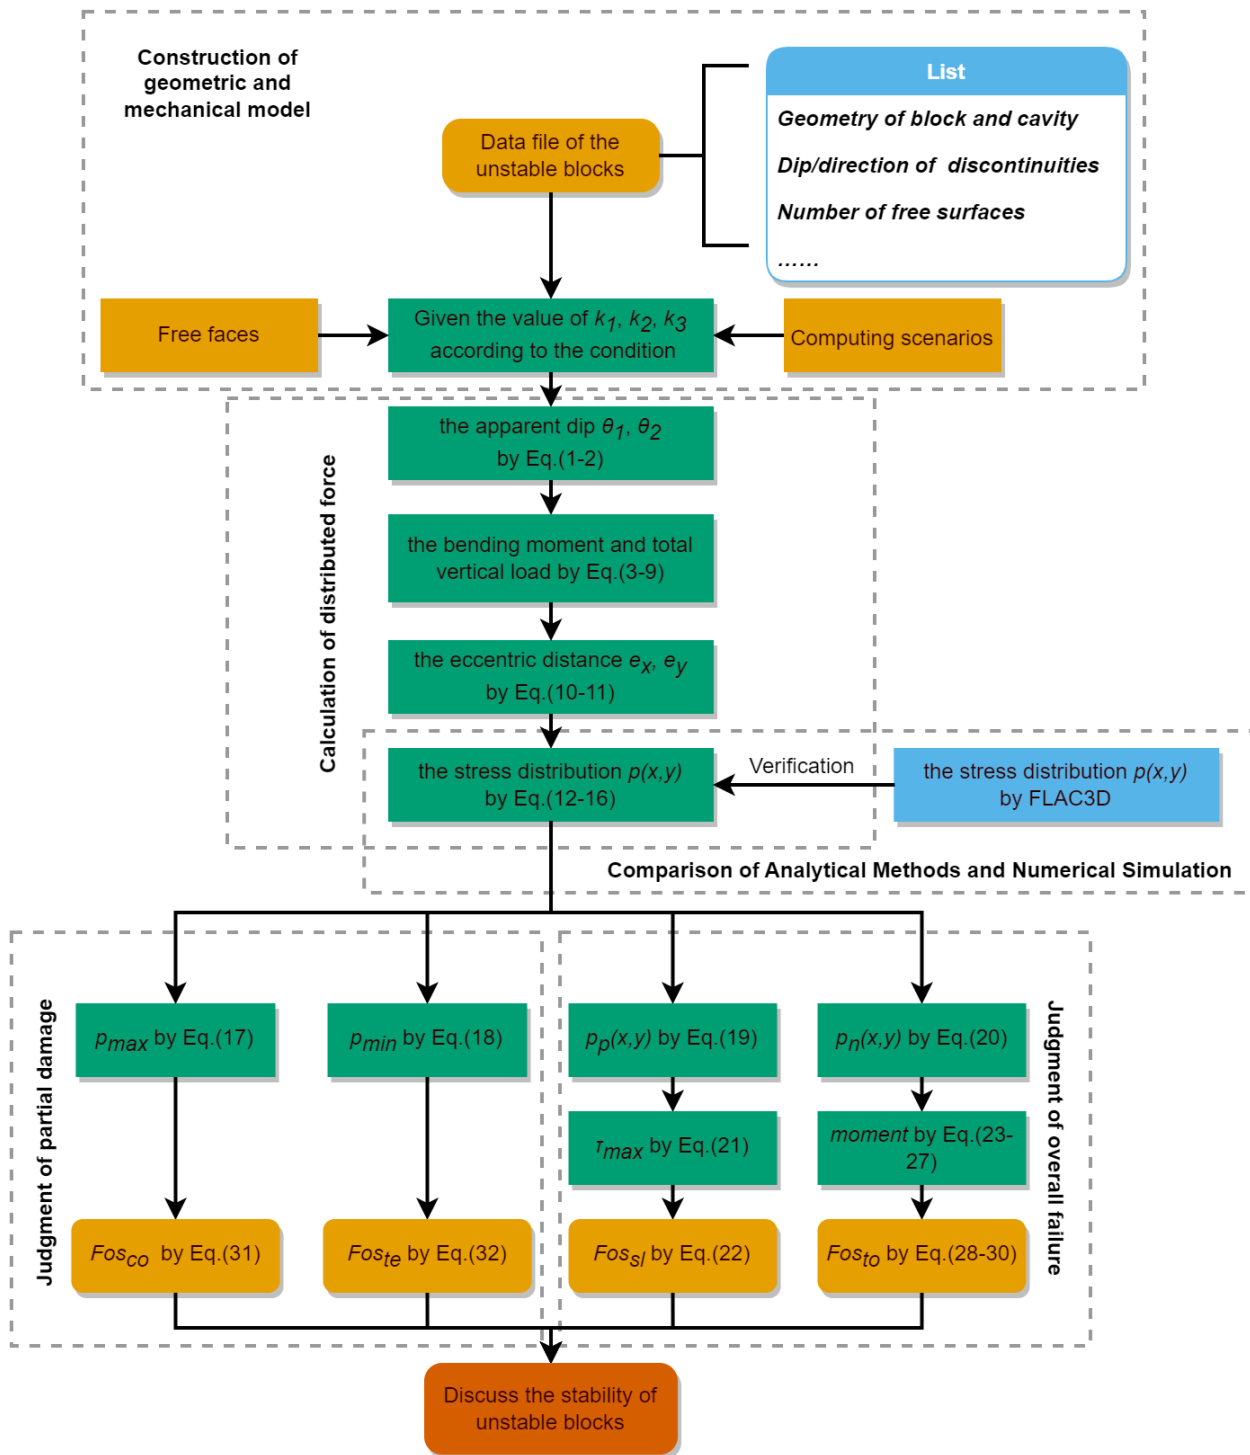

$$296 \quad Fos_{co} = \frac{\sigma_{cmax}}{p_{max}} \quad (31)$$

$$297 \quad Fos_{te} = \frac{\sigma_{tmax}}{-p_{min}} \quad (32)$$

298 Fos_{co} and Fos_{te} represent the current damage degree of mudstone due to compressive stress and tensile stress, respectively.

299 When the stress exceeds the ultimate strength, the strength of the mudstone is reduced to the residual value, and the initial
 300 deformation appears. The ability of mudstone to provide resistance to the sliding and toppling of sandstone blocks is thus

301 reduced, and Fos_{sl} and Fos_{to} subsequently decline. The smaller the value of Fos_{co} and Fos_{te} , the greater the damage to the
302 underlying mudstone. The effective contact area between sandstone and mudstone becomes smaller as the development of
303 compressive and tension damage, which significantly affects the stability of the overhanging sandstone block.
304 Summarizing, four Fos of unstable rock block are obtained. Fos_{sl} and Fos_{to} are routine indicators directly representing the
305 stability of sandstone blocks. Fos_{co} and Fos_{te} are two indicators proposed in this study for the stability analysis of biased
306 rockfall, which describe the damage state of the underlying mudstone base. It is necessary to simultaneously consider four Fos
307 to evaluate the stability of unstable biased rockfall. The entire calculation process is shown in Fig. 9.
308

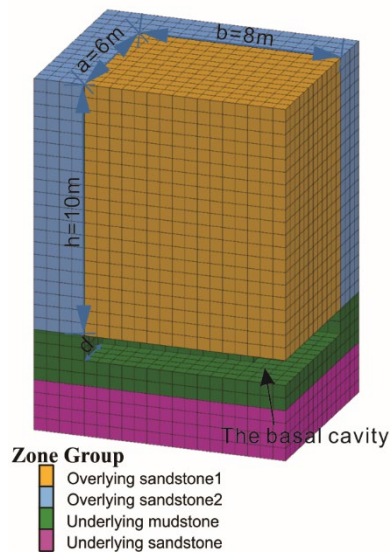

309

310 **Figure 9** Calculation process of FoS of the unstable rock blocks.

311 4 Validation of analytical methods by numerical simulation

312 The damage mechanisms at the base of the rock block play an important role in the rockfall evolution process. However, the
313 stress distribution on the contact surface calculated by the proposed analytical methods is difficult to be validated by the field
314 data. Therefore, numerical simulation of a biased rockfall was conducted in this study to determine the stress distribution on
315 the contact surface between overhanging sandstone and underlying mudstone. Numerical simulations can take into account
316 material deformation which is a drawback of the analytical methods. FLAC3D, a professional software that utilizes the finite
317 difference method (FDM) for three-dimensional analysis of rocks, soils, and other materials, was employed for the 3D
318 numerical simulation. Based on the geological models, a 3D numerical simulation model was conducted with FLAC3D 6.00
319 to analyse the stress distribution on the contact surface (Fig. 10).

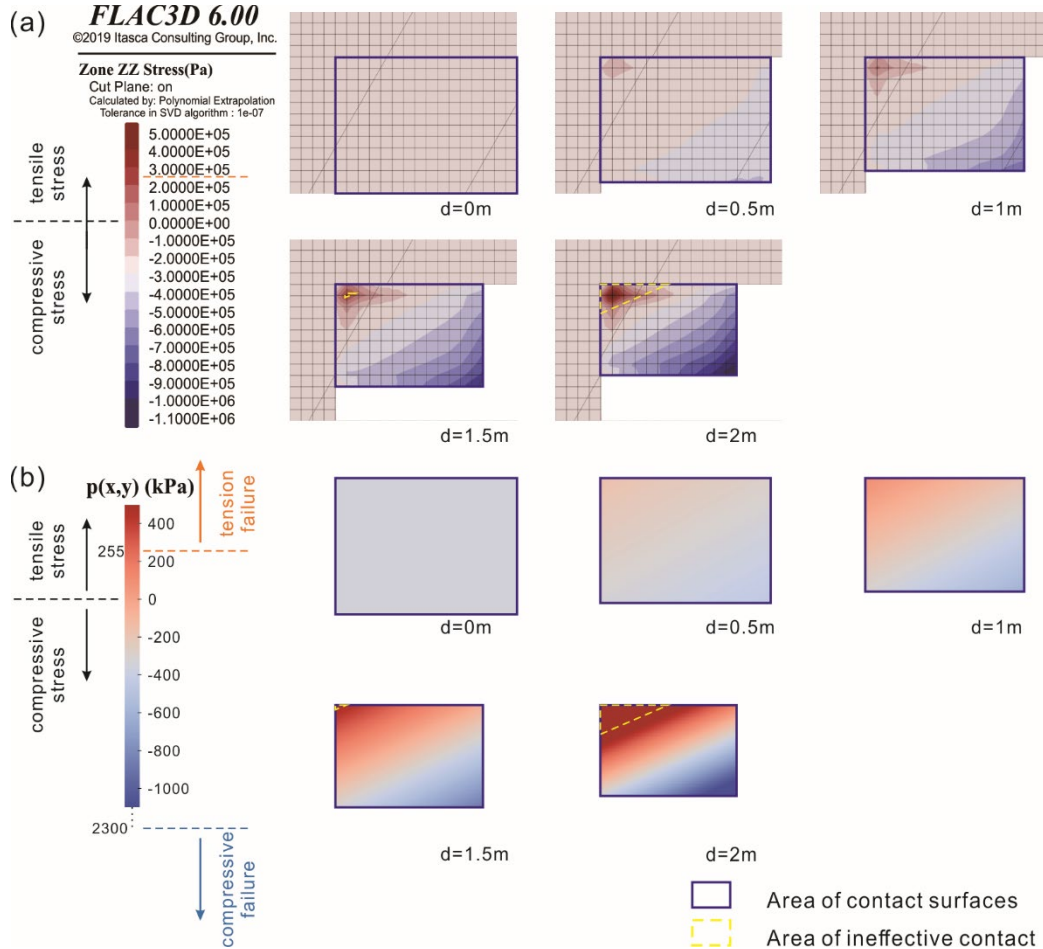

320

321 **Figure 10** Numerical model built in FLAC3D.

322

323 The model is mainly composed of sandstone and mudstone, which the Overhanging sandstone1 represents an unstable rock
324 block (dimensions $a \times b \times h$ are 6 m, 8 m, 10 m respectively), and the weathering process of the mudstone is represented by
325 excavating in stages in the underlying mudstone. Considering the deformation of the materials, sandstone was considered as
326 elastic model, and mudstone was assigned Mohr-Coulomb model. Material properties were determined by referring to
327 published literature and investigation reports in the study area. The sandstone has a unit weight (γ_s) 25 kN/m³, an elastic
328 modulu of 4530 Mpa and a Poisson's ratio of 0.183(Tang et al., 2010), and the mudstone has a unit weight 22.54 kN/m³, an
329 elastic modulu of 587 Mpa and a Poisson's ratio of 0.232. The friction angle of the contact surface (φ) is set to 25° and the
330 cohesion (c) is set to 70 kPa (Zhang et al., 2016). Because of the strength degradation of mudstone foundations due to intense
331 weathering, the maximum compressive stress of mudstone (σ_{cmax}) is replaced by the bearing capacity of mudstone
332 foundations (2300 kPa), which is obtained through plate load tests in adjacent areas (Zheng et al., 2021). In addition, the

333 maximum tensile stress of mudstone (σ_{tmax}) is valued as one-ninth of σ_{cmax} . The west, north and bottom boundaries of the
 334 model are constrained by roller boundary conditions. The cohesion and internal friction angle of the interface between
 335 Overhanging sandstone1 and Overhanging sandstone2 are set to 0. After reaching the initial force-equilibrium state, the
 336 mudstone was excavated to simulate the weathering process, and the vertical stress distribution on the sand-mudstone interface
 337 at different basal cavity depths was obtained, as shown in Figure 11.

338
 339 **Figure 11** Diagram of stress distribution in the vertical direction on the contact interface through different methods, (a) the results of
 340 numerical simulation by FLAC3D, (b) the results of proposed analytical method.

341
 342 When there is no cavity present, represented by $d = 0$ m, the stress distribution is uniform compressive stress (According to the
 343 FLAC3D software, compressive stresses are negative). At $d = 0.5$ m, the stress remains entirely compressive, but non-uniform
 344 stress distribution occurs on the contact surfaces. At $d = 1$ m, the vertical stress value in the upper left corner of the contact
 345 interface surpasses 0 (Fig. 11), indicating the presence of tensile stress. As d increases to 1.5 m or 2 m, the tensile stress in the
 346 upper left corner gradually intensifies, exacerbating the non-uniform stress distribution. The results obtained from the

347 numerical simulation align with those from the analytical method, confirming the existence of tensile stress at the contact
348 interface in the biased rockfall due to external erosion development (Fig.11). Tensile stress commonly emerges within the
349 contact surface, making it challenging to observe directly in the field.

350 In the context of the limit equilibrium method, the contact area plays a vital role in stability analysis, as shown in Eq. (21)-(30)
351 in Section 3. The numerical simulation process provides an intuitive understanding of the influence of non-uniform stress
352 distribution on the contact surfaces on the stability of rock blocks. Whether subjected to tension or compression, the rock layer
353 has an ultimate strength. In Fig.11, when $d=1.5$ m or 2 m, the tensile stress exceeds the ultimate tensile strength, leading to
354 tensile failure in the upper left corner of the stress distribution diagram. The region enclosed by a yellow dotted line represents
355 ineffective contact, where no anti-slip force or overturning moment can be generated due to tension failure at the contact
356 surface. Therefore, this area needs to be subtracted from the total contact area when calculating Fos_{sl} and Fos_{to} . Similar
357 situations occur when the compressive stress exceeds the ultimate compressive strength. The current maximum compressive
358 stress has not reached the ultimate compressive strength in Figure 11. However, as d continues to increase, the area of
359 compression failure will appear in the lower right corner of diagram in Figure 11. This occurrence diminishes the area capable
360 of providing anti-slip force or overturning moment, thereby reducing the stability of the rock blocks.

361 The traditional LEM method does not account for distributed forces and fails to consider changes in the contact surface. The
362 method proposed in this study addresses this issue and is applied to the calculation of the Fos_{sl} and Fos_{to} as presented in Eq.
363 (21), (25) and (26).

364 **5 Results**

365 A detailed field investigation was carried out in the source area of rockfall (Fig. 3d). The size of the blocks was determined by
366 on-site measurement with tape and a laser rangefinder. The external erosion in mudstone were measured with a steel ruler, and
367 the morphological characteristics of mudstone foundation were mainly described with the average erosion depth of the basal
368 cavity. The attitude of discontinuities was measured by compass. The mechanical parameters have been given in Section.4.

369 The height of the water level (h_w) is set to be one-third of h , and an earthquake contribution coefficient k_e of 0.05 is considered
370 in stability calculations. The data obtained from the field survey were organized according to the coordinate system of the
371 geological model in Section 3.1, and Fos was calculated according to the calculation steps in Section 3.2. The calculated
372 geometric parameters and Fos results are shown in Table 2.

Table 2 Geometric parameters of rock blocks in the study area and Fos results.

Note: When there is no tensile stress in the mudstone foundation, Fos_{te} has no value. For the case of an anacinal slope, blocks do not slide and Fos_{st} has no value. Both parameters are replaced by "-".

374 6 Discussion

375 6.1 Characteristics of rock block stability

376 There are up to 12 results of Fos per potential unstable block with the consideration of three scenarios and four failure modes
377 (i.e., partial damage and overall failure). Most Fos_{te} values are less than 1 in all scenarios (yellow points in Fig.12), except
378 for two blocks (i.e., W17 and W20), whose Fos_{te} values are also close to 1 under rainfall or earthquake scenarios. Although
379 most of Fos_{co} values (green points in Fig. 12) are greater than 1, they are closer to the critical state of $Fos = 1$ than Fos_{sl} and
380 Fos_{to} (represented by blue and orange points in Fig. 12, respectively). The compression damage of the exposed mudstone can
381 be investigated in the field survey (Fig. 4d). However, it is difficult to observe the phenomenon of tensile damage inside the
382 mudstone base. In the case of weak tensile strength, the mudstone base suffers from tensile failure, and compression failure
383 usually occurs before tension failure. According to the results, their Fos_{te} and Fos_{co} are less than 1 or close to 1, which means
384 that the underlying mudstone has been partially damaged due to slight compressive or tensile failure, and the blocks are
385 potentially unstable with the current depth of the basal cavity. However, most of the blocks do not exhibit overall failure, and
386 they still exist on the slope. Moreover, their Fos_{sl} and Fos_{to} values are greater than 1 in different scenarios, which is consistent
387 with this actuality. The results indicate that most of the blocks are close to a critical state, in which they are partially damaged
388 but the whole block is still stable.

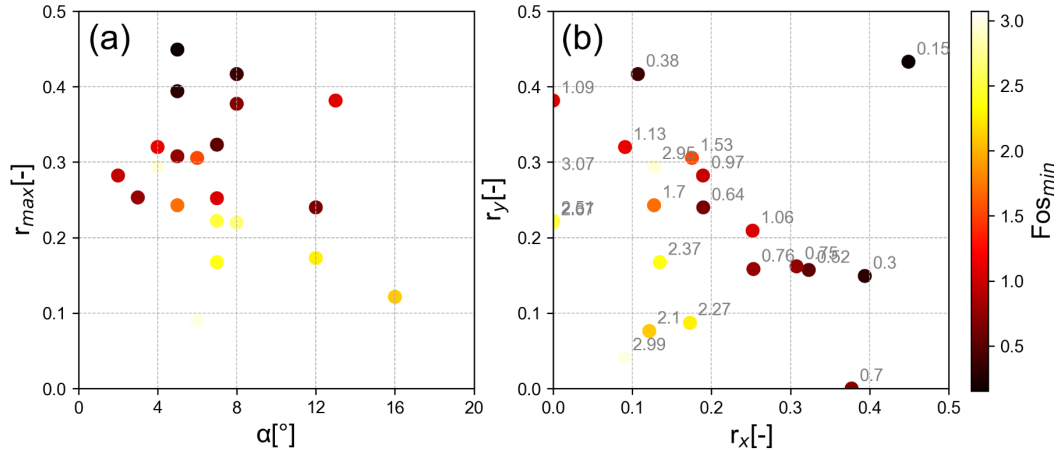

389

390 **Figure 12** Distribution of Fos in different scenarios. Shapes represent different scenarios and colours represent different failure modes.

391 6.2 Relationship between Fos and geometric parameters

392 Fig. 13 presents the relationship between Fos_{min} and two main geometric parameters, the dip of the contact surface and the
393 retreat ratio. In general, the dip angle of the contact surface (α) is the key factor influencing the sliding failure mode. The

394 horizontal axis in Fig. 13a is α between the rock blocks and underlying mudstone. Most of the points in Fig. 13a are in the
 395 interval $[0, 8^\circ]$, which is consistent with the features of sub-horizontal strata in the study area. The shade of the points does not
 396 change significantly in the x -axis direction, as Fig. 13a shows. Therefore, compared with the maximum retreat ratio (r_{max}),
 397 the dip of the contact surface has less influence on rockfall stability in the study area. There was a significant positive
 398 correlation between the retreat ratio (r_{max}) and Fos_{min} . In Fig. 13b, as the retreat ratios increase in the positive direction of
 399 the x -axis and y -axis, the rock blocks show a notable tendency to be unstable.

400
 401 **Figure 13** Correlation between Fos and the dip of contact surface and retreat ratio. Here, α is the dip angle of the contact surface between
 402 rock block and underlying mudstone, r_x and r_y are the retreat ratio along x direction and y direction, respectively, equal to d_1/a and d_2/b ,
 403 and r_{max} is the larger of r_x and r_y .

404 6.3 Definition of rockfall susceptibility

405 To explore the variation in Fos with the progressive erosion process of the mudstone on the blocks, the mudstone retreat
 406 velocities in different directions are assumed to be equal (5 mm/year, Zhang et al. (2016)). Fig. 14 shows the variations in Fos
 407 of two specific blocks during the evolution process of the basal erosion in the mudstone. In the initial stage, the basal cavity is
 408 small, and the overhanging block is stable; all Fos values are greater than 1.0. The basal cavity expands over time as the
 409 mudstone weathers; then, the contact area decreases, and non-uniform distributed stress arises. When the stress exceeds the
 410 ultimate strength of mudstone in a partial area, Fos_{co} and Fos_{te} decrease significantly, as shown in Fig. 14. The instability of
 411 the blocks starts from the failure (or damage) of the foundation. Fos_{te} and Fos_{co} reach the critical state much earlier than
 412 Fos_{sl} and Fos_{to} . For these two specific blocks, when r_{max} increases to 0.4, Fos_{sl} and Fos_{to} are still higher than 1.0. This
 413 means that the rock blocks can remain globally stable in this condition.

414 These results further elucidate the stability analysis model proposed in this study. Fos_{co} and Fos_{te} introduced in this model
 415 present the damage state of basal mudstone caused by compressive and tensile stresses, which do not provide global instability
 416 of the overhanging block as sliding and toppling. However, Fos_{co} and Fos_{te} are important preliminary signs of subsequent

417 global failure of the rock block, as presented through the numerical simulation in Section 4. The damage in the basal mudstone
 418 can significantly accelerate weathering and prompt expansion of the basal erosion, which will lead to global failure. The lower
 419 Fos_{co} and Fos_{te} are, the lesser the safety margin of the blocks. Therefore, the four Fos used in this study can provide a more
 420 comprehensive quantification of rockfall stability.

421 This result is consistent with Fig. 12, in which 63.7% of the yellow and green points (Fos_{te} and Fos_{co}) are located between
 422 $Fos = 0.7$ and $Fos = 2.0$. This result can be validated by the field phenomena. In the study area, rock damage (e.g., micro-
 423 fractures and cleavages) can be observed in the underlying mudstone. However, most overhanging rock blocks are stable at
 424 the present time. This means that even if Fos_{sl} or Fos_{to} is higher than 1, its foundation has begun to be damaged. In the case
 425 of heavy rain or earthquakes, Fos_{sl} and Fos_{to} may be reduced to less than 1, and the rockfall occurs.

426
 427 **Figure 14** Variation in Fos with r_{max} . (a) and (b) are the results for W01 and W09, respectively, which represent the situation of the blocks
 428 with two and three free faces. The black dotted line (CS) approximately represents the current state of the unstable blocks. The red dotted
 429 lines correspond to the critical values of r in different scenarios.

430
 431 Based on the meaning of four Fos , rockfall susceptibility can be divided into three levels. When both Fos_{co} and Fos_{te} are
 432 greater than 1, the overall rock block is stable, and the mudstone base is not damaged, which is defined as “low susceptibility”
 433 and represented by the blue area in Fig. 15. With the development of basal erosion, when Fos_{co} or Fos_{te} is less than 1 and
 434 Fos_{sl} and Fos_{to} are higher than 1, the base undergoes be damaged, and the overhanging sandstone blocks remain relatively
 435 stable. This state is defined as “moderate susceptibility” and represented by the yellow area. When Fos_{sl} or Fos_{to} is less than
 436 1 in some scenarios, the rock blocks are in a “high susceptibility” state, which means that rockfalls are highly likely to occur.
 437 Fig. 15a indicates that along with the increase in the mudstone retreat ratio, the susceptibility of W01 and W09 changes from
 438 low susceptibility to moderate susceptibility in the natural scenario. As Fig. 15b and c show, when rainfall or earthquake occurs,
 439 Fos_{sl} or Fos_{to} of some blocks is less than 1, which means that some blocks have evolved to the state of high susceptibility
 440 and the overall sandstone blocks are unstable.

441

442 **Figure 15** Rockfall susceptibility based on the combination of four Fos . The susceptibility is defined as three levels, represented by red,
 443 yellow and blue. (a) shows the progressive failure process of the rock block changing from low susceptibility to moderate susceptibility as
 444 the mudstone retreat ratio increases (illustrated by W01 and W09 in the natural scenario). (b) and (c) show the change in susceptibility of
 445 biased rock blocks, when the scenario changes from natural conditions to rainfall and earthquake conditions.

446 6.4 Critical retreat ratio in the study area

447 The basal erosion in the mudstone plays an important role in the progressive failure process of biased rockfall. To analyse the
 448 effect of the retreat ratio on the stability of rock blocks, all blocks in the study area were selected to calculate their Fos and
 449 susceptibility level with the increasing r , whose retreat velocities in different directions are assumed to be equal. Fig. 16 shows
 450 that along with the increase in the retreat ratio, the susceptibility level of rock blocks changes from low to moderate
 451 susceptibility. Corresponding to the critical state of $\min\{Fos_{co}, Fos_{te}\} = 1$ of all blocks, the minimum retreat ratio is 0.26,
 452 and the maximum retreat ratio is 0.41, as marked by the vertical black dotted line in Fig. 16. According to the statistical analysis
 453 of critical retreat ratios, both mean and median are 0.33. Therefore, the critical retreat ratio of the rock blocks in the study area
 454 can be determined as 0.33, which is marked by the vertical red dotted line in the Fig. 16. The critical retreat ratio calculated
 455 by this method can be used for the preliminary identification of potential unstable rock blocks in a specific area, which can
 456 help concentrate limited risk treatment resources on these priorities. It should be emphasized that the mechanical parameters
 457 and analysis scenarios significantly affect the critical value. Therefore, the elaborative risk control of a given rockfall should
 458 be arranged based on its specific parameters and analysis scenarios.

459

460 **Figure 16** Effect of the retreat ratio (r) on the Fos of the rock block, which is illustrated by all blocks in the study area.

461 6.5 Limitations

462 This study involves the development of an analytical model for the three-dimensional stability of biased rockfall, combining
 463 the basic LEM method and the consideration of the non-uniform distribution. Due to the complexity of rock structure and force
 464 analysis, it is necessary to highlight the limitations of this model.

465 First, this study uses a three-dimensional coordinate system and bending theory. It is difficult to consider diverse shapes of
 466 rock blocks, and the rock block was simplified as a prismatic column. The assumption of fully persistent discontinuities may
 467 underestimate the stability of rock blocks, and ignores the stress transmission in joints or rock bridges. Then, following the
 468 basic framework of the general LEM method, this study assumed that the rock is not subjected to deformations. The complete
 469 stress–strain behaviour, such as the deformation in the mudstone layer, is not considered in this study. The mode of tension
 470 failure is very difficult to observe in the field, and it is currently verified by means of numerical simulation. Furthermore, the
 471 block stability is strongly influenced by the uncertainty of mechanical parameters. However, because of the difficulties in
 472 sampling strongly weathered mudstone, it is difficult to obtain adequate parameter values for uncertainty statistics. These
 473 limitations will be important considerations in future studies.

474 7 Conclusions

475 Due to differential weathering in sub-horizontally interbedded of hard rock and soft rock, multi-layer biased rockfalls develop
 476 on steep slopes. In mountainous ranges, cut slopes, and coastal cliffs, rockfall may cause significant facility damage and
 477 casualties in residential areas and transport corridors. The aim of this study was to present a new three-dimensional analytical
 478 method for the stability of rock blocks with basal cavities. In this method, a non-uniform distributed stress due to the
 479 eccentricity effect is applied at the contact surface instead of a point force. The development of non-uniform distributed stress
 480 calculated by the proposed analytical methods was validated by numerical simulation, which presents the evolution process of
 481 biased rockfall from partial damage of the soft underlying layer, caused by non-uniform distributed stress, to toppling and

482 sliding of overhanging hard rock block due to overall unbalanced force. The method considers four failure modes according
483 to the rockfall evolution process, including partial damage of the soft foundation (FOS_{co} and FOS_{te}) and overall failure of the
484 rock block (FOS_{sl} and FOS_{to}).

485 Taking the northeast edge of the Sichuan Basin in Southwest China as the study area, the proposed method is used to calculate
486 the FOS of biased unstable rock blocks. The results show that in the natural scenario, the underlying mudstone of some rock
487 blocks has been partially damaged, and compression failure of the mudstone has been observed in the field. Some rock blocks
488 are expected to fail as a whole in rainfall or earthquake scenarios. The statistical analysis indicates that the retreat ratio is the
489 crucial factor influencing the FOS of biased rockfall. On the basis of different combinations of four FOS , rockfall susceptibility
490 was classified into three levels. As the retreat rate increases, the rock blocks undergo an evolution process from stability to
491 partial instability and then overall instability. Based on the current mechanical parameters of the eastern Sichuan Basin, the
492 critical retreat ratio from low to moderate rockfall susceptibility is 0.33.

493 The proposed method improves the three-dimensional mechanical model of a rock block with the basal erosion by considering
494 non-uniform distributed stress at the contact surface, which could promote the accuracy of rockfall stability analysis. Due to
495 the assumptions adopted and the complexity of the failure mechanism of biased rockfall, there are some limitations in this
496 method, mainly including the simplification of boundary conditions and rock deformation. These limitations will be important
497 considerations in future studies.

498 **Data availability**

499 All raw data can be provided by the corresponding authors upon request.

500 **Author contributions**

501 XS, BC and JD planned the campaign; XS and BC performed the field measurements; XS, BC, WW and BL designed and
502 developed the methodology. XS, BC and JD analysed the data; XS and BC wrote the manuscript draft; JD and WW reviewed
503 and edited the manuscript.

504 **Competing interests**

505 The authors declare that they have no conflicts of interest.

506 **Acknowledgements**

507 This research is funded by the National Natural Science Foundation of China (No. 42172318 and No. 42177159). The first
508 author thanks Master Chengjie Luo and Yu Wang for data collection in the field. We also appreciate the assistance of the

509 Research Center of Geohazard Monitoring and Warning in the Three Gorges Reservoir, China. We also thank the reviewers
510 for their suggestions that improved the quality of this paper.
