Abstract. Warming of the Arctic due to climate change means the Arctic Ocean is now ice-free for longer as sea ice melts earlier and refreezes later. It remains unclear how the extended ice-free period will impact carbon dioxide (CO_2) fluxes due to scarcity of surface ocean CO_2 measurements. Baseline measurements are urgently needed to understand how air-sea CO_2 fluxes will spatially and temporally vary in a changing Arctic Ocean. It is uncertain whether the previous basin-wide surveys are representative of the many smaller bays and inlets that make up the Canadian Arctic Archipelago. By using a research vessel that is based in the remote Inuit community of Cambridge Bay (Ikaluqtutiak, Nunavut), we have been able to reliably survey $p\text{CO}_2$ shortly after ice melt and access previously unsampled bays and inlets in the nearby region. We present four years of consecutive summertime $p\text{CO}_2$ measurements collected in the Kitikmeot Sea in the southern Canadian Arctic Archipelago. Overall, we found that this region is a sink for atmospheric CO_2 in August (average of all calculated fluxes over the four cruises was $-8.3 \text{ mmol m}^{-2} \text{ d}^{-1}$) but the magnitude of this sink varies substantially between years and locations (average calculated fluxes of 0.41 , -7.70 , -21.26 and $-2.08 \text{ mmol m}^{-2} \text{ d}^{-1}$ during the 2016, 2017, 2018 and 2019 cruises respectively). Surface ocean $p\text{CO}_2$ varied by up to $142 \text{ } \mu\text{atm}$ between years; this highlights the importance of repeat observations in the Arctic as this high interannual variability would not have been captured by sparse and infrequent measurements. We find that the $p\text{CO}_2$ value of the surface ocean at the time of ice melt is extremely important in constraining the magnitude of the air-sea flux throughout the ice-free season. Further constraining the flux in the Kitikmeot Sea will require a better understanding of how $p\text{CO}_2$ changes outside of the summer season. Surface ocean $p\text{CO}_2$ measurements made in the bays and inlets in the Kitikmeot Sea were $\sim 20\text{-}40 \text{ } \mu\text{atm}$ lower than in the main channels, and $p\text{CO}_2$ measurements made close to ice breakup (i.e. within 2 weeks) were $50\text{-}100 \text{ } \mu\text{atm}$ lower than measurements made >4 weeks after breakup. As basin-wide surveys of the CAA have focused on the deeper shipping channels and rarely measure

close to the ice break-up date, we hypothesize that there may be an observational bias in previous studies, leading to an underestimate of the CO₂ sink in the Canadian Arctic Archipelago. These high-resolution measurements constitute an important new baseline for gaining a better understanding of the role this region plays in the uptake of atmospheric CO₂.

40 **1 Introduction**

The Arctic Ocean plays an important role in the global carbon cycle as a sink for atmospheric carbon dioxide (CO₂). The solubility of CO₂ increases at low temperatures meaning that gas exchange and carbon drawdown is enhanced in cold polar surface waters; this is commonly known as the ocean solubility pump (Parmentier et al., 2013). Despite its role as a sink for CO₂, the magnitude of CO₂ uptake by the Arctic Ocean is poorly constrained as the region remains spatially and temporally
45 under-sampled due to difficult seasonal access heavily skewing measurements to the ice-free summer period (DeGrandpre et al., 2020). Additionally, logistical constraints in poorly charted nearshore waters also tend to bias underway CO₂ measurements to established shipping routes and the deep ocean basins, leaving much of the Arctic coastal zone under-sampled in the Surface ocean CO₂ Atlas (SOCAT v2022) (Bakker et al., 2016). This is not a trivial oversight, given that the Arctic Ocean is encircled by coasts and their associated shelf seas: 53% of the ~10.7×10⁶ km² Arctic Ocean surface area is
50 <200m in depth (Bates and Mathis, 2009).

The Arctic is already being heavily impacted by climate change (Landrum and Holland, 2020), with potentially devastating impacts on the Inuit and other indigenous communities who live there (Ford et al., 2008). It is not certain how the Arctic carbon system will respond to the present changes and how the effects of processes like ocean acidification will manifest and
55 impact Inuit communities. Projecting long-term change in regions with complex biogeochemistry (i.e. the coastal domain) is particularly difficult. To better predict how the Arctic carbon system will change in the future requires baseline measurements, including detailed surveys and regular monitoring of oceanic pCO₂ that reflect the diverse nature of Arctic marine environments.

60 The Canadian Arctic Archipelago (CAA) is made up of numerous islands that cover 13% of the Arctic Ocean (Macdonald et al., 2010). The numerous islands account for the Canadian Arctic having 162,000 km of coastline (Wynja et al., 2015). The islands of the CAA form a complex bathymetry which is important in determining the circulation in the CAA (Wang et al., 2012). The majority of existing pCO₂ measurements made in the CAA were collected along the southern route through the Northwest Passage on the research icebreaker *CGGS Amundsen* (Ahmed et al., 2019). This large pCO₂ dataset was used to
65 estimate a -7.7 ± 4 Tg C yr⁻¹ sink for the CAA during the open water season (Ahmed and Else, 2019). The *CCGS Amundsen* pCO₂ dataset provides excellent broad spatial coverage of the CAA but the vast area surveyed was limited in temporal coverage and fine spatial detail. The *CCGS Amundsen* typically only transited through the central straits, channels, gulfs and

seas that make up the southern route through the Northwest Passage once each summer. The numerous bays and inlets that are off the main channel were not sampled, meaning that local-scale $p\text{CO}_2$ variability was potentially unaccounted for during the synoptic scale sampling. This small-scale $p\text{CO}_2$ variability is difficult to predict empirically and may be better observed via regional studies. For example, the model of Ahmed et al. (2019) is known to underestimate $p\text{CO}_2$ by an average of ~ 26 μatm in Coronation Gulf and Dease Strait regions of the Kitikmeot Sea, likely due to river inflow. Understanding what caused this deviation from the model warrants further investigation and makes the Kitikmeot Sea a prime location for focused study.

Our understanding of the inorganic carbon system in the Kitikmeot Sea region comes from three distinct sources of measurements. Firstly, the 2010-2016 summertime ship measurements of $p\text{CO}_2$ in the central channel of the Kitikmeot presented by Ahmed et al. (2019). Their measurements show the region to be slightly undersaturated at the beginning of August, becoming slightly oversaturated in the middle of August through to the middle of September and then becoming undersaturated again in early October. Coronation Gulf is one of the few areas of the CAA that was consistently observed to be supersaturated with CO_2 in summer. Oversaturation of $p\text{CO}_2$ in Coronation Gulf is likely a result of high summer surface seawater temperatures (CO_2 thermodynamics mean that a 1°C temperature increases $p\text{CO}_2$ by 4.23% (Takahashi et al., 1993)) and high river discharge, particularly to the west (Geilfus et al., 2018). The second source of carbonate system measurements in the region are CO_2 flux observations at the Qikirtaarjuk Island observatory in the Finlayson Islands in Dease Strait (Butterworth and Else, 2018). Their measurements from the 2017 ice breakup season through to the summer indicate that there is CO_2 drawdown, and thus, undersaturation at breakup and for the first two weeks of open water. Near the end of July, the region transitions into a CO_2 source through to the end of August (Butterworth and Else, 2018). The region reverts to a sink in late August as the sea cools and surface $p\text{CO}_2$ declines; the region remains a sink until almost full ice cover in November (Butterworth et al., 2022). A similar pattern was observed in the summer of 2018, except notably, when $p\text{CO}_2$ began to fall in late August the region did not revert all the way back into a sink (Butterworth et al., 2022). The third source of carbonate system measurements are provided by Duke et al. (2021) who report autonomous $p\text{CO}_2$ measurements at a depth of 7 m from an instrument installed on the Ocean Networks Canada (ONC) underwater sensor mooring in Cambridge Bay between August 2015 and August 2018. The sensor measurements from Cambridge Bay indicate that $p\text{CO}_2$ is oversaturated in winter and undersaturated by the start of June at the onset of sea ice melt (Duke et al., 2021). Their measurements show that there is a short period of oversaturation in the middle of August coinciding with increased sea temperature, the ocean then quickly returns to a sink and remains undersaturated up until freeze-up (Duke et al., 2021).

All three sources of measurements indicate that there is notable interannual variability in surface $p\text{CO}_2$ in the Kitikmeot Sea. The ship-based measurements provide a snapshot of spatial variability across the wider region during the open-water season whereas the time series from Qikirtaarjuk Island observatory and the ONC mooring provide insights into seasonal and interannual variability at specific locations. There are obvious shortcomings to both approaches. Icebreaker-based studies

may under-represent small-scale variability that exists in nearshore regions that are inaccessible due to the vessel's large draft. Whereas the fixed observatories may over-represent temporal variability which is location-specific; for example, the ONC mooring is in an enclosed Bay close to the outlet of a large river (Manning et al., 2020) and the flux footprint of the Qikirtaajuk Island observatory spans a hotspot for mixing and productivity (Dalman et al., 2019). Given the limitations of each of these data sources, there is a need to understand how representative these data sources are of the wider Kitikmeot Sea region.

In this paper, we present surface $p\text{CO}_2$ measurements made during annual summertime surveys of the Kitikmeot Sea between 2016 and 2019. We use these new $p\text{CO}_2$ measurements to determine the magnitude of CO_2 uptake in the Kitikmeot Sea shortly after ice breakup. These new $p\text{CO}_2$ measurements also allow us to bridge the gap between previous measurements which were made at contrasting spatial scales (e.g. the low spatial variability point-scale observation from the local carbon observatories and the large-scale CAA-wide $p\text{CO}_2$ measurements). We use our new measurements to explore whether there are small-scale regional $p\text{CO}_2$ differences in the inlets and bays of the CAA which are not adequately represented by CAA-wide sampling. We also use our new measurements to explore $p\text{CO}_2$ variability in the proximity of these observatories to see whether they are representative of the wider region. In attempting to unify existing measurements we aim to unravel the seasonal and interannual variability of $p\text{CO}_2$ in the region.

2 Methods

2.1 Oceanographic setting

The Kitikmeot Sea (Figure 1) is a shallow shelf sea within the CAA that encompasses Coronation Gulf to the west, linked via Dease Strait to Queen Maud Gulf in the East, Bathurst Inlet to the South, and Chantrey Inlet to the Southeast (Williams et al., 2018). The communities of Cambridge Bay, Kugluktuk, and Gjoa Haven, Nunavut, are the main year-round settlements in the Kitikmeot Sea region. River inputs from mainland Canada and snow and ice melt provide a considerable source of freshwater in the region (Williams et al., 2018), resulting in some of the lowest salinity surface waters in the CAA (Ahmed et al., 2019). The Kitikmeot sea is nutrient-limited (Back et al., 2021), and as a result chlorophyll concentrations are also low in the region (Kim et al., 2020). Modelling results suggest that the stratification regime in Dease Strait and Queen Maud Gulf is characterised by a ~40 m warm fresh surface layer and a cold salty bottom layer which extends down to around 100 m (Xu et al., 2021). Coronation Gulf has a three layer regime composed of a 40 m warm fresh surface layer, a colder salty layer down to 100 m and a stable deep layer down to 350 m (Xu et al., 2021). Vertical mixing in the Kitikmeot Sea is prohibited by strong stratification throughout most of the year; however after sea ice breakup wind driven mixing gradually deepens the surface mixed layer resulting in an almost fully mixed water column in Dease Strait (Xu et al., 2021).

The oceanographic boundary for the Kitikmeot Sea has been designated as where the shelf shoals to <30 m in the west (Dolphin and Union Strait) and northeast (Victoria Strait) (Williams et al., 2018). At the Dolphin and Union Strait, warm
 135 fresher surface seawater flows out across the sills while subsurface flows of more saline nutrient-rich Pacific waters enter the sea. Another feature of the Kitikmeot Sea is that strong tidal currents in narrow channels can keep certain areas ice-free in winter (Williams et al., 2018). Strong tidal currents beneath sea ice such as around the Finlayson Islands in Dease Strait act to slow winter sea ice growth and enhance primary production by introducing nutrients (Dalman et al., 2019). First-year sea ice dominates the Kitikmeot Sea although some multiyear ice may be blown into Queen Maud Gulf from the northern part of
 140 the CAA (Xu et al., 2021). Seawater temperatures across the Kitikmeot Sea vary considerably throughout the year; they are around -2°C in winter and reach upwards of 10°C in summer (Xu et al., 2021). The bounding sills, large freshwater inputs and low nutrient loads make the Kitikmeot Sea unique within the CAA.

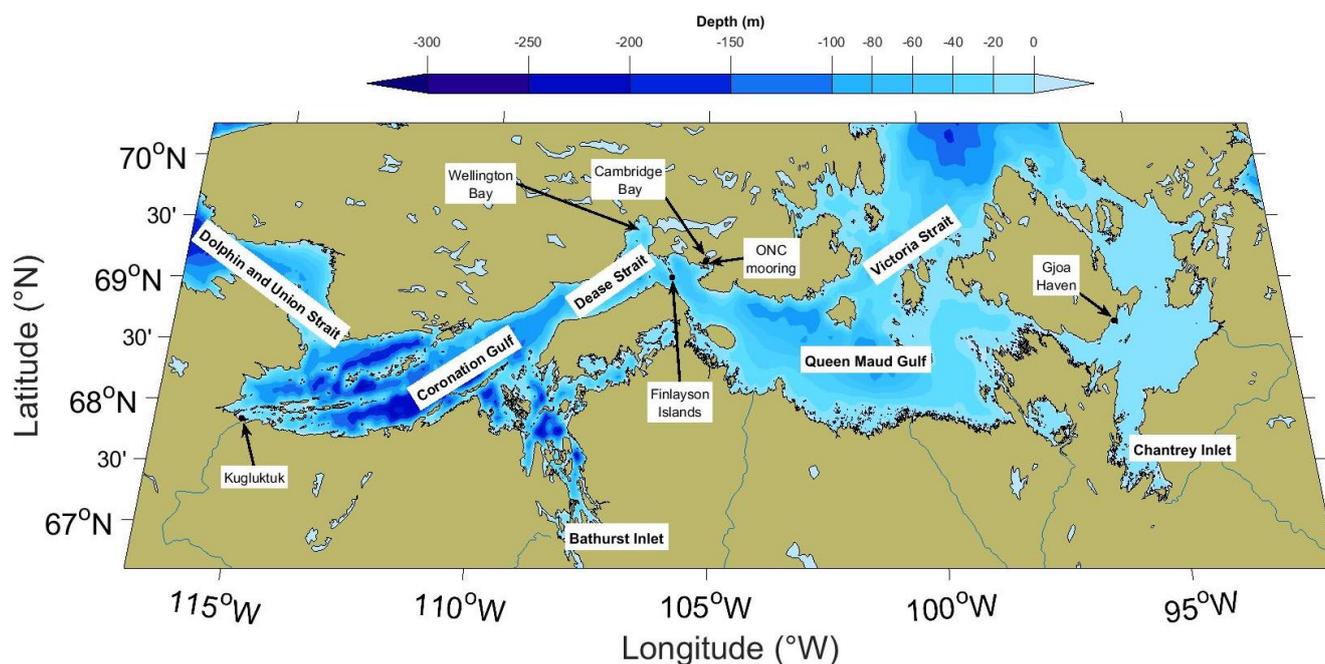

Figure 1: A map of the Kitikmeot Sea. The main settlements in the region (Cambridge Bay, Kugluktuk and Gjoa Haven) are labelled as are the Ocean Networks Canada mooring and the Qikirtaarjuk Island observatory where the eddy covariance tower is located. Shoreline data is from the World Vector Shoreline database and river data is taken from the CIA World Data Bank II (WDBII), both of which were accessed via the Global Self-consistent, Hierarchical, High-resolution Geography Database (GSHHG) (Wessel and Smith, 1996). Bathymetry data is taken from the 2-minute Gridded Global Relief Data (ETOPO2) v2 database (NGDC, 2006). This map was made using tools from the M_Map Matlab plotting package (Pawlowicz, 2020).

2.2 Field campaign description

145 Annual oceanographic surveys of the summertime surface seawater partial pressure of carbon dioxide ($p\text{CO}_2$ (sw)) were conducted between 2016 and 2019 in the Kitikmeot Sea (Figure 1) aboard the *RV Martin Bergmann* as part of the Marine

Environmental Observation, Prediction and Response Network (MEOPAR) and Kitikmeot Sea Science Study (K3S) programs (cruise details in table S1). In each of the four years, an underway $p\text{CO}_2$ system was deployed on cruises conducted under ice-free conditions between early August and mid-September. The Canadian High Arctic Research Station in Cambridge Bay, Nunavut acted as a staging ground for this work since Cambridge Bay is the home port for the *RV Martin Bergmann*.

Between 2016 and 2019, the cruise track varied from year to year depending on the focus of the work (Figure 2). The first week of each summer field season was typically used to complete work for the MEOPAR program, the majority of the ship time was spent in the proximity of Cambridge Bay, the Finlayson Islands, Wellington Bay and the western region of Queen Maud Gulf. Cruises in mid to late August were used to conduct work for the K3S program; the ship typically ventured further afield heading into Bathurst Inlet, the central region of Queen Maud Gulf and Chantry Inlet. The opportunistic nature of the data collection meant that data density varied between regions, as not every region was surveyed each year.

Sea ice concentrations in the months preceding each annual survey are taken from the daily gridded 3.125 km AMSR2 satellite radiometer product (Spreen et al., 2008). To determine weeks since open water, the nearest point on the AMSR2 grid was determined for each $p\text{CO}_2$ (_{sw}) measurement. The time between the measurement and when sea ice concentration fell constantly below the threshold value for the marginal ice zone (85%) (Cruz-García et al., 2021) was then calculated.

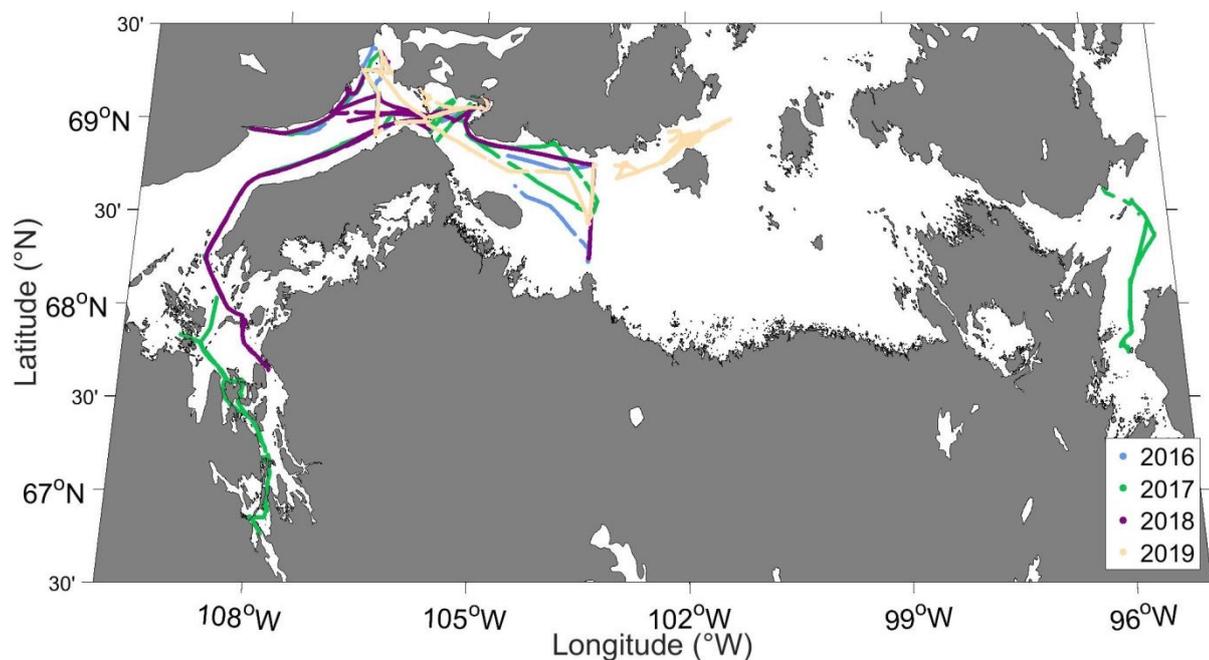

Figure 2: Ship cruise tracks for each of the four surveyed years.

2.3 Underway system

The *RV Martin Bergmann* is a 20 m repurposed commercial fishing trawler from Newfoundland with a draft of 3.4 m (Figure 3a and 3b). The ship does not have its own dedicated integrated underway system; instead surface seawater was sampled from an inlet at a depth of ~1 m through ~2 m of 1/2" ID PVC tubing securely draped over the bulwark of the vessel through an external hatch (Figure 3c and 3d). A Waterra Tempest WSP-12V-3 submersible pump was used to pump surface seawater through this inlet tubing at a rate of 10 L min⁻¹. *In situ* surface seawater temperature (SST_(1m)) was measured by a Campbell Scientific 107 temperature sensor attached to the tubing inlet.

Upon entering the ship, the flow of seawater passed through a SoMAS MSRC VDB-1 vortex debubbler and was then split between several instruments via Tygon tubing (Figure 3). The Idronaut Ocean Seven 315 On-line module thermosalinograph measured seawater temperature (SST_(tsg)) and salinity at a seawater flowrate of 0.5 L min⁻¹. The Wetlabs ECO BBFL2B Triplet measured fluorescence at a flowrate of 2.5 L min⁻¹. The ECO fluorescence sensor output was post-processed to remove spikes from bubbles and particles but was not calibrated against *in situ* measurements. A flow of 2 L min⁻¹ was directed to the seawater equilibrator. Instrument flowrates were set with manual flowmeters so that the internal instrument volumes and associated tubing of the Idronaut, ECO and equilibrator were flushed at the same rate, this meant that approximately half of the 10 L min⁻¹ flow from the pump was not analysed and was discarded overboard.

for the equilibrator was approximately 2 L min^{-1} . Seawater temperature was measured at the equilibrator seawater inlet using a thermistor (T_{equ}). The gas counter flow into the equilibrator was supplied by an air pump at a flowrate of 100 ml min^{-1} . CO_2 has been shown to fully equilibrate in this model liqui-cel when set up in a single pass setup at these water and gas flowrates (Sims et al., 2017). The system does not utilise a dryer and thus requires a water vapour correction in post-processing. For additional accuracy, the inbuilt H_2O sensor was calibrated with a LI-610 Portable Dew Point Generator on-site before each deployment. The Super CO_2 system has a standard multi-position valve and alternates between equilibrator air, atmospheric samples, and three gas standards. The timing of the valve switching was set so that each of the three CO_2 standards (mixing ratios ($x\text{CO}_2$) of 255.1, 409.9, and 566.4) were flushed through the system at 200 ml min^{-1} for 5 minutes every 6 hours. Standard gases were certified at the University of Manitoba against standards obtained from Environment and Climate Change Canada, and are thus traceable to World Meteorological Organization standards. The Super CO_2 system has an integrated air pump configured to make atmospheric measurements; these measurements were not used due to contamination from the ship's exhaust. The Super CO_2 system also measures atmospheric pressure $P_{\text{(atm)}}$.

Variables were logged every minute: $x\text{CO}_2$ and related variables were logged to the computer of the Super CO_2 system, the data recorded by the ECO were logged to a separate data file, and the latitude and longitude recorded with a Garmin GPS16X-HVS GPS unit were logged to a Campbell Scientific CR300 data logger. The CO_2 measured by the system was processed following (Dickson et al., 2007) SOP 5. Partial pressure of CO_2 ($p\text{CO}_2$) is measured by the Licor 850 in the Super CO_2 system, this is converted to the gas mixing ratio of CO_2 ($x\text{CO}_2$) using the pressure in the Licor (P_{licor}). The $x\text{CO}_2$ is calibrated using a piecewise linear interpolation in time with the three standards. The partial pressure is then determined in the equilibrator ($p\text{CO}_2_{\text{(equ)}}$) using the $P_{\text{(atm)}}$ and assuming full humidity. $p\text{CO}_2_{\text{(equ)}}$ is converted to $p\text{CO}_2_{\text{(1m)}}$ using the $T_{\text{(equ)}}$, $\text{SST}_{\text{(1m)}}$, and the fractional temperature change constant of (Takahashi et al., 1993). The depth of the seawater inlet was validated each year by comparing the thermosalinograph salinity and the in situ temperature sensor with surface temperature and salinity from CTD rosette measurements at the surface. There was no in situ temperature sensor during the 2017 and 2018 field seasons, the warming was then characterised from $T_{\text{(equ)}}$ and CTD rosette measurements following Ahmed et al. (2019), details of this can be found in the supplementary materials. Additionally, median observational values of -0.17°C and $+0.1$ were added to the in situ temperature and salinity to account for ubiquitous skin effects when calculating interfacial seawater $p\text{CO}_2$ (Woolf et al., 2019).

Using an identical setup DeGrandpre et al. (2020) estimate the $p\text{CO}_2$ uncertainty as $\pm 5 \mu\text{atm}$, this is the uncertainty for our 2016 and 2019 measurements. In 2017 and 2018, there is an additional uncertainty component associated with using an empirical relationship to obtain $\text{SST}_{\text{(1m)}}$. This additional uncertainty is calculated by taking the RMSD values from those empirical relationships (2017 = 0.49°C , 2018 = 0.64°C) and propagating them through the temperature equation for $p\text{CO}_2_{\text{(1m)}}$ (Takahashi et al., 1993). This results in an additional 2.09% and 2.74% uncertainty in $p\text{CO}_2_{\text{(1m)}}$, these values are similar to the 2% uncertainty reported by (Ahmed et al., 2019) following the same method. For a $p\text{CO}_2_{\text{(equ)}}$ value of $300 \mu\text{atm}$ this

equates to an additional 6.3 and 8.2 μatm uncertainty for each year respectively. Propagating uncertainties gives final uncertainties of 8.04 and 9.60 μatm for 2017 and 2018 respectively, these calculation of these uncertainties is consistent with the International Bureau of Weights and Measures (BIPM) Guide to the expression of uncertainty in measurement (GUM) methodology (JCGM, 2008).

220

The standard system configuration during the four cruises is detailed above; changes from this configuration during specific cruises are detailed in the supplementary materials (Table S2). There are several logistical aspects associated with deploying, operating, and maintaining an underway $p\text{CO}_2$ system in a remote Arctic location on a small vessel like the *RV Martin Bergmann*; this is discussed further in supplementary materials.

225 2.4 Calculations: Air sea CO₂ fluxes

In the absence of a reliable ship-based atmospheric CO₂ record, hourly measurements are taken from the atmospheric observatory in Barrow Alaska (71.32°N, 156.61°W) (K.W. Thoning, 2020; Peterson et al., 1987). Despite the long distance between Barrow and the Kitikmeot Sea (around 1800 km), atmospheric CO₂ should be quite similar at both locations as the atmosphere is well mixed for a long residence time gas like CO₂ and both locations are remote northern sites away from
230 biogenic and industrial emissions. Wind speed adjusted to a reference height of 10 m (U_{10}) is taken from the Qikirtaarjuk Island observatory (Butterworth and Else, 2018) for the 2017 and 2018 field seasons whereas a four times daily record of U_{10} from the NCEP-DOE v2 reanalysis product (Kalnay et al., 1996) is used for 2016 and 2019 field seasons.

The air-sea fluxes of CO₂ (F , $\text{mmol m}^{-2} \text{d}^{-1}$) is calculated as

$$F_{(\text{sea-air})} = k_w k_0 \Delta p\text{CO}_2 \text{ SF}$$

235 The water phase gas transfer velocity (k_w , cm hr^{-1}) is calculated using U_{10} and the parameterisation of Nightingale et al. (2000), a unitless Schmidt number (Sc) normalised to a Sc of 660 (Wanninkhof, 2014) is used to scale k_w .

$$k_w = (0.222 (U_{10})^2 + 0.333 (U_{10})) (Sc/660)^{-1/2}$$

$\Delta p\text{CO}_2$ (μatm) is the partial pressure difference between the seawater interface and air $\Delta p\text{CO}_2 = p\text{CO}_{2(\text{sw})} - p\text{CO}_{2(\text{air})}$. The solubility of CO₂ in seawater (k_0 , $\text{mol L}^{-1} \text{atm}^{-1}$) is taken from (Weiss, 1974). A unit scaling factor (SF) of 0.24 is used to
240 convert the units of k_w to md^{-1} . The Schmidt number and solubility are calculated using the *in situ* temperature and salinity values adjusted for skin effects (Woolf et al., 2019).

Direct measurements of the air-sea CO₂ fluxes ($F_{(\text{sea-air})}$) made using the micrometeorological eddy covariance technique (Butterworth and Else, 2018) can be used to infer $p\text{CO}_{2(\text{sw})}$ by rearranging the flux equation as follows using $p\text{CO}_{2(\text{air})}$ from the Licor 7200 at the Qikirtaarjuk Island observatory and SST and SSS from a mooring at 13m which was 1 km from the
245 tower (Butterworth et al., 2022).

$$(F_{(\text{sea-air})} / k_w k_0 \text{ SF}) + p\text{CO}_{2(\text{air})} = p\text{CO}_{2(\text{sw})}$$

3. Results

To facilitate comparisons between cruises made in different years, observations have been partitioned into separate oceanographic zones based on the local geography, observational data density, previous $p\text{CO}_2$ (sw) measurements, and proximity to the local carbon observatories (Figure 4a). Bathurst Inlet and Chantry Inlet were designated zones based on their large freshwater inputs. The Finlayson Islands and Cambridge Bay are where the Qikirtaarjuk Island observatory and ONC mooring are located, respectively; these regions were also heavily surveyed because the *RV Martin Bergmann* often returned to port in Cambridge Bay and passed the islands to access Wellington Bay and Bathurst Inlet. Wellington Bay (Figure 1) is a shallow, partially enclosed basin for which a relatively large amount of data was collected due to annual fish-tagging surveys associated with the local subsistence char fishery (Harris et al., 2020). All the measurements in the Dease Strait West zone were made in the central channel and are in the same approximate geographically region to those collected by Ahmed et al. (2019). Most of the measurements in the Queen Maud Gulf zone were made in the west; the box is large enough to include sparse measurements in the central and Northern regions which do not warrant being considered separately.

Observations of temperature, salinity, $p\text{CO}_2$ (sw), fluorescence, U_{10} , and CO_2 flux during the four field seasons are plotted as time series and coloured by the sub-region of the measurement (Figure 4b-4g). Summary statistics (mean, standard deviation, and range) of each variable in each region for all four cruises are presented in Table 1. Plots showing the timing of the cruise track, temperature, salinity, $p\text{CO}_2$ (sw), and chlorophyll-a fluorescence can be found in the supplementary materials (Figures S2 to S6).

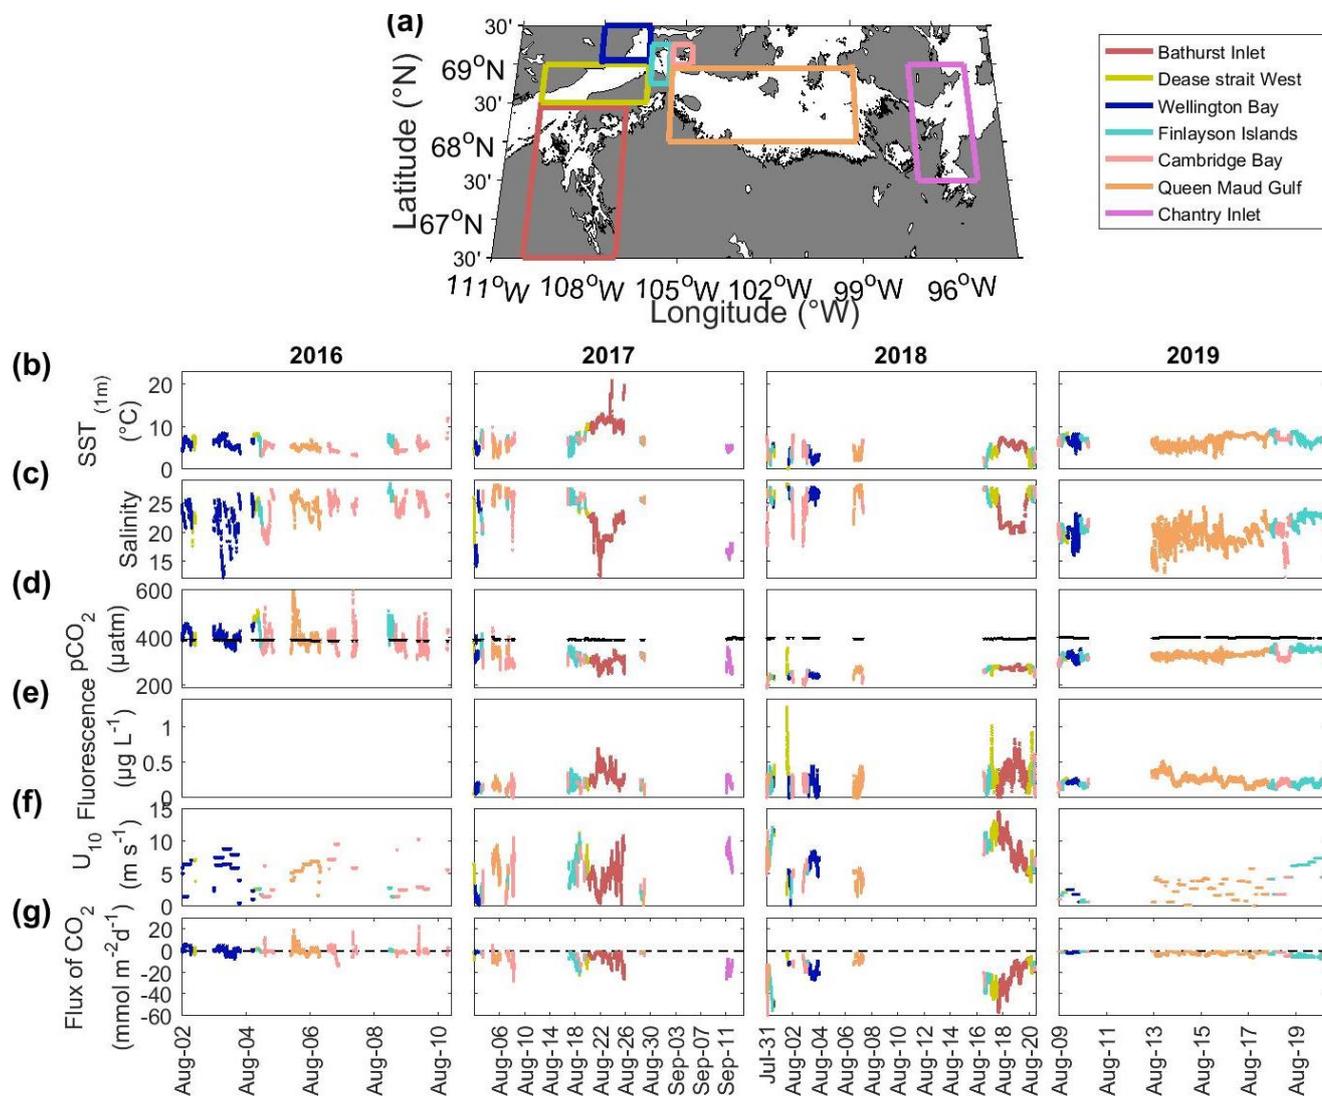

Figure 4: (a) Map of Kitikmeot Sea showing the region surveyed by the *RV Martin Bergmann* between 2016 and 2019. The sampled region was subdivided as described in the main text; these sub regions are shown as coloured boxes and correspond to the names in the legend. Timeseries subplots of underway surface ocean (1m) observations for 2016 through to 2019 of (b) SST (1m), (c) salinity, (d) $p\text{CO}_2$ (sw) (with $p\text{CO}_2$ (atm) in black), (e) fluorescence, (f) U_{10} , and (g) flux of CO_2 (no flux is indicated by a dashed black line). The time series data are coloured according to the sampling regions in panel (a). The period of measurements was not consistent between years so the date label tick spacing and the range are different between years. Large data gaps correspond to when the ship was in port between cruise legs or data outages.

SST_(1m) interannual variability was on the order of several degrees (Figure 4b), for example the SST_(1m) in 2018 was cooler than SST_(1m) in 2017 (Table 1). Inter-region SST_(1m) differences of $\sim 10^\circ\text{C}$ were observed during all four surveys (Figure 4b). Summertime warming of several degrees can be observed in the data for certain sub regions which were visited multiple times such as Cambridge Bay in 2016 and Queen Maud Gulf in 2019 (Figure 4b). Some of the sub regions were considerably

warmer than others (e.g., Bathurst Inlet in 2017 and 2018), whereas other regions like Queen Maud Gulf were consistently colder (tab11).

275 There was large interannual variability in surface salinity; for example salinity in 2019 was generally lower than 2018
(Figure 4c). Salinity values were much lower in Chantry Inlet in 2017 and Bathurst Inlet in both 2017 and 2018 relative to
the salinities in other regions in those years (Table 1). Salinity ranges on the order of ~5 – 10 were observed between regions
in all years. The salinity data are marked by rapid changes of ~5 which did not coincide with equivalent temperature changes
(Figure 3c); these salinity transitions are evident in the 2017 and 2018 Bathurst Inlet data, much of the Cambridge Bay data
and the Wellington Bay data from 2016 and 2019. There is evidence of freshening in the first week of August 2016 and in
280 Queen Maud Gulf in 2019, but there does not appear to be a seasonal freshening trend in 2017 or 2018.

285 There was high interannual $p\text{CO}_2(\text{sw})$ variability (Table 1), where $p\text{CO}_2(\text{sw})$ was close to equilibrium with the atmosphere in
2016 and highly undersaturated in 2017, 2018 and 2019 (Figure 4d). The $p\text{CO}_2(\text{sw})$ interannual variability was larger than the
observed regional variability each year (Table 1). $p\text{CO}_2(\text{sw})$ increased across all regions in both 2018 and 2019; this is also
seen as increases on return visits to the Finlayson Islands and Cambridge Bay several weeks apart from each other (Figure
4d). In all four years, Cambridge Bay had low $p\text{CO}_2(\text{sw})$ relative to the other regions. Low $p\text{CO}_2(\text{sw})$ values were also seen in
Bathurst Inlet, Chantry Inlet and Wellington Bay. Many low $p\text{CO}_2(\text{sw})$ regions were also low salinity regions. Fluorescence
was generally low throughout all the cruises in all years except for the relatively higher fluorescence signal in Bathurst Inlet
and around the Finlayson Islands (Figure 4e). The air–sea CO_2 flux (Figure 4g) reflects the trends in the predictor variables,
290 particularly $p\text{CO}_2(\text{sw})$ and U_{10} (Figure 4d and 4f). The air–sea flux calculated in 2016 was small ($0.41 \text{ mmol m}^{-2} \text{ d}^{-1}$) reflecting
the fact that the $p\text{CO}_2(\text{sw})$ was close to equilibrium with the atmosphere. In 2017 and 2019 $p\text{CO}_2(\text{sw})$ was quite undersaturated
(309 and $330 \mu\text{atm}$ respectively), the 2017 flux was larger ($-7.7 \text{ mmol m}^{-2} \text{ d}^{-1}$) than the 2019 flux ($-2.1 \text{ mmol m}^{-2} \text{ d}^{-1}$) as the
wind speed was very low in 2019 (3.1 ms^{-1}).

Table 1: Underway surface ocean (1m) observation summary table for the *RV Martin Bergmann* cruises from 2016 through 2019. Geographical sub regions are defined in Figure 4a. Top line is the mean \pm 1 standard deviation and the bottom row is the measurement range. Table averages are the average of all the observations for each variable for each year and have not been scaled to the spatial extent of each region. Whilst yearly averages are provided, as the spatial extent of the measurements from each year was different, comparisons between years should be made with caution.

Year	Sub region	No of obs	SST _(1m) (°C)	Salinity	pCO _{2(sw)} (µatm)	Fluorescence	U ₁₀ (m s ⁻¹)	Flux (mmol m ⁻² d ⁻¹)

295 4. Discussion

Presented in the results above are the multiyear summertime $p\text{CO}_2(\text{sw})$ observations made on *RV Martin Bergmann*. These data reveal the spatial and inter-annual variability of $p\text{CO}_2(\text{sw})$ near the beginning of the open-water season in the Kitikmeot Sea. To maximise the value of the $p\text{CO}_2(\text{sw})$ observations made on *RV Martin Bergmann* we will now present and discuss these new measurements alongside previous measurements and in the context of our current understanding of the carbonate system in the region.

300

4.1 Local scale – comparisons with the ocean carbon observatories

The two local observatories, the ONC mooring in Cambridge Bay and the Qikirtaarjuk Island observatory, provide measurements throughout the year that are not readily possible with shipboard observations. $p\text{CO}_2(\text{sw})$ is directly measured on the ONC mooring whereas $p\text{CO}_2(\text{sw})$ is calculated from the flux derived using measurements from the Qikirtaarjuk Island observatory eddy covariance “EC tower”. By taking the $p\text{CO}_2(\text{sw})$ observations from these two observatories alongside the new *RV Martin Bergmann* measurements we can create a multiyear timeline of $p\text{CO}_2(\text{sw})$ in the region (Figure 5). It should be noted that the three measurement sources in Figure 5 are not co-located, the Qikirtaarjuk Island observatory on the Finlayson Islands is 35 km west of the ONC mooring (Figure 1) and the Bergmann measurements span a slightly wider area (Figure 2). Despite the spatial disparity in these measurements, it should also be acknowledged that for calculations of global

305

310 CO₂ flux on a 1° x 1° grid, the majority of these measurements would fall within the same grid cell. It might be expected that on these sorts of spatial scales the measurements should agree close to perfectly, but that is not the case (Figure 5).

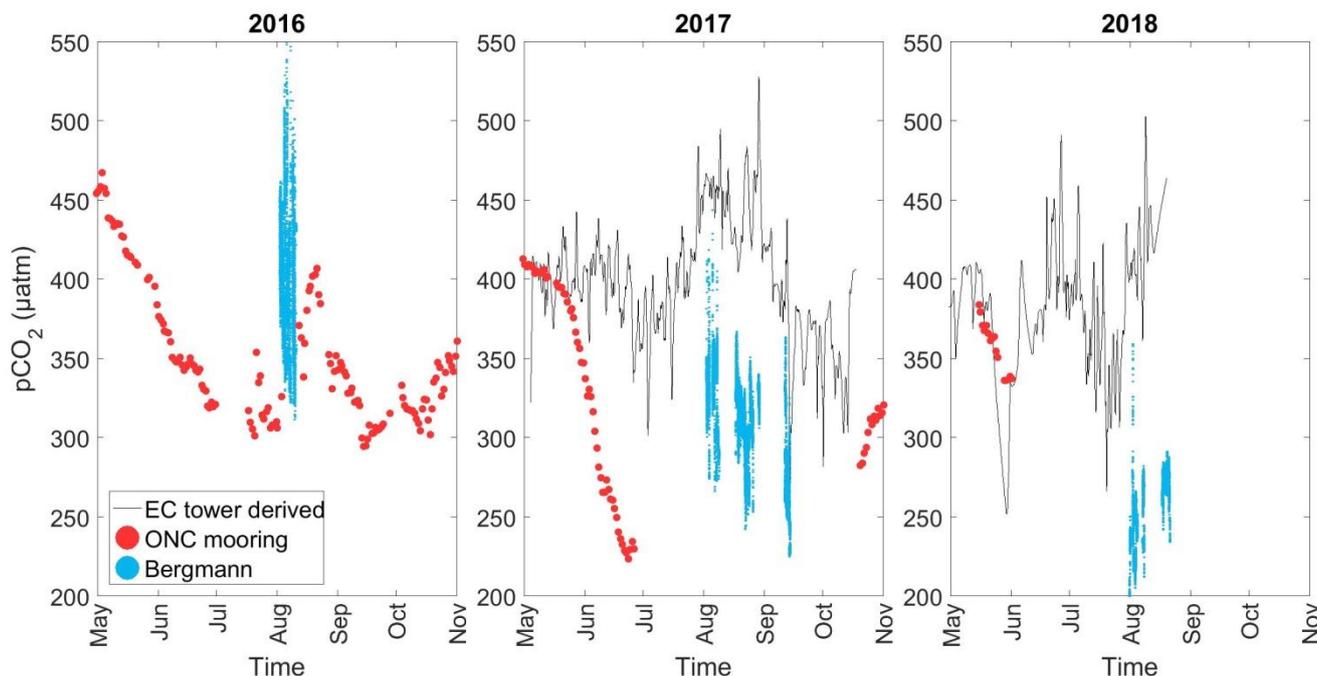

Figure 5: Surface $p\text{CO}_2$ (sw) from across the Kitikmeot Sea made in (a) 2016, (b) 2017 and (c) 2018. $p\text{CO}_2$ (sw) measurements from the ONC mooring are shown as red dots, all $p\text{CO}_2$ (sw) measurements from the *RV Martin Bergmann* are shown as blue dots and $p\text{CO}_2$ (sw) inferred from Eddy covariance at the Qikirtaarjuk Island observatory are shown as a black line.

The *RV Martin Bergmann* $p\text{CO}_2$ (sw) data are much lower in 2017 (Figure 5b) and 2018 (Figure 5c) relative to the values predicted from the EC tower, even when measurements were made in the footprint of the EC tower (18:30 – 23:10 3rd August 2017 $p\text{CO}_2$ (sw) from the tower was 414.67 and from *RV Martin Bergmann* was 344.21, 05:50– 06:40 August 1st 2018 $p\text{CO}_2$ (sw) from the tower was 408.69 and from *RV Martin Bergmann* was 237.40). The large differences between the methods can not be reasonably explained by changes due to SST as this would require an extremely large temperature gradient ~5–10 °C between the *RV Martin Bergmann* SST at 1 m and SST at the interface. The most likely explanation is that even though the *RV Martin Bergmann* measurements are being made close to the surface (at a depth of 1 m), surface stratification in the surface meter is driving the differences being observed. The impact of surface stratification on $p\text{CO}_2$ (sw) has been observed elsewhere in the Arctic (Ahmed et al., 2020; Dong et al., 2021) including for cases where differences can be up to 200 µatm (Miller et al., 2018). Surface stratification in the Kitikmeot Sea is caused by melting of first-year sea ice and the large freshwater input by rivers which alone contribute 70 cm of freshwater to the surface annually (Williams et al., 2018). The fact that the EC tower $p\text{CO}_2$ (sw) was higher than the *RV Martin Bergmann* $p\text{CO}_2$ (sw) would suggest that this is due to river induced stratification as river Arctic riverine water is often higher in $p\text{CO}_2$ (sw) (Cai et al., 2010). Interestingly,

the predicted $p\text{CO}_2(\text{sw})$ from the EC tower show a peak in early August 2017 and a downwards trend through to the end of August, something that is also seen in the ship based $p\text{CO}_2(\text{sw})$ observations (Figure 5b). Similarly, the predicted $p\text{CO}_2(\text{sw})$ from the EC tower increases in August 2018 at a similar rate to the increase seen in the shipboard $p\text{CO}_2(\text{sw})$ observations (Figure 5c). The fact that similar trends can be observed in the *RV Martin Bergmann* and the EC tower $p\text{CO}_2(\text{sw})$ does
330 suggest that seasonal trends in the region are detectable with both methods. The disagreement between the *RV Martin Bergmann* measurements and those from the EC tower highlights the need for year-round $p\text{CO}_2(\text{sw})$ in the flux footprint of the EC tower. Additionally, interfacial $p\text{CO}_2(\text{sw})$ measurements and vertical profiles may help reconcile the observed disparities seen between the two measurement sources of data.

335 There is good agreement in the $p\text{CO}_2(\text{sw})$ values between the EC tower and the ONC mooring in May, June, and October 2017 (Figure 5b) and in May and June 2018 (Figure 5c). The breakdown of stratification at the end of the ice-free summer period and over the winter (Xu et al., 2021) may explain the good agreement between the EC tower and the ONC mooring at these times. In June 2017 the two systems diverge, the $p\text{CO}_2(\text{sw})$ at the ONC mooring decreases due to a spring bloom (Duke et al., 2021) whereas $p\text{CO}_2(\text{sw})$ from the EC tower does not. As the bloom in Cambridge Bay is caused by wastewater
340 discharge (Back et al., 2021) it might be expected that this signal would not be detectable at the EC tower.

There appears to be an agreement between the *RV Martin Bergmann* collected data and ONC mooring in the summer of 2016. Unfortunately, the servicing period of the ONC mooring overlapped with the *RV Martin Bergmann* cruise dates meaning there was no period of direct data overlap. The four periods when the *RV Martin Bergmann* was moored up within
345 0.5 km of the mooring on 05:20–11:10 5th August 2016, 05:40–01:20 7/8th August 2016, 08:20–14:30 9th August 2016, 00:50–21:40 10th August 2016 the average $p\text{CO}_2(\text{sw})$ values were 392.58, 384.33, 365.85 and 370.02 μatm respectively. The ONC mooring on 10:00 3rd August was 326.11 and on 12:40 12th August was 371.03. Disagreement between the ONC mooring and the *RV Martin Bergmann* here may be due to different intake depths of the two systems. Stratification may mean the ONC mooring is not representative of $p\text{CO}_2(\text{sw})$ closer to the air-sea interface for parts of the ice free period of the year.
350 The spring 2016 measurements from the ONC mooring show that $p\text{CO}_2(\text{sw})$ was high in the spring leading into that field season, the trend towards increasing $p\text{CO}_2(\text{sw})$ due to warming is captured in August 2016 by the ONC mooring and the *RV Martin Bergmann* observations.

Combining the data sources in this way highlights the value of having these different observatories to look at multiyear
355 changes. The observatories provide context to the variability in the summertime $p\text{CO}_2(\text{sw})$ measurements from ships. The patchiness of the measurements from the ONC mooring and the Qikirtaarjuk Island observatory reflects the challenges in making these novel measurements in an extreme environment. Knowledge about how to run them and prevent instrument outages means that future measurements will build towards much needed continuous and complementary multiyear datasets.

4.2 Regional scales – spatial variability in the underway data

360 Focusing back on the *RV Martin Bergmann* data, there is clear evidence of spatial regional variability in the underway data. $p\text{CO}_2$ (sw) was typically lower by ~20-40 μatm in the small bays (Cambridge Bay, and Wellington Bay) and larger inlets surveyed (Bathurst Inlet, Chantry Inlet) compared to the central channel (e.g. Dease Strait West, the Finlayson Islands, and Queen Maud Gulf) (Table 1). The reason for relatively lower $p\text{CO}_2$ (sw) in the Bays and Inlets is not readily apparent. For this trend to be driven by temperature, the bays and inlets would need to be ~2°C colder, which was not observed. In fact, many

365 of these regions such as Bathurst Inlet were warmer which would usually predict higher $p\text{CO}_2$ (sw). Although the fluorescence sensor was not robustly calibrated against *in situ* measurements the fluorescence signal was consistent with previous measurements that showed the region to have widespread low primary production at the surface (Martin et al., 2013). Even though these regions did not have consistently higher surface chlorophyll-a concentrations, biological production at depth can not be ruled out as an explanation for lower $p\text{CO}_2$ (sw) in the bays. For example, wastewater discharge

370 has been shown to cause a deep chlorophyll bloom in Cambridge Bay (Back et al., 2021). A large under ice (Arrigo et al., 2012; Mundy et al., 2009) or ice edge (Perrette et al., 2011) phytoplankton bloom could also explain lower values in these bays and inlets. It is possible that these regional differences are driven by regional freshwater inputs; all four identified regions are fed by rivers and there are sharp salinity transitions of ~5 that point to the existence of mixing and fronts (Figure 4c). Rivers are typically thought to be highly oversaturated in $p\text{CO}_2$ (sw) in the Arctic due to organic matter breakdown

375 (Teodoru et al., 2009) so it might be expected that there would be higher $p\text{CO}_2$ (sw) in these bays and inlets. However, whilst the freshwater rivers are high in $p\text{CO}_2$ (sw) (Manning et al., 2020), they are unbuffered and thus have much lower DIC relative to seawater. Dilution by low $p\text{CO}_2$ (sw) ice meltwater does lower $p\text{CO}_2$ (sw) (Cai et al., 2010), a greater impact of ice meltwater in these bays and inlets may be contributing to the lower observed $p\text{CO}_2$ (sw).

380 The ONC mooring is located in Cambridge Bay in shallow water (9 m), at this depth the mooring is not impacted by the Freshwater Creek plume (Duke et al., 2021). It is still unclear how much of an impact being located in the isolated Bay has on the representativeness of these measurements for the Kitikmeot region. As the *RV Martin Bergmann* travelled into and out of the Bay multiple times during the four years of observations, differences in $p\text{CO}_2$ (sw) measured in the Bay and outside the Bay may help identify whether the ONC mooring site is representative of the region as a whole. All transects into and out

385 of Cambridge Bay are shown in Figure 6. Two sub-regions are designated, inside the Bay and outside the Bay, $p\text{CO}_2$ (sw) from the *RV Martin Bergmann* was averaged every two days for which there was data (Table 2). $p\text{CO}_2$ (sw) was largely similar inside and outside of the bay with $p\text{CO}_2$ (sw) typically $<\pm 12 \mu\text{atm}$. On the 17th August 2017 $p\text{CO}_2$ (sw) was much higher (33.29 μatm) in the Bay, as measurements are similar before (8th/9th) and after (19th/20th) this would point to this being due to something only happening in the Bay; possibly the river plume. Overall, the agreement between the measurements inside

390 and outside of the Bay is encouraging and suggests that $p\text{CO}_2$ (sw) in Cambridge Bay, at least broadly agrees with that in the

main Channel. Without more information, it is difficult to conclude whether the mooring is truly representative of the wider Kitikmeot Sea.

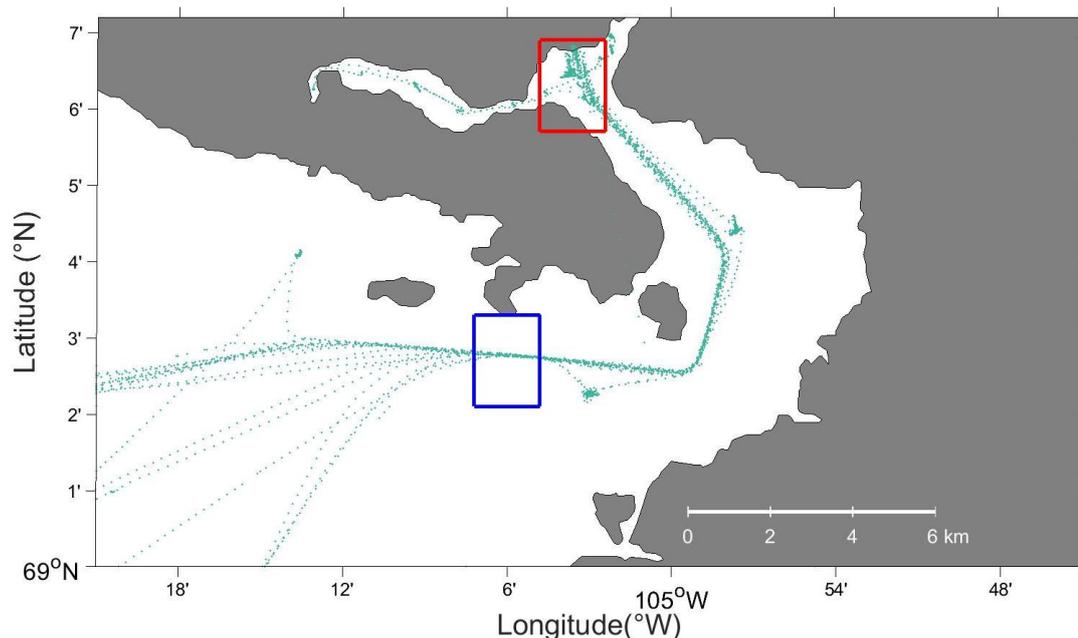

Figure 6: Zoomed in view showing the location of all the $p\text{CO}_2$ (sw) transects (green) measured in and out of Cambridge Bay during the four years of transects. The regions used to define inside the Bay and outside the Bay are shown by a red and blue box respectively.

Table 2: Average $p\text{CO}_2$ (sw) measured by the *RV Martin Bergmann* inside and outside of Cambridge Bay.

Date	$p\text{CO}_2$ (sw) inside Cambridge Bay	$p\text{CO}_2$ (sw) outside Cambridge Bay	$p\text{CO}_2$ (sw) difference (inside Bay – outside Bay)

395 4.3 Interannual variability and large scale seasonal trends

We have identified local scale differences between the $p\text{CO}_2(\text{sw})$ values from the *RV Martin Bergmann* and the ONC and the Qikirtaajuk Island observatories and regional scales differences between the bays and inlets and the main channel. The largest differences in the *RV Martin Bergmann* $p\text{CO}_2(\text{sw})$ values occurs between years. The measurement start date of all four cruises spanned a very short window of 10 days (2nd August 2016, 2nd August 2017, 31st July 2018, 9th August 2019).

400 Ahmed et al. (2019) have established the importance of the timing of sea ice breakup on $p\text{CO}_2(\text{sw})$ values in the CAA. During our study, ice breakup began (4th July 2016, 22nd June 2017, 15th July 2018, 14th July 2019) ~2–6 weeks before the start of these cruises. We will now discuss the main controls of the inter-annual variability in the *RV Martin Bergmann* $p\text{CO}_2(\text{sw})$ data.

405 The very low $p\text{CO}_2(\text{sw})$ values (261 μatm) observed in 2018 (Table 1) could be caused by a combination of low $\text{SST}_{(1\text{m})}$, springtime CO_2 depletion by primary production and recent dilution by sea ice melt (Else et al., 2012; Ahmed et al., 2021; Geilfus et al., 2015) or river runoff at salinities >20 (Cai et al., 2010). Without identifying clear chemical signatures that can be attributed to each process it is difficult to say with certainty which of these processes was most important in producing these low $p\text{CO}_2(\text{sw})$ values. As the ice breakup was late in 2018 (resulting in samples collected shortly after

410 breakup), it can be assumed that surface ocean CO_2 exchange with the atmosphere was limited by the ice cover until just before these measurements were made as sea ice is essentially impermeable to gases (Loose et al., 2011; Butterworth and Else, 2018). Additionally, sea ice cover prevented warming of surface seawater as $\text{SST}_{(1\text{m})}$ was low in 2018. Light penetrating through sea ice between March and June could have driven primary production below and within the ice (Else et al., 2019). Indeed, an increase in under-ice chlorophyll *a* concentration together with a draw-down of surface nutrients

415 between April to June 2018 supported under-ice phytoplankton production during this period (Dalman et al., 2019). However, concentrations did not exceed $0.6 \mu\text{g L}^{-1}$, limited by surface nutrient availability in the region (Back et al., 2021). It is likely that the melting sea ice stratified the surface and diluted surface $p\text{CO}_2(\text{sw})$ as has been observed in other parts of the Arctic (Miller et al., 2018; Ahmed et al., 2020); low salinity values in the first weeks of the survey support this.

Measurements several weeks into the 2018 cruise show that $p\text{CO}_2(\text{sw})$ increased quickly in the following weeks likely due to
420 a combination of air–sea exchange and the observed surface warming. Interestingly, at no point during the five years of
passing through the Kitikmeot Sea did Ahmed et al. (2019) observe $p\text{CO}_2(\text{sw})$ values below 300 μatm . Therefore, 2018 could
be an anomalously low year for $p\text{CO}_2(\text{sw})$, or the discrepancy could highlight the fact that (Ahmed et al., 2019) did not make
any measurements immediately after breakup in the region. Furthermore, the discrepancy could be influenced by the
difference in sampling depth of the two $p\text{CO}_2$ systems between the *CCGS Amundsen* (7 m) and *RV Martin Bergmann* (1 m).
425 The best way to assess the impact of the sampling depth would be to take simultaneous measurements via the ships intake
and at the interface as in Ho and Schanze (2020).

Whilst not as heavily undersaturated as 2018, $p\text{CO}_2(\text{sw})$ was still highly undersaturated with respect to atmospheric values in
both 2017 and 2019. In these two years, measurements were made ~4–8 weeks after sea ice breakup and $p\text{CO}_2(\text{sw})$ values
430 were in the ~300–350 μatm range. Having been ice free for longer, $\text{SST}_{(1\text{m})}$ was 3–4 °C warmer in 2017 and 2019 which
accounts for much of the $p\text{CO}_2(\text{sw})$ difference relative to 2018. Warming $\text{SST}_{(1\text{m})}$ in 2017 and 2019 and a gradual increase in
surface salinity in 2019 mirror the seasonal trends seen in Ahmed et al. (2019) where the CAA becomes saltier and warmer.
The 2017 and 2019 $p\text{CO}_2(\text{sw})$ values are lower than the majority of $p\text{CO}_2(\text{sw})$ values observed in Coronation Gulf by Ahmed
et al. (2019) which again likely reflects the earlier sampling period of this study, where recently ice-free surface waters have
435 not had long to equilibrate with the atmosphere.

$p\text{CO}_2(\text{sw})$ was much higher in 2016 compared to 2017 and 2019 around four weeks after sea ice breakup. Ahmed et al. (2019)
also observed $p\text{CO}_2$ oversaturation in the region in 2016 when they made their observations ~2 weeks later than what we
show here. $p\text{CO}_2(\text{sw})$ oversaturation requires either the upwelling of high $p\text{CO}_2(\text{sw})$ deep waters, net heterotrophy, or for $p\text{CO}_2$
440 (sw) to be close to equilibrium with the atmosphere and then for the seawater to subsequently heat up (Chierici et al., 2011).
The most plausible and observable of these is the warming of the surface waters. It is not apparent why there would be
oversaturation in 2016 but not in 2017 and 2019 which were both warmer years if $\text{SST}_{(1\text{m})}$ variability was the main factor
controlling $p\text{CO}_2(\text{sw})$. The sea ice breakup time in 2016 was similar to both 2017 and 2019 suggesting that the timing of
breakup was also not the only determining factor. The high $p\text{CO}_2(\text{sw})$ values in 2016 observed under similar conditions to
445 both 2017 and 2019 may point to the importance of the $p\text{CO}_2(\text{sw})$ value in the previous autumn and wintertime modulation of
 $p\text{CO}_2(\text{sw})$. To determine what processes are altering $p\text{CO}_2(\text{sw})$ between summertime field seasons would require year round
sampling or a full biogeochemical model would need to be run over multiple years.

Clearly many interacting processes are involved in determining the $p\text{CO}_2(\text{sw})$ values in the Kitikmeot Sea. This would
450 indicate that predicting the $p\text{CO}_2(\text{sw})$ value is difficult. Ahmed et al. (2019) proposed a model for $p\text{CO}_2(\text{sw})$ in the CAA as a
function of weeks since ice breakup, their model underestimated $p\text{CO}_2(\text{sw})$ in the Kitikmeot Sea by ~26 μatm which they
suggest may be due to the impact of rivers. Following their approach, the surface $p\text{CO}_2(\text{sw})$, SST, and salinity measurements

from this study are presented as a function of time since ice melt (when sea ice concentration declines below 85%; Figure 7). The *RV Martin Bergmann* observations are fairly consistent with the general $p\text{CO}_2$ model of Ahmed et al. (2019), where low $p\text{CO}_2$ values ($\sim 300 \mu\text{atm}$) are seen shortly after sea melt and higher values ($\sim 300\text{-}350 \mu\text{atm}$) are seen in the following two months. However, the 2016 $p\text{CO}_2$ values are much higher and the 2018 values are much lower than predicted by the model. The model is also not able to predict the observed salinity values in 2016 and 2019. The CAA flux estimate (Ahmed and Else, 2019) using the (Ahmed et al., 2019) model remains the best estimate for the region. However, the model is clearly unable to capture the full inter-annual variability in the *RV Martin Bergmann* observations. This could be because as a CAA wide model it is not tuned to the Kitikmeot Sea where freshwater inputs are greater. Fundamentally, understanding the drivers of the large interannual variability in $p\text{CO}_2$ seen in the Kitikmeot Sea requires an understanding of the interconnected processes involved and their timing. The interannual variability SST_(1m) and salinity are comparable to the modelling results of Xu et al. (2021), by expanding on that modelling work with a complex biogeochemical model that can incorporate all the known processes impacting $p\text{CO}_2$, it may be possible to accurately reproduce the $p\text{CO}_2$ observations in this region.

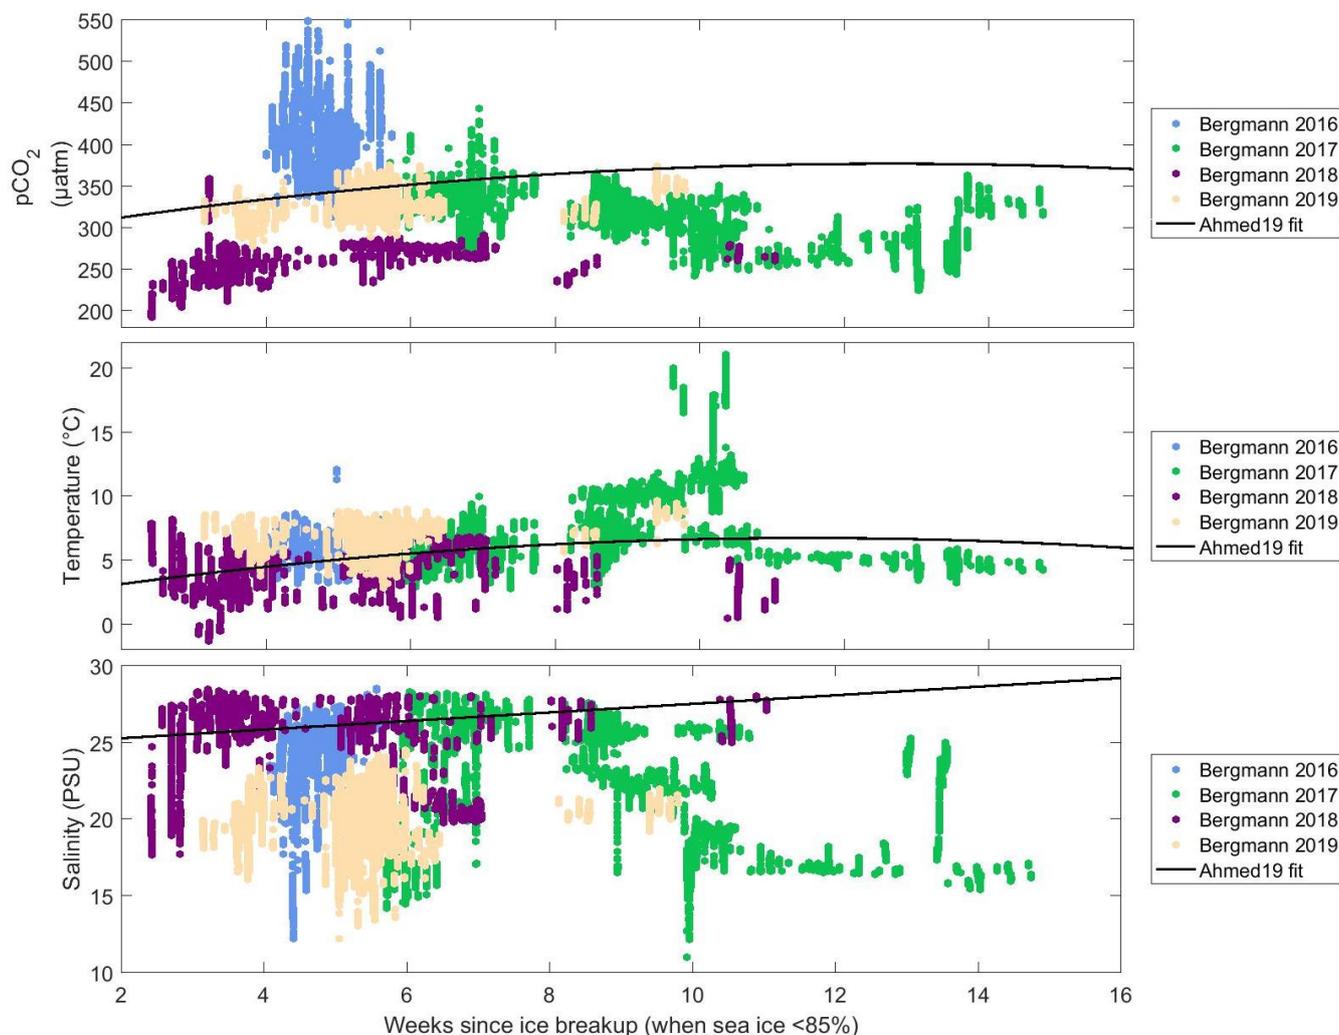

Figure 7: Surface (a) $p\text{CO}_2_{(\text{sw})}$, (b) SST, and (c) salinity from the *RV Martin Bergmann* as a function of weeks of open water for years 2016 to 2019. Black curves represent the model output of Ahmed and Else (2019).

4.4 The Kitikmeot Sea as a sink for $p\text{CO}_2$

The *RV Martin Bergmann* $p\text{CO}_2_{(\text{sw})}$ measurements indicate that the region is a sink in early August most years (Table 1). At ice breakup low $\text{SST}_{(1\text{m})}$ impacts solubility resulting in large $\Delta p\text{CO}_2$ gradients, these conditions persist for several weeks after ice breakup. Warming of the surface when $p\text{CO}_2_{(\text{sw})}$ is slightly undersaturated is the likely cause of $p\text{CO}_2_{(\text{sw})}$ oversaturation in some years, resulting in the region becoming a net source once the saturation threshold is met. Whilst not demonstrable with the *RV Martin Bergmann* measurements cooling $\text{SST}_{(1\text{m})}$ at the end of the ice-free season should lower $p\text{CO}_2_{(\text{sw})}$ thereby providing a second period when there are large $\Delta p\text{CO}_2$ gradients. The magnitude of the $\Delta p\text{CO}_2$ and thus the size of the sink throughout the summer appears to not only be driven by time since ice breakup but also by the absolute $p\text{CO}_2$

475 $p\text{CO}_2$ (sw) value at the time of ice breakup. Ahmed and Else (2019) used remote sensing products to identify this region as a net sink when the flux is integrated over the full ice-free period. Our measurements corroborate these findings.

The large variability in $p\text{CO}_2$ (sw) measured in the four years of observations highlights the fact that, in the Arctic, single cruises in only part of the ice-free season are likely not capturing the full variability in these regions. Many $p\text{CO}_2$ (sw) observations in the Arctic are temporally biased towards the middle of the ice-free season. As these single cruises are the only measurements in many of these regions in databases like SOCAT (Bakker et al., 2016), they could result in a biased flux estimates in these regions. It should be acknowledged that the majority of the CAA is not included in the state of the art observational based products (Landschützer et al., 2020).

5. Conclusions

The ONC mooring and EC tower both provide similar $p\text{CO}_2$ (sw) values in spring and autumn showing good agreement between the two platforms. Measured $p\text{CO}_2$ (sw) from the EC tower was much higher than what was measured from the *RV Martin Bergmann* but similar trends were seen in both data sources which may be attributable to surface stratification caused by riverine flows. Comparing measurements collected by the *RV Martin Bergmann* in and out of Cambridge Bay indicates that Cambridge Bay $p\text{CO}_2$ (sw) is not drastically different from the main channel in August. This may indicate that $p\text{CO}_2$ (sw) at the ONC mooring may be broadly representative of Dease Strait.

490 The Kitikmeot Sea was a CO_2 sink or a very weak source over the summers of 2016 – 2019, consistent with previous measurements from Ahmed and Else (2019). The CO_2 sink was highly variable from year to year at the beginning of August (average observed fluxes of 0.41, -7.70, -21.26 and -2.08 $\text{mmol m}^{-2} \text{d}^{-1}$ during the 2016, 2017, 2018, and 2019 cruises respectively) with average $p\text{CO}_2$ (sw) as low as $261.19 \pm 19.70 \mu\text{atm}$ and as high as $403.65 \pm 44.44 \mu\text{atm}$. $p\text{CO}_2$ (sw) was much lower in 2018 due to the much lower $\text{SST}_{(1\text{m})}$ that year. The magnitude of the $\Delta p\text{CO}_2$ throughout the summer appears to be controlled by the absolute $p\text{CO}_2$ (sw) value at the time of ice breakup. Low $p\text{CO}_2$ (sw) values increase in August due to exchange with the atmosphere and warming broadly following the predicted trends using the model developed by Ahmed et al. (2019). In years where $p\text{CO}_2$ (sw) is high when ice breakup occurs, warming can cause a period of slight $p\text{CO}_2$ (sw) oversaturation in summer, in these situations the magnitude of this oversaturation is likely moderated by the air sea flux reducing $p\text{CO}_2$ (sw). $p\text{CO}_2$ (sw) was found to be ~20-40 μatm lower in the Bays and Inlets that were surveyed; this could be driven by freshwater inputs into these isolated regions. Lower $p\text{CO}_2$ in bays and inlets would represent an observational bias in the CAA-wide surveys (Ahmed et al., 2019). Freshwater fluxes into the southern CAA are much greater than elsewhere in the CAA meaning that this bias might be more prominent in the Kitikmeot Sea. Further observations in these regions may complement the basin-level $p\text{CO}_2$ mapping.

505

510 These findings provide a more nuanced picture of the considerable inter-annual variability in $p\text{CO}_2$ (sw) observed during repeat cruises in the same region, underscoring how much may be missed by relying on data collected during one-off cruises along the dynamic Arctic coasts. The $p\text{CO}_2$ (sw) at the time of ice melt is very important as it dictates the magnitude and direction of the flux for much of the ice-free period. A better understanding of $p\text{CO}_2$ (sw) through the ice covered period is needed to help unravel the seasonal and interannual variability.

6. Acknowledgements

515 Parts of this research were completed on or adjacent to Inuit Owned Lands under the authority of the Nunavut Land Claim Agreement, and the work was licensed by the Nunavut Research Institute. We thank the Ekaluktutiak Hunters and Trappers Organization and the community of Cambridge Bay for their hospitality and support of this project. Richard Sims was supported through the University of Calgary's Eyes High Postdoctoral fellowship program. This work was funded by The Marine Environmental Observation, Prediction and Response Network (MEOPAR, project number 1-02-02-004.1), The Kitikmeot Sea Science Study (K3S), the Natural Sciences and Engineering Research Council of Canada (Discovery and Northern Research Supplement grants to B. Else, RGPIN-2015-04780), and the Canada Foundation for Innovation (John R. Edwards Leaders Fund grant to B. Else, 34814). Logistical support was provided by the Arctic Research Foundation. 520 Samantha Jones, Stephen Gonski and Patrick Duke were supported by Polar Knowledge Canada through the Northern Scientific Training Program. We thank Polar Knowledge Canada and the Canadian High Arctic Research Station for their support and for providing accommodation and vehicles during field campaigns. Data from Ocean Networks Canada was accessed under their Creative Commons CC-BY 4.0 License. We thank the captain and crew of the *RV Martin Bergmann* for all their assistance. We also thank Shawn Marriott and Francis Emingak for all their assistance in the field, and Sophia 525 Ahmed for her work on data interpretation.

7. Author Contributions

530 This manuscript was written by RPS, all co-authors made contributions to the final paper. BTGE installed the underway system at the start of each field season. The performance of the underway system was monitored by BTGE with help from SFJ, SFG, KAB, PJD and RPS. RPS organised and processed the data. RPS made the figures and interpreted the results and with support from MA and BTGE. BJB analysed the data from the EC tower and provided that data for this paper. PJD provided the data from the ONC mooring. BTGE, CJM and WJW secured have been central in planning the cruise programme. BTGE oversaw completion of the work.

8. Data and code availability

The processed underway data from the *RV Martin Bergmann* which is the new data described in this paper is available in the supplement as .mat files. The raw and processed underway data from the *RV Martin Bergmann* data will also be available via Zenodo. The wind data and inferred seawater $p\text{CO}_2$ data from the EC tower are included in the supplement as .mat files. The ONC mooring data is freely available at <https://data.oceannetworks.ca/home>. The AMSR2 sea ice data https://seaice.uni-bremen.de/data/amr2/asi_daygrid_swath/n3125/ the NCEP winds <https://psl.noaa.gov/data/gridded/data.ncep.reanalysis2.html> and the atmospheric $p\text{CO}_2$ data from Barrow ftp://ftp.cmdl.noaa.gov/data/greenhouse_gases/co2/in-situ/surface/ which were used in this paper are all freely available from their online repositories. Processing code and the code needed to reproduce the figures was written in Matlab 2016a. The code is provided in the supplement and is also available at https://github.com/Richard-Sims/Sims_2022_Bergmann_pCO2.
