Abstract

15 Ashfall from volcanic eruptions endangers crop production and food security, while
jeopardising agricultural livelihoods. As population in the vicinity of volcanoes continues to
grow, strategies to reduce volcanic risks to and impacts on crops are increasingly needed.

18 Current models of crop vulnerability to ash are limited. They also rely solely on ash thickness
(or loading) as the hazard intensity metric and fail to reproduce the complex interplay of other
volcanic and non-volcanic factors that drive impact. Amongst these, ash retention on crop
21 leaves affects photosynthesis and is ultimately responsible for widespread damage to crops. In
this context, we carried out greenhouse experiments to assess how ash grain size, leaf
pubescence and humidity conditions at leaf surfaces influence the retention of ash (defined as
24 the percentage of foliar cover coated with ash) in tomato and chilli pepper plants, two crop
types commonly grown in volcanic regions. For a fixed ash mass load ($\sim 570 \text{ g m}^{-2}$), we found
that ash retention decreases exponentially with increasing grain size and is enhanced when
27 leaves are pubescent (such as in tomato) or their surfaces are wet. Assuming that leaf area
index (*LAI*) diminishes with ash retention in tomato and chilli pepper, we derived a new
expression for predicting potential crop yield loss after an ashfall event. We suggest that the
30 measurement of crop *LAI* in ash-affected areas may serve as an impact metric. Our study
demonstrates that quantitative insights into crop vulnerability can be gained rapidly from
controlled experiments. We advocate this approach to broaden our understanding of ash-plant
33 interaction and to validate the use of remote sensing methods for assessing crop damage and
recovery at various spatial and time scales after an eruption.

36 **Introduction**

The livelihood and food security of hundreds of millions of people living near and on volcanoes intricately depend on agriculture (Small and Naumann, 2001; Brown et al., 2015). However, 39 farming activities in these regions are exposed to short-term, i.e. usually less than one year, negative impacts of volcanic eruptions, an issue amplified by the expanding population living under volcanic risk (Brown et al., 2015; Freire et al., 2019). Where cropping activity dominates 42 (for example, in Indonesia), widespread damage to agriculture during eruptive activity arises from crop exposure to ashfall (e.g. Burket et al., 1980; de Guzman, 2005; Tampubolon et al., 2018), causing adverse effects that range from temporary perturbations in leaf physiology to 45 irreversible mechanical damage (Eggler, 1948; Blong, 1984; Grishin et al., 1996; Ayrís and Delmelle, 2012). As a result, crop fields impacted by ash deposition produce lower or poor-quality harvests that can translate into significant economic losses to farmers and food shortages 48 at the local or even regional scale, and even more so when subsistence agriculture dominates (Neild et al., 1998; Wilson et al., 2007; Ligot et al., 2022).

In this context, the development of strategies that can support disaster risk reduction and 51 strengthen resilience for agrarian communities in volcanically active regions is critical, especially in less-economically developed countries (FAO, 2021). Such measures require a sound understanding of agriculture vulnerability to ashfall (UNDRO, 1980; Jenkins et al., 2015; 54 Craig et al., 2021). Over the past 15 years, a dozen or so of post-eruption impact assessments (post-EIA) have contributed to document the responses of farming systems exposed to ash (e.g. Wilson et al., 2007; Wilson et al., 2011; Magill et al., 2013; Blake et al., 2015; Craig et al., 57 2016a; Craig et al., 2016b; Ligot et al., 2022). These field-based investigations have underpinned the development of empirical relationships that link ash accumulation (also referred to as ash mass load or deposit thickness) to an estimated level of production loss for

60 different agriculture types characterised by specific vulnerabilities (Wilson and Kaye, 2007;
Jenkins et al., 2014; Craig et al., 2021). In parallel, new methodologies harvesting the potential
of big Earth observation data acquired from satellite-based sensors (e.g. Landsat, MODIS and
63 Sentinel) and interpretable machine learning are being developed to complement post-*EIA*
studies (Biass et al., 2022).

Despite these recent efforts, current ash-loss of crop production relationships remain
66 overshadowed by uncertainties (Jenkins et al., 2015), which are rooted in three main sources.
Firstly, they lean on limited observational data, acquired in post-*EIA* studies. Most of these
have been conducted in temperate volcanic regions, but tropical and semi-arid environments
69 are increasingly receiving attention. Secondly, it is assumed that ground ash accumulation
(thickness or ash mass load) is the principal hazard intensity metric governing impact level on
crops. However, other volcanic (e.g. ash grain size, surface composition) and non-volcanic
72 factors (e.g. environmental conditions, plant traits, crop development stage) play a key role in
dictating impact and vulnerability (Jenkins et al., 2015; Ligot et al., 2022). Finally, current
approaches lack an impact metric that can be applied to assess crop yield loss from ashfall.
75 These limitations are hindering the development of accurate process-based risk assessment
models that can inform targeted strategies to build resilience of agriculture-based community
in the case of an explosive eruption; for example, in relation to aid allocation, land-use
78 planning and insuring.

Jenkins et al. (2022) estimated that an explosive eruption of *VEI* 4 (Volcanic Explosivity Index,
Newhall and Self (1982)) on the island of Java, Indonesia, has on average a 50% probability of
81 affecting $\sim 700 \text{ km}^2$ of crops with 5 kg m^{-2} of ash. The surface area potentially affected by ash
fallout is ~ 17 times larger for an eruption of *VEI* 5. Ash deposits thin exponentially from the
source. Close to the vent, ash fallout usually results in destructive impacts, e.g. smothering of

84 the vegetation and direct mechanical breakage of plant's parts (leaves, twigs, stem) (Ayrís and
Delmelle, 2012; Arnalds, 2013; Jenkins et al., 2015; Craig et al., 2021). With increasing
distance from the vent, impacts gradually become less severe disturbances. Thin ash deposits,
87 able to affect several hundred to thousands of square kilometres, retain the potential to cause
serious crop yield loss without threatening plant structural integrity (Magill et al., 2013; Ligot
et al., 2022). At distal sites, in the absence of structural damage to plants, the capacity of ashfall
90 to initiate damage to crop yield hinges on the capacity of leaves coated with a thin ash deposit
to operate photosynthesis and produce biomass. While the release of harmful chemical
compounds from ash can cause leaf tissue injuries and affect photosynthesis, this effect, if
93 occurring, is limited to ash emissions from phreatic and phreatomagmatic eruptions (Le Guern
et al., 1980; Ayrís and Delmelle, 2012). For purely magmatic explosive events, impact on crops
over a wide area far from the volcano primarily relates to the shading effect exerted by the
96 presence of solid particles on leaf surfaces, reducing light interception and decreasing
photosynthetic activity (Thompson et al., 1984; Hirano et al., 1995). Thus, ash retention on
foliage (i.e. the percentage of the leaf surface area covered with ash) is a critical variable for
99 developing accurate models that can assess and predict widespread impacts on crop production
from ashfall. Although ash grain size, leaf pubescence and ambient humidity have been
suspected to affect ash retention on foliage, we are still lacking a (i) systematic investigation of
102 factors controlling ash retention on foliage and (ii) quantitative impact metric reflecting crop
production loss.

Here, we adopt an experimental setup to investigate the influence of ash grain size, leaf
105 pubescence and humidity conditions at leaf surfaces on ash retention by crop foliage using
tomato and chilli pepper as model plants. By integrating the effect of both volcanic and non-
volcanic factors on ash retention, we formulate a novel conceptual model that uses *LAI* as the

108 impact metric for predicting crop yield loss when ash deposited on plants does not threaten
their integrity.

Material and methods

111 *Plant material and growing conditions*

Tomato (*Solanum lycopersicum* L.) and chilli pepper (*Capsicum annuum* L.) were chosen to
illustrate contrasting behaviours between plants of agronomical interest; they have a similar
114 stand in early growth period, but tomato has hairy leaves whereas chilli pepper has glabrous
leaves. The experiment took place in Belgium. The seeds were sown in a sieved peat-based
compost (pH 5-6.5) maintained at 24 °C. Four weeks after sowing, the seedlings were
117 transplanted in 1-litre plastic pots also filled with peat-based compost. The average day and
night temperatures in the greenhouse were 30 and 24 °C, respectively. Due to summer heats
in Belgium, temperature during the day occasionally rose above 35 °C. Combined with
120 natural light, the use of *LED* lamps ($120 \mu\text{moles m}^{-2} \text{s}^{-1}$) provided a 16 h-photoperiod. Tomato
and chilli pepper plants were watered three times a week. They were exposed to ash six weeks
after sowing, when tomato and chilli pepper were at the seven- and eight-leaf stage,
123 respectively. The corresponding plant heights were ~40 and ~30 cm. The foliage surface area
was ~400 and ~100 cm² for tomato and chilli pepper, respectively.

Simulated ash deposition

126 We investigated the influence of ash grain size on the ability of tomato and chilli pepper
leaves to retain ash under dry and moist conditions. Six ash size ranges were tested, namely ≤
90, 90-125, 125-250, 250-500, 500-1000 and 1000-2000 μm. Each size range was tested in
129 combination with either dry or wet leaf surface conditions, i.e. a total of 24 treatments for
both crops. A treatment consisted of 15 replicates, corresponding to 360 measurements in

total. The ash material was obtained by crushing a phonolite rock (bulk composition: $\text{SiO}_2 =$
132 52.5 , $\text{Al}_2\text{O}_3 = 21.8$, $\text{K}_2\text{O} = 9.6$, $\text{Na}_2\text{O} = 7.8$, $\text{Fe}_2\text{O}_3 = 2.9$, $\text{CaO} = 1.5$, $\text{TiO}_2 = 0.3$, $\text{MgO} = 0.2$
wt.%; density = 2.54 g cm^{-3} ; Van Den Bogaard and Schmincke, 1984) obtained from a quarry
close to Laacher See volcano in Germany. The shape characteristics of the six ash size
135 fractions obtained by grinding the Laacher See phonolite were examined by scanning electron
microscopy (*SEM*). The *SEM* images (Fig. S1) reveal that, regardless of their size, most
particles are blocky, but rounded and platy shapes also occur. Similar shapes are commonly
138 reported for ash particles from explosive eruptions (e.g. Wohletz (1983); Coltelli et al. (2008);
Nurfiani and Bouvet de Maisonneuve (2017)). However, the vesicular ash type that is also
often associated with the magma fragmentation of gas-rich magmas cannot be generated by
141 rock grinding and was absent in our experimental ash material. The crushed phonolite was dry
sieved for 10 minutes using an AS 200 Control Retsh vibrating sieve shaker with six sieves
(90, 125, 250, 500, 1000, 2000 μm). The five size fractions coarser than 90 μm were wet
144 sieved to remove particles $< 90 \mu\text{m}$. The grain size distribution of the six ash size ranges was
measured between 0.04 and 2000 μm by laser diffraction (Beckman Coulter LS13 320) (Fig.
S2). The median diameter was equal to 5, 98, 174, 401, 774 and 1465 μm for the ≤ 90 , 90-
147 125, 125-250, 250-500, 500-1000 and 1000-2000 μm ash size ranges, respectively.

An ash load of $\sim 570 \text{ g m}^{-2}$ was selected for the experiments. Assuming a bulk density of 1 g
 cm^{-3} for the ash deposit (Eychenne et al., 2012), this corresponds to a relatively thin deposit of
150 $\sim 0.6 \text{ mm}$ (i.e. considering a bulk deposit density of 1 g cm^{-3} , Eychenne et al. (2012)), best
representing accumulations encountered at distal sites (and over wide areas) affected by ash
fallout from explosive eruptions (Fierstein and Nathenson, 1992; Jenkins et al., 2022). Pre-
153 tests carried out with higher ash loads ($\geq 1000 \text{ g m}^{-2}$) already led to lodging of some tomato
and chilli pepper plant specimens, a phenomenon that needed to be avoided in order to
maximise the experiment's reproducibility. Neild et al. (1998) and Craig (2015) consider that

156 an ash mass load of 6-30 kg m⁻² on plants leads to mechanical damage. Our observations
indicate that lower loads can affect crop plants. In other words, the threshold value above
which mechanical injury occurs varies with plant phenology (i.e. the combination of genotype
159 and environment).

The selected ash load was applied uniformly to each plant using a homemade ashfall
simulator (Fig. S3). The device consists of a 135 cm-high PVC tube (of diameter 29.5 cm)
162 with three 1-mm opening meshes placed at 75, 110 and 120 cm from the tube base. The ash
fractions <1000 µm were poured carefully through a 2 cm-mesh sieve installed on the top of
the PVC tube. Bouncing of the ash particles passing through the three inner 1-cm sieves
165 allowed formation of a uniform deposit. Application of the coarsest ash (1000-2000 µm) was
carried out with the same device, but the inner meshes were removed. Wet conditions at leaf
surfaces were obtained by spreading ~1.5 g of water on each plant using a commercial manual
168 sprayer held one meter above the ground. In order to simulate the presence of water droplets
on plant leaves, we applied four sprays of water, one in each cardinal direction just before ash
treatment. Water spraying of the plant foliage, ash application and photo acquisition all took
171 place within the black chamber. Less than five minutes elapsed between the spraying
operation and photo acquisition of the ash-treated plant (Fig. S4).

Estimating the foliar cover from digital photos

174 We took photos of each plant before and immediately after ash treatment (Fig. S4). To
minimise uncontrolled variations in light colour and brightness, plants were photographed in a
1.6 x 1.2 x 2.2 m black chamber equipped with four led bulbs (6.5 W, cold white, Fig. S3 and
177 S4). We used a DX Nikon camera with an AF-S DX NIKKOR 18-55mm f/3.5-5.6G VR II
lens mounted on a 0.9 m-high tripod. Sheets of paper were placed on the floor and plant pot to
produce a uniform background. A ribbon placed in a fixed position provided a reference scale.

180 We analysed the digital photos taken just before and after ash application with ImageJ 1.52
(Schindelin et al., 2015). The foliar cover, a measure of the vertical projection of exposed leaf
area, was estimated using a dedicated macro (<https://github.com/NoaLigot/ImageJ-macro.git>).

183 While digital photos are recorded as a raster of red/green/blue (*RGB*) pixels, the values are not
standardised and can vary depending on the camera (Darge et al., 2019). The ImageJ macro
transforms the *RGB* colour space into the International Commission on Illumination (*CIE*)
186 1976 $L^*a^*b^*$ colour space (McLaren, 1976), which has linear measures of lightness (L^*) and
two colour dimensions (a^* and b^*). The a^* dimension represents a spectrum from green
(negative) to magenta (positive) and the b^* dimension represents a spectrum from blue
189 (negative) to yellow (positive). The a^* attribute is useful to identify green pixels and was used
in the ImageJ macro to identify and select green parts of leaves. Values of 1 and 0 are
attributed to a green and non-green (background) pixel, respectively. This allows delineation
192 of the shape of the green leaf portion and calculation of its surface area.

Data treatment

The percentage of foliar cover coated with ash was inferred for each plant by comparing the
195 foliar cover estimated from the image analysis, before and after ash application. A Tukey
HSD (Honest Significant Difference) test was applied to determine if means differ between
treatments. Tomato and chilli pepper plant measurements carried out under dry and wet leaf
198 surface conditions were processed separately, i.e. four sub-datasets were used in order to
compare the means separately for each combination of crops and moisture conditions.

Results

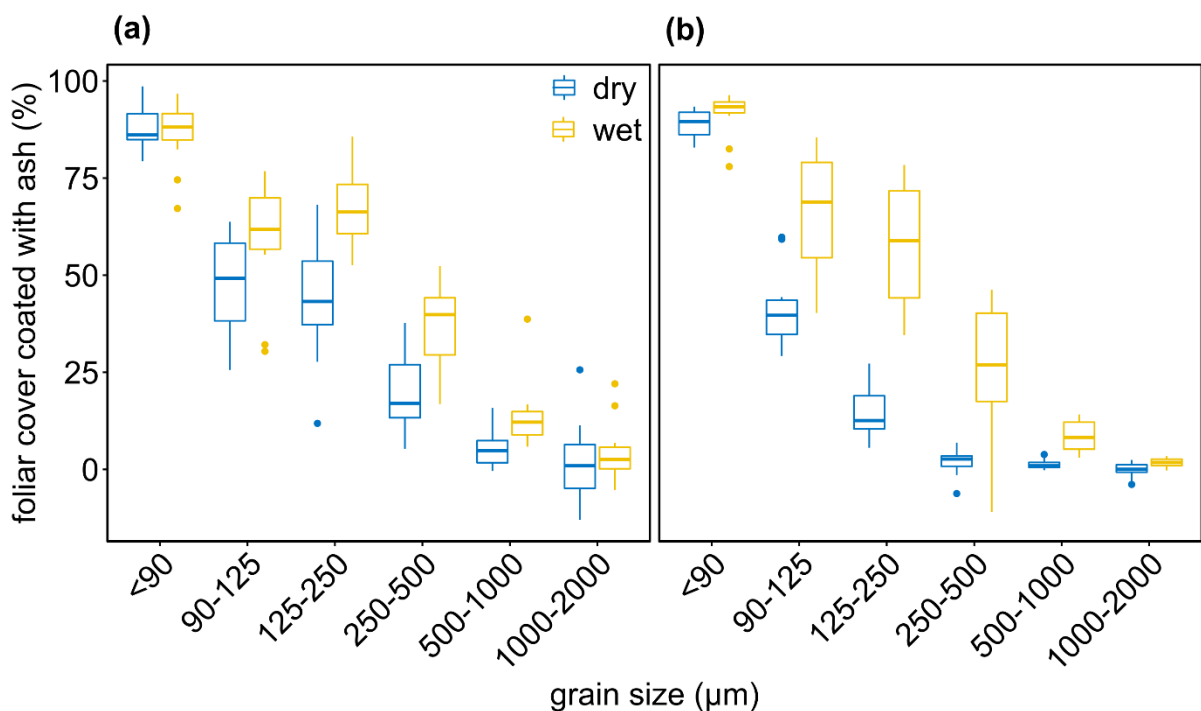

201 *Foliar cover coated with ash*

The percentage of foliar cover coated with ash ranged from 0 to 99%, with an average value of $36 \pm 33\%$ (Table S1). The effect of ash grain size, humidity conditions at leaf surfaces and

204 leaf pubescence on the foliar cover coated with ash is illustrated in Fig. 1. In general, foliar cover coated with ash increased with decreasing ash grain size. Grain size $\geq 500 \mu\text{m}$ covered only 10% of the foliar cover, with coverage increasing up to $\sim 90\%$ for ash $\leq 90 \mu\text{m}$. Wetting

207 of tomato and chilli pepper leaves prior to ash application had no significant effect on the retention of fine ash ($\leq 90 \mu\text{m}$). Nevertheless, significant higher tomato and chilli pepper leaf surface coverages ($+17 \pm 5\%$ and $+31 \pm 10\%$) were inferred for intermediate ash grain sizes

210 between 90 and 500 μm (Table S1, S2). We also note that for the ash grain size ranges 125-250 and 250-500 μm in dry conditions, coverage of tomato leaves with ash was significantly greater, by ~ 30 and 20% on average, compared to chilli pepper leaves.

213 Figure 1: Percentage of foliar cover coated with ash for tomato plant, i.e. which has pubescent

216 leaves, (a) and chilli pepper plant, which has glabrous leaves (b). The percentage of foliage

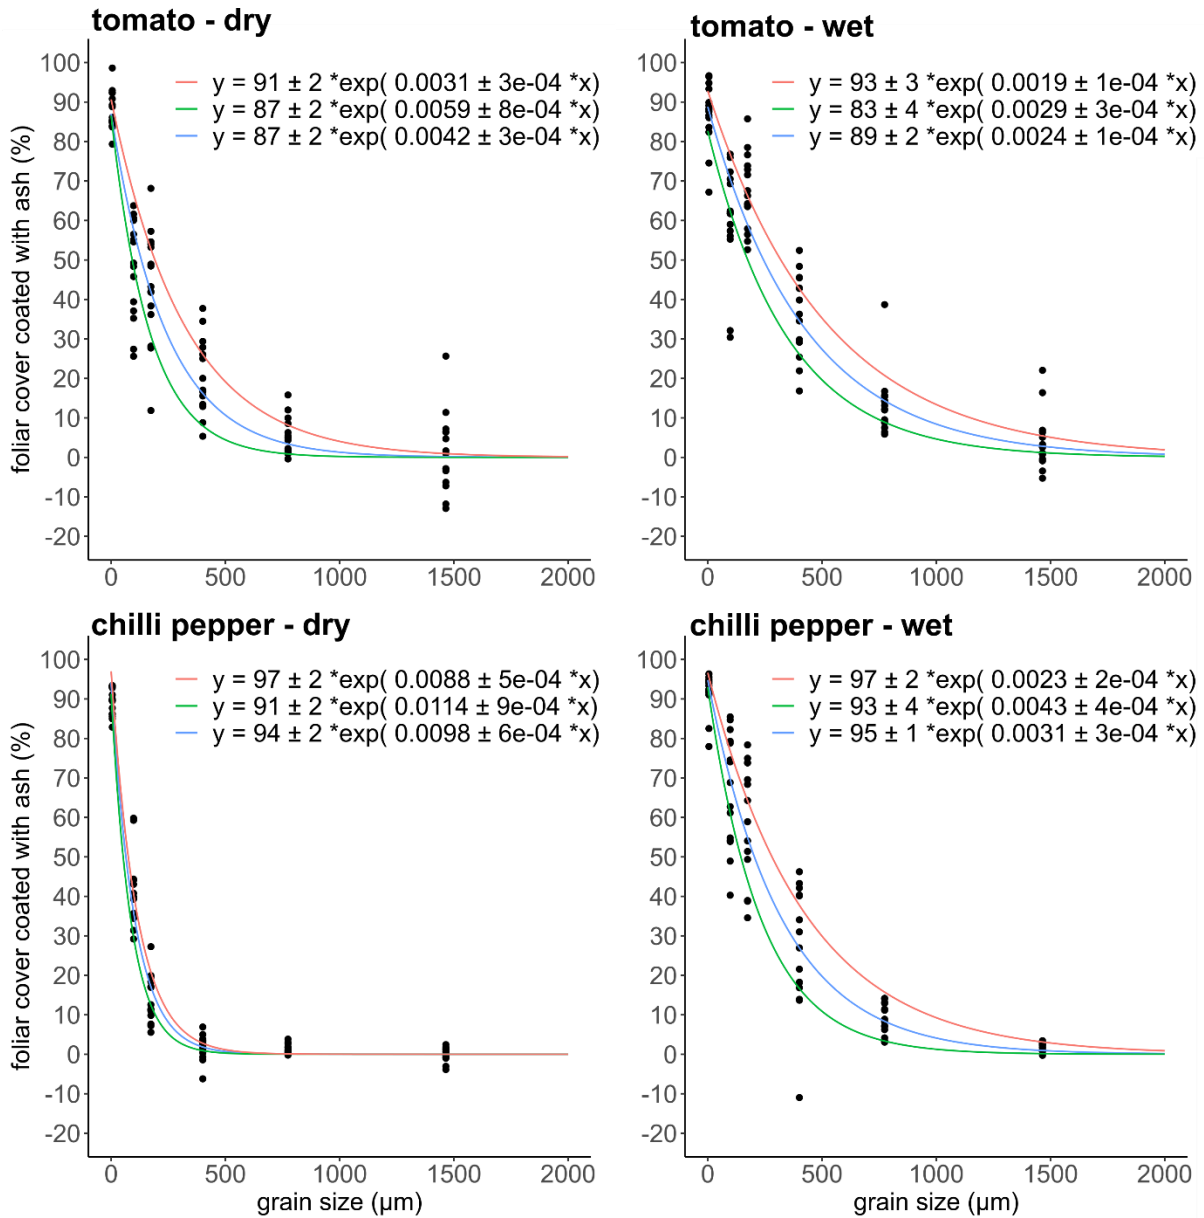

219 cover was measured for the six grain size ranges tested in dry and wet conditions at leaf surfaces. Each boxplot represents 15 repetitions. The median value sits within the box and represents the centre of the data. Fifty % of the data values lie above the median and 50% lie below the median. Measurement outliers are displayed as dots.

Quantifying ash retention as a function of grain size

Using the experimental results obtained for tomato and chilli pepper (Fig. 1), we predicted the
222 percentage of foliar cover coated with ash as a function of grain size, when leaf surfaces are
dry or wet. Five convex models (i.e. exponential decay, power curve, rectangular hyperbola,
asymptotic curve and logarithmic curve) were fitted to the data points using the *aomisc* and
225 *nlme* packages in *R* (Onofri, 2020; Pinheiro and Bates, 2022) (Fig. S5). The median grain size
was used to represent the corresponding grain size range. A lack-of-fit sum of squares test
was applied to evaluate the relevance of each model. Since the five models have different
228 numbers of parameters, their test statistics (F^*) could not be compared directly. Instead, the
models were assessed based on their p -values (Table S3). All the models have p -values $> 5\%$,
with no evident lack-of-fit. The exponential decay model had the highest p -value for the four
231 sub-datasets (0.82, 0.98, 1, 1 for dry tomato, wet tomato, dry chilli pepper and wet chilli
pepper, respectively) and it was chosen for the predictions.

Quantile regressions using the exponential decay model indicate that for 500 μm ash particles,
234 there is a 50% chance to cover ~ 10 and $\sim 27\%$ of tomato foliar cover in dry and wet
conditions, respectively (Fig. 2). Similarly, for chilli pepper, foliar covers of < 1 and 20% are
estimated in dry and wet conditions, respectively. By the same tenet, there is a 50%
237 probability that ash with a median of 63 μm in diameter covers up to $\sim 67\%$ (dry conditions)
and $\sim 77\%$ (wet conditions) of the foliar cover in tomato, and $\sim 51\%$ (dry conditions) and
 $\sim 78\%$ (wet conditions) of the foliar cover in chilli pepper.

240

243 Figure 2: Quantile regression with the first quartile (green), median (blue) and third quartile (red) for tomato and chilli pepper plants in dry and wet conditions at leaf surfaces.

Distribution of ash retention on the foliar cover

In addition to controlling ash retention on leaves, grain size, conditions of humidity at leaf surfaces and leaf pubescence affect the location of ash retention (Fig. 3). For tomato plants in dry conditions, ash $\leq 90 \mu\text{m}$ tended to be lodged on the leaf surface wherever it had settled. For glabrous chilli pepper leaves, leaf angle dictates if the ash particles remain on the leaf surface after deposition or slide off and relocate elsewhere. Ash with intermediate grain sizes between 90 and 500 μm behaved differently, depending on humidity conditions. For both

246

249

tomato and chilli pepper plants, the ash material was found mainly along the primary and secondary veins of the horizontal upper leaves when they were dry. However, in wet conditions, ash was more homogeneously distributed over the leaf surface. Coarser ash ($\geq 500 \mu\text{m}$) accumulated preferentially in the folds of growing leaves.

255

		$\leq 90 \mu\text{m}$	90-125 μm	125-250 μm	250-500 μm	500-1000 μm	1000-2000 μm	control

	wet							

Figure 3: Photos processed with ImageJ of tomato and chilli pepper plants before (control) and after exposure to $\sim 570 \text{ g m}^{-2}$ of ash varying in grain size (≤ 90 , 90-125, 125-250, 250-500, 500-1000, 1000-2000 μm) and in dry and wet conditions at leaf surfaces. The part of the foliar cover depicted in black corresponds to the green leaf surface area that was not covered with ash. The image surface area is equivalent to $\sim 800 \text{ cm}^2$. The original photos of the ash-covered plants are provided as supplementary material (Fig. S6).

Discussion

264 *Influence of grain size on ash retention*

The foliar cover coated with ash increases exponentially (from ~ 10 to 90%) when grain size decreases from 500 to 90 μm , whether in dry or humid leaf conditions (Fig. 2). This relationship was established for a single ash mass load ($\sim 570 \text{ g m}^{-2}$). For ash in the intermediate size range, a higher load could result in enhanced retention of the particles,

particularly along the primary and secondary leaf veins as these consist of less elastic tissues
270 that can better absorb the kinetic energy of impinging ash particles of intermediate grain size.
However, for fine ash, we do not expect more retention to occur if tomato and chilli pepper
leaves were exposed to higher loads because a large proportion of the uncovered foliage is
273 comprised of leaves that, due to their steep angle, cannot retain ash particles efficiently. As
mentioned earlier, coarse ash particles tend to lodge primarily on leaf folds. Thus, their
retention on foliage will likely be limited by the number of leaf folds. Overall, we anticipate
276 that for ash load values $>570 \text{ g m}^{-2}$, the exponential dependence of ash retention on ash grain
size will start to degrade and instead, a linear relationship would be a better model. The
increased ash retention when grain size decreases is in accordance with the field observations
279 of Miller (1967) after the 1963 eruption of Irazú volcano, Costa Rica, who found a higher
degree of retention of the smaller particles by crop foliage (alfalfa, maize, bean, beet,
cabbage, carrot, pea, pepper, potato, radish and squash). Johnson and Lovaas (1969) and
282 Witherspoon and Taylor (1970) reached a similar conclusion after dusting various crops
(alfalfa, maize, squash, soybean, sorghum, peanut and clover) with quartz powders differing
in grain size (88-175 and 175-350, and 44-88 and 88-175 μm , respectively).

285 The fate of a solid particle falling from the atmosphere and hitting a leaf surface will depend
on how much of its initial kinetic energy is absorbed through tissue deformation (Vogel,
1989; Niklas, 1999; Benson, 2015). Ignoring aggregation processes and considering a
288 constant particle bulk density, the coarser the particles, the larger their terminal fall velocity
and thus, kinetic energy (Dellino et al., 2005; Benson, 2015), simply reflecting that mass
increases with grain size. If particles retain enough kinetic energy after impact, they can
291 bounce back and be ejected off the leaf or deposited elsewhere (Gregory, 1961; Chamberlain,
1967; Starr, 1967; Chamberlain and Chadwick, 1972). Otherwise, they will settle on the upper
side of leaves, although they may be subsequently displaced as new particles impinge the leaf

294 surface. Based on the drag model for non-spherical particles of Bagheri and Bonadonna
(2016), we estimated the terminal fall velocity of individual particles of 10, 100, 170, 410,
710 and 1470 μm , representing the median values of the six ash size ranges used in our
297 experiment. Terminal fall velocity increases with grain size and is five times lower for
particles of 100 μm diameter (assimilated to the fine ash fraction) than for particles of 410 μm
diameter (corresponding to coarse ash) (Table S4). This result suggests that the kinetic energy
300 of the finest ash particles is $\sim 10,000$ times smaller than that of the coarsest material. The low
kinetic energy of fine particles probably explains why ash in the $\leq 90 \mu\text{m}$ size fraction
produces a greater foliar cover compared to ash $\geq 500 \mu\text{m}$ (Fig. 2). In contrast, coarse ash
303 particles with higher kinetic energy will tend to lodge on less elastic leaf structures, such as
primary and secondary veins and folds (Fig. 3). As mentioned above (section Material and
methods), an inherent limitation of our experimental study is that the ash material did not
306 contain the vesicular particles that are usually found in various proportions in ash fallout from
explosive eruptions. We speculate that the irregular shape of vesicular ash could enhance
retention on foliage, perhaps even more so if the leaf surfaces are pubescent or wet. Thus, our
309 measurements may be regarded as conservative estimates.

Influence of leaf pubescence on ash retention

On average, ash particles in the intermediate size range 125-500 μm cover $\sim 25\%$ more foliar
312 cover in tomato than in chilli pepper (Fig. 2, Table S1). This is attributed primarily to the
presence of leaf hairs in tomato. Sæbø et al. (2012) and Ram et al. (2012) demonstrated that
dust accumulation on the foliage of various trees and shrubs is proportional to leaf hair
315 density. Leaf hairs enhance dust collection area and capacity to absorb the falling particles'
kinetic energy. In addition, leaf pubescence may prevent particles from sliding off the leaf
surface. By increasing friction on particles, leaf hairs counteract the gravity force generated

318 by mass loading on the leaf surface which pulls a leaf downward (Smith and Staskawicz,
1977). In our experiments, ash $\leq 90 \mu\text{m}$ adhered to the tip of pubescent leaves with a steep
inclination angle in tomato plants, whereas it barely encroached on the glabrous surface of
321 chilli pepper leaves (Fig. 3). Previous field observations of ash-impacted crops also highlight
a stronger adherence of ash on pubescent leaves (such as barley, corn, tobacco, tomato and
apple tree) and hairy fruits (such as peach, apricot, kiwi-fruit, strawberry and raspberry)
324 (Miller, 1967; Cook et al., 1981; Wilson et al., 2007; Sword-Daniels et al., 2011; Ligot et al.,
2022). Witherspoon and Taylor (1970) concluded that the pubescent leaves of squash and
soybean favour a uniform retention of quartz particles (88-175 μm). In contrast, the glabrous
327 leaves of rose plants exposed to the 1963 eruption of Irazú volcano, Costa Rica, collected
little ash material (Miller, 1967).

Influence of humidity conditions at leaf surfaces on ash retention

330 Wetting of leaves prior to application of ash with an intermediate grain size of 90-500 μm
increased the foliar cover coated with ash of tomato and chilli pepper by $17 \pm 5\%$ and $31 \pm$
10%, respectively (Fig. 2, Table S2). We also noted that the ash deposit that formed on pre-
333 wetted leaves appeared more homogeneous compared to that observed when the leaf surface
was dry (Fig. 3). Similarly, Miller (1967) reported during the 1963 eruption of Irazú that wet
leaf surfaces facilitated retention of ash $< 300 \mu\text{m}$ and formation of a homogeneous deposit.
336 Enhanced ash retention on wet leaves likely relates to the surface tension generated by water
molecules present on the leaf surface (Tabor, 1977; Israelachvili, 2011). Conversely, as plant
leaves are hydrophobic (Bhushan and Jung, 2006), more water on leaves, such as after a
339 heavy or prolonged light rain, could lead to formation of large water droplets able to erode
particle from the leaf surface, thereby reducing ash retention.

Modelling potential yield loss in tomato and chilli pepper plants exposed to ash

342 Our experimental results indicate that $\sim 570 \text{ g m}^{-2}$ fine ash can readily cover the upper side of
leaves (Fig. 2). Assuming an ash material comprised of spherical particles $90 \mu\text{m}$ of diameter
and with a density of 2.54 g cm^{-3} (i.e. the density of phonolite), we calculated that a mass load
345 as low as $\sim 8.6 \text{ g m}^{-2}$ can form a monolayer deposit on a leaf surface. While this estimate
represents an oversimplified situation, it is more than fifty times less the ash load ($\sim 570 \text{ g m}^{-2}$)
used in our experiment. Since fine particles are ubiquitous—albeit in various proportions—in
348 ash fallout (Rust and Cashman, 2011; Costa et al., 2016), an ash coating on leaf surfaces is
likely to be the rule in vegetated areas affected by explosive eruptions. Importantly, the
presence of solid particles on foliage exerts a shading effect, which reduces light interception
351 (LI , dimensionless) by leaves (Thompson et al., 1984; Hirano et al., 1990). For example,
Hirano et al. (1991) measured a $\sim 20\%$ decrease in LI after treating mandarin tree leaves with
only 4 g m^{-2} of road dust ($0.1\text{-}100 \mu\text{m}$). Similarly, deposition of 10 g m^{-2} of ash ($0\text{-}100 \mu\text{m}$)
354 on cucumber plants led to a $\sim 20\%$ reduction in LI (Hirano et al., 1992).

Considering that LI drives net photosynthesis rate and thereby, total biomass production
(Wilson, 1967; Biscoe et al., 1977; Monteith, 1977; Weraduwege et al., 2015), we contend
357 that even a thin ash deposit on crop leaves can drive yield loss. Thus, the interference of ash
with LI provides an indirect mean to predict the potential crop production loss for ash mass
loads below the threshold ($\sim 6\text{-}30 \text{ kg m}^{-2}$ mass load) of direct mechanical damage to plants.
360 Although we did not measure LI in our experiment, this parameter can be inferred using the
following expression (Monteith, 1969):

$$LI = (1 - e^{-k \times LAI}) \quad (1)$$

363 where k is the light interception coefficient (dimensionless). The temporal evolution of LAI
during plant growth has been documented for tomato and chilli pepper in several studies (e.g.

Campillo et al., 2010; Monte et al., 2013; Al Mamun Hossain et al., 2017; Mendoza Perez et al., 2017), allowing the estimate of LI via Eq.(1).

In light-limited situation, i.e. the other growth parameters (e.g. water and nutrient status) being optimum, the daily biomass accumulation by crop canopy ($CBIO_c$, $g\ m^{-2}\ day^{-1}$) depends on LI according to (Monteith, 1972; Hatfield, 2014):

$$CBIO_c = Q \times LI \times RUE \quad (2)$$

where Q is the incident radiation ($MJ\ m^{-2}\ day^{-1}$) and RUE ($g\ MJ^{-1}$) the radiation use efficiency. Representative values for Q in Belgium ($10.6\ MJ\ m^{-2}\ day^{-1}$, warm temperate humid climate, Solargis, 2022) and RUE are available from the scientific literature (Table S5). The crop harvested biomass ($CBIO_h$, $g\ m^{-2}\ day^{-1}$) is calculated as the sum of the $CBIO_c$ in the time period considered (i.e. number of days elapsed between transplanting and harvest) multiplied with the harvest index, i.e. the fraction of the total aboveground biomass allocated to the harvested parts of the plant (HI , dimensionless) (Kemanian et al., 2007; Hay, 2008):

$$CBIO_h = \sum_{sowing}^{harvest} CBIO_c \times HI \quad (3)$$

Figure 4 depicts the concepts underpinning Eqs. (1), (2) and (3).

We consider two effects of ash on plant yield: reduction in LAI and premature biomass senescence. The former leads to lower accumulated biomass after formation of the ash deposit, whereas the latter is responsible for a loss of biomass that accumulated prior to ash fall. We hypothesise that LAI reduction and biomass dying in crop plants exposed to ash is directly proportional to the percentage of foliar cover coated with ash deposits (Fig. 2), presupposing that ash-affected leaves lose their ability to perform photosynthesis efficiently. Based on this, and using Eqs. (1), (2) and (3), potential crop yield loss ($CYL_{\%}$, %) can be

387 deduced by comparing the harvested biomass in the absence ($CBIO_h^{no\ ash}$) and presence
 (390 $CBIO_h^{ash}$) of ash (see Supplementary materials):

$$CYL_{\%} = 100 \times \frac{CBIO_h^{no\ ash} - CBIO_h^{ash}}{CBIO_h^{no\ ash}} \quad (4)$$

390

Figure 4: Cartoon conceptualising the relationships between canopy leaf area index (LAI), light interception by canopy, canopy total biomass and harvested biomass.

393 To illustrate our approach, we estimated $CYL_{\%}$ for tomato and chilli pepper plants exposed to
 ~0.6 mm (~570 g m⁻²) of ash. We tested different ash size distributions and evaluated the
 influence of humidity conditions at leaf surfaces on ash retention. Two scenarios of plant
 396 exposure to ashfall were considered: one in which 25% of the plant growth period is
 completed (i.e. 32 days after transplanting for tomato and 57 days after transplanting for chilli
 pepper), and one in which 75% is achieved (i.e. 97 days after transplanting for tomato and
 399 172 days after transplanting for chilli pepper). The daily LAI evolution of tomato and chilli
 pepper plants during growth was computed in R using published data (Fig. S6).

In our model, the entire plant canopy received the same amount of ash, although some leaves
 402 may be less exposed due to their position on the stem. As the ash mass load is low (570 g m⁻²),
 we also considered that ash deposition on leaves neither halt plant growth nor production
 of new leaves (Neild et al., 1998; Ligot, 2022). On the day of the eruption, the LAI is reduced
 405 by an amount corresponding to the percentage of foliar cover coated with ash. On the
 following days, it re-increases as new leaves formation resumes at a rate similar to that before

exposure to ash. If time permits, the *LAI* may reach a value identical to that of a plant that
408 would not have received ash. The calculated temporal evolution of the *LAI* of tomato plant
that has completed 25% of its growth period when it receives ash (90-125 μm in diameter,
mass load of $\sim 570 \text{ g m}^{-2}$) in dry conditions is illustrated in Fig. 5a. A similar temporal
411 evolution of *LAI* is obtained for chilli pepper (Fig. S7).

The presence of ash on plant canopy may lead to premature leaf senescence (as reported by
Miller, 1967; Neild et al., 1998; Wilson et al., 2007; Ligot et al., 2022), impacting *CBIO_h* (Eq.
414 3). To account for this effect, we subtracted the ash-coated leaf biomass from the total canopy
biomass, the latter being comprised of the leaves and stem. For tomato and chilli pepper
plants, leaf biomass represents $\sim 60\%$ of canopy biomass (Kleinhenz et al., 2006; Elia and
417 Conversa, 2012; Poorter et al., 2015). The leaf biomass fraction affected by ash can be
inferred from Fig. 1. Resolving Eqs. (1) and (2), the temporal evolution of *CBIO_c* for tomato
or chilli pepper subjected to ash can be predicted. Fig. 5b illustrates this for tomato plant
420 exposed in dry conditions to ash deposition (90-125 μm in diameter; mass load of $\sim 570 \text{ g m}^{-2}$)
32 days after transplanting (i.e. at 25% of growth period). Since the leaf-to-canopy biomass
ratio and percentage of leaf biomass covered with ash which dies are equal for both crops
423 (Table S5, Kleinhenz et al., 2006; Elia and Conversa, 2012; Poorter et al., 2015), a similar
trend is inferred for chilli pepper (Fig. 6).

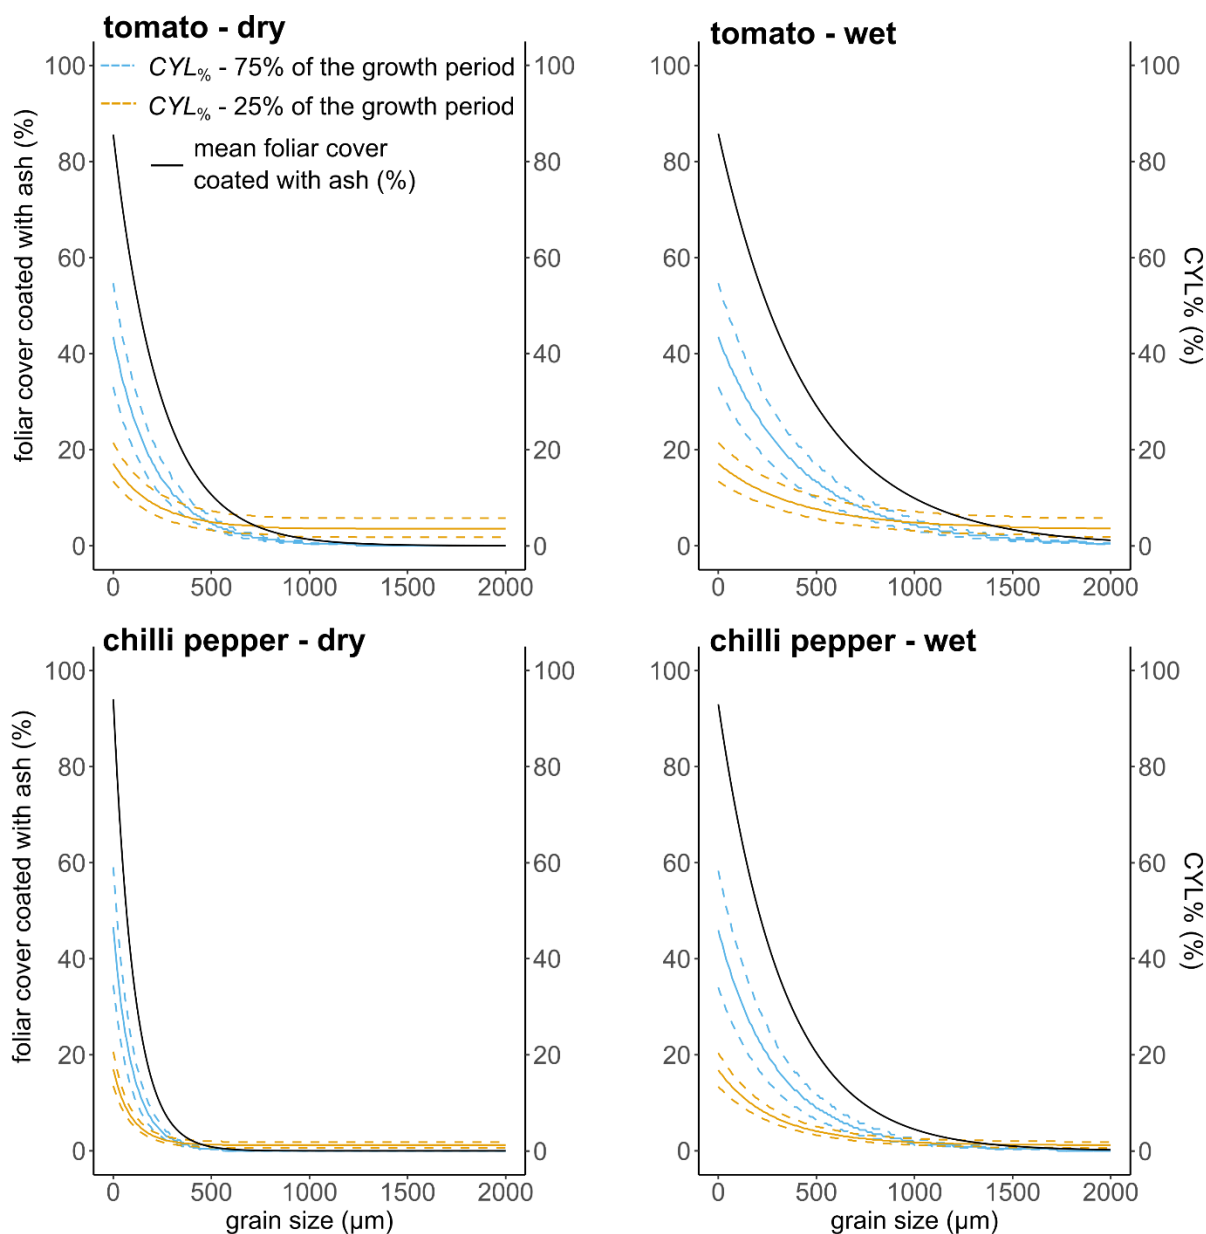

426 Figure 5: Temporal evolution of leaf area index (*LAI*) (a) and daily biomass accumulation
 (429 *CBIO_c*) (b) of tomato plant exposed to $\sim 570 \text{ g m}^{-2}$ of ash (size range: 90-125 μm) 32 days
 after transplanting (i.e. at 25% of the growth period) in dry leaf surface conditions. The
 hatched area represents the leaf biomass produced by the plant before the ashfall event and
 which will undergo premature senescence after it. The ash covered leaf biomass is inferred
 from the leaf-to-canopy biomass ratio (i.e. 60%) and the percentage of leaf biomass covered
 with ash (i.e. 48% for tomato in dry leaf surface conditions, Table S1).

As detailed above, ash impact on *CBIO_h* is modulated by different factors, including the *LAI*
 fraction that becomes photosynthetically inactive due to the presence of ash coatings on
 leaves (i), number of days elapsed between ash deposition and emergence of new leaves (ii),
 leaf-to-canopy biomass ratio (iii), and percentage of leaf biomass covered with ash and which
 eventually dies (iv). Our model calculations revealed that crop growth period determines the
 relative importance of each of these factors in determining *CYL%*. For example, if 90 μm ash
 affects tomato and chilli pepper plants in dry conditions at 25% of their growth period, *CYL%*

is most sensitive to (i) and (ii), whereas for older plants that have completed 75% of their
441 growth, (iii) and (iv) are the main factors driving *CYL%* (see Supplementary materials).

In order to assess the error on *CYL%* estimates, we applied a stochastic approach with 10,000
simulation runs using a random value for each of the four factors (as listed above) that can
444 influence the final model output. We posited that the values taken by factors (iii) and (iv)
follow a gaussian distribution (Table S5), whereas variable (i) and (ii), which are always in
the range 0-1 and positive, respectively, are described by a truncated gaussian distribution.
447 Fig. 6 shows the uncertainties on *CYL%* as computed by fitting the first and third quartiles
around the median *CYL%* value for tomato and chilli pepper plants exposed to ash of different
grain sizes, either in dry or wet leaf conditions. Calculations were repeated for plants that
450 receive ash when at 25 and 75% of their growth period. For tomato, *CYL%* increases with
decreasing ash grain size (Fig. 6). Tomato plants at 25% of their growth may experience a 2-
17% decrease in yield depending on grain size and humidity conditions at leaf surfaces. A
453 significantly higher *CYL%* (0-42%) is anticipated when ash affects plants at 75% of their
growth. A similar pattern emerges for chilli pepper where *CYL%* varies between 1-17 and 0-
46% when considering that the plant receives ash when at 25 and 75% of its growth period,
456 respectively (Fig. 6). For intermediate ash grain sizes between 125 and 500 μm , the *CYL%* is
5, 3, 8 and 4% greater for tomato compared to chilli pepper when exposure to ash occurs at
25% of the growth in dry conditions, 25% of the growth in wet conditions, 75% of the growth
459 in dry conditions and 75% of the growth in wet conditions, respectively.

462 Figure 6: Potential crop yield loss ($CYL\%$, first quartile, median and third quartile) estimated
 463 for tomato and chilli pepper plants as a function of ash grain size in dry and wet conditions at
 464 leaf surfaces.

465 *Towards using LAI as an impact metric for predicting potential yield loss in ash-affected
 466 crops*

467 While deployment of field-based post-*EIA* will continue to enrich our understanding of ash-
 468 loss of production relationships, progress is contingent on eruption occurrence, site
 accessibility, limited field time, variations in environmental conditions and incomplete ranges
 of ash characteristics such as thickness and grain size (Jenkins et al., 2015). Here, we have

471 shown, using established theories of plant-physiological processes (Monteith, 1969; Monteith,
1972), how empirical data from experimental testing can be transformed into quantitative
insights for predicting potential yield loss in tomato and chilli pepper crops exposed to ash.

474 Changes in *LAI* and premature biomass loss in ash-affected crops are interpreted as dependent
on ash retention on leaves, a process influenced by grain size, plant traits and environmental
conditions (Fig. 1). Here, we exclude the possible effect of ash surface composition on ash
477 retention. As detailed in Eqs. (1), (2) and (3), crop yield depends on *LAI* and therefore, the
latter is regarded as an integrative impact metric. From this, we propose that *LAI*
measurements in crop plants subjected to ashfall offer a new method for analysing crop
480 vulnerability and assessing potential yield loss for ash mass loads below the threshold (~6-30
kg m⁻²) of direct mechanical damage to plants. The rapidly increasing ability to monitor crop
characteristics, including type, *LAI* and biomass, using optical and radar earth observation
483 data (Hosseini et al., 2015; Fang et al., 2019; Rosso et al., 2022) provides an unprecedented
opportunity to collect a spatially- and time-resolved information that can support the
development of more realistic and more complete ash-loss of crop production relationships.

486 In order to unlock the full potential of *LAI* estimates for investigating the vulnerability of
crops to ash events, more knowledge on how ash coatings on leaves interfere with *LI* is
required. In our model of potential yield loss in tomato and chilli pepper (Fig. 6), we equated
489 *LAI* reduction with the foliar cover percentage covered with ash. In essence, this means that
an ash deposit on leaves renders light interception inoperative. This may not always be the
case because *LI* by a crop canopy is determined not only by the *LAI* of the species, but also by
492 the light absorption characteristics of the leaves (Liang et al., 2012), here modified by the ash
deposit. Further laboratory investigations can generate the empirical observations needed to
better constrain the changes in *LI* in relation to the characteristics (thickness/mass load, grain
495 size, albedo) of the ash material deposited onto the leaf surface.

The evolution of *LAI* following an ash deposition event (Fig. 5a) was modelled by assuming that ash-affected plants will grow new leaves after a set period of time. Our analysis showed
498 that *CYL%* is sensitive to this parameter, therefore requiring adjustment depending on crop
type (Klepper et al., 1982). We also note that many crops (including major ones such as
wheat; Hay and Porter, 2006) have a determinate growth habit and as such, may not be able to
501 sprout new leaves if they receive ash late in their development cycle. Another assumption
made to evaluate the *LAI* trend over time is that the entire plant canopy received the same
amount of ash. Although this was verified for tomato and chilli pepper when at the seven- and
504 eight-leaf stage, respectively, it may not be necessarily the case at a later stage of their growth
if upper leaves partly shield the surfaces of leaves located below them from direct exposure to
ash. Thus, the effect of ashfall on crop *LAI* hinges both on plant growth characteristics and
507 timing of the volcanic eruption. We considered in our model that an ash deposit induces
premature leaf senescence, in agreement with field observations (Miller, 1967; Neild et al.,
1998; Wilson et al., 2007; Ligot et al., 2022). While this process probably relates to leaf
510 chlorosis due to *LI* reduction (Bilderback 1897; Mack, 1981; Ligot et al., 2022), its
temporality and precise mechanism remain unclear. New experimental investigations with
various crop plants will help to better constrain the proportion of leaf biomass affected by ash
513 which will be subjected to premature senescence.

We have highlighted that grain size, leaf pubescence and humidity conditions at leaf surfaces
control ash retention, which in turn drives *LAI* reduction. Other factors may influence ash
516 retention. For example, leaf microstructural features such as stomatal density and presence of
a waxy epicuticle have been shown to influence retention of non-volcanic dust particles
(Sæbø et al., 2012; Zhang et al., 2017). In addition, in the natural environment, wind- and
519 rain-driven erosion processes can remove ash deposited on foliage. Conversely, light rain may
induce crusting of ash, prolonging its residence time on leaves (Miller, 1966; Ayrís and

Delmelle, 2012; Le Pennec et al., 2012; Ligot et al., 2022). The significance of these
522 environmental variables in controlling ash retention time by leaves has never been assessed
quantitatively, calling for further field and experimental investigations linking ash residence
time on plants and impacts.

525 Finally, our approach for modelling production loss in tomato and chilli pepper exposed to
ash neglects impact to flowers or harvested plant parts, and assumes that light interception is
the main variable governing plant growth. While this is true in our study where water and
528 nutrient supply were never limited, more stringent conditions may be encountered in crop
fields subjected to ashfall. For example, an ash layer on the ground may alter water and gas
movements into and through the soil and surface runoff (Ayrís and Delmelle, 2012; Neslon,
531 2013; Tarasenko, 2018), in turn impacting the soil water balance. A better comprehension of
the side effects of ash deposition on the soil plant-system is needed in order to identify the
primary mechanisms driving the short- and long-term consequences for crop production.

534 **Conclusions**

Our study highlights the usefulness of conducting experimental measurements to supplement
observations obtained from post-*EIA*. It provides a new perspective into the volcanic and non-
537 volcanic factors that control ash impact on crops. The experimental results obtained for
tomato and chilli pepper plants demonstrate that ash retention on leaf surfaces increases with
decreasing grain size and is enhanced when leaves are pubescent and wet. We also showed
540 that, for a given ash mass load ($\sim 570 \text{ g m}^{-2}$), the leaf surface percentage covered with ash is an
exponential decay function of grain size of which the parameters are influenced by leaf
pubescence and humidity conditions at leaf surfaces. Thus, we conclude that the proportion of
543 fine material in ash fallout is an important hazard metric for assessing risk to crops. The

corollary to this finding is that relying on ash thickness (or mass load) alone to anticipate crop damage from ash is inaccurate and possibly misleading.

546 Using the empirical relationship linking ash retention to ash grain size and equating ash retention with *LAI* reduction, we have developed a novel model framework to predict *CYL%*. This approach identifies *LAI* as a promising impact metric that can be quantified for assessing
549 crop production following an ashfall event. *LAI* is commonly retrieved *via* remote sensing measurements. The rapid deployment of new satellites allows data collection at increasingly high spatial and temporal resolution (for example, the European Space Agency's Sentinel-2
552 mission), paving the way for estimating *LAI* at the crop field scale. Additionally, the technology gives access to *FPAR*, i.e. the fraction of the solar radiation absorbed by live leaves for the photosynthesis activity, which should also record a reduction in light
555 interception for leaves covered with ash. We anticipate that tapping into satellite-derived measurements will considerably improve our quantitative understanding of crop vulnerability to ash fallout. However, for exploiting their full potential, field- and laboratory-based
558 validations are required, including experiments aimed at constraining *LI/LAI* reduction in relation to ash retention and characteristics. Acquiring this knowledge will significantly enhance our capacity to estimate ash-related risks to crops accurately. Governments and
561 payout agencies need such assessments in order to develop and implement effective risk reduction strategies for ashfall damage to crops in volcanically active agricultural regions.

Code availability

564 The Image J macro to analyse the plant photos and estimate the foliar cover coated with ash and the R script to compute the daily tomato and chilli pepper *LAI*, *LI*, *CBIO_c* and *CYL%* are available on GitHub (<https://github.com/NoaLigot/ImageJ-macro.git> and

567 <https://github.com/NoaLigot/R-script-LAI-LI-biomass-yield-loss/blob/main/script>,
respectively).

Data availability

570 All raw data can be provided by the corresponding author upon request.

Author contribution

NL, PD and GL conceptualized the experiments and NL carried them out. PB advised on the
573 statistical analysis and modelling approach. NL analysed the data, wrote the R script and ran
the simulations with the help of SB. NL and PD wrote the original draft with contributions
from all co-authors. PD secured funding for this research and provided the resources.

Competing interests

The authors declare that they have no conflict of interest.
