10 **Abstract.** Although numerous studies on mesoscale eddies in the Gulf of Mexico (GoM)
11 have been conducted, a comprehensive study on their temporal and spatial characteristics is
12 still lacking. In this study, we combine three eddy detection algorithms to detect eddies from
13 the 26-year sea surface height record in the GoM and examine their characteristics. We find
14 distinct characteristics between Loop Current Eddies (LCEs), Loop Current Frontal Eddies
15 (LCFEs), and mesoscale eddies that are not directly related to the Loop Current (LC).
16 Seasonal variability appears in both the LCFEs and non-LCFE cyclonic eddies and shows
17 large uncertainties. More specifically, more LCFEs are formed in January to July than in
18 August to December, likely related to the seasonal variation of the northward penetration of
19 the LC. And the formation of non-LCFE cyclonic eddies shows a biannual variability, which
20 could be linked to the position and strength of the background current in the western GoM.
21 Low-frequency (interannual to multidecadal) variability is also detected. In the eastern GoM,
22 the extent of northward penetration of the LC can affect the generation of LCFEs and result
23 in low-frequency variations. In the western GoM, the low-frequency variability of eddy
24 occurrence and amplitude could be related to the surface circulation strength. This study can
25 serve as an up-to-date reference for eddy-related investigations in the GoM.

26

27 **1 Introduction**

28 Mesoscale eddies are ubiquitous in the Gulf of Mexico (GoM). Different types of eddies have
29 been identified, such as anticyclonic Loop Current Eddies (LCEs), cyclonic Loop Current
30 Frontal Eddies (LCFEs), and eddies that are not directly related to the Loop Current (LC).
31 Those eddies are crucial in transporting heat, salt/freshwater, and other materials and affecting
32 the bottom currents in the GoM (e.g., Beron-Vera et al., 2018; Brokaw et al., 2019; Chang &
33 Oey, 2010; Meunier et al., 2018; Zhu & Liang, 2020). Besides, those eddies can modify the
34 atmospheric environment. In particular, hurricanes in the GoM can be intensified when
35 encountering warm-core rings by absorbing a large amount of heat from eddies (e.g., Bosart et
36 al., 2000; Hong et al., 2000).

37 Various measurements, including drifters, gliders, mooring, and satellite data, have been used
38 to characterize eddies in the GoM (e.g., Elliott, 1982; Hamilton, 1992; Hamilton, 2007;
39 Hamilton et al., 1999; Kirwan et al., 1984; Lewis et al., 1989; Meunier et al., 2018;
40 Paluszkiwicz et al., 1983; Rivas et al., 2008; Rudnick et al., 2015; Vukovich & Maul, 1985;
41 Zhang Y. et al., 2019). Some eddy characteristics, such as diameter and propagation speed,

42 have been reported in previous studies. In the eastern GoM where the LC is the dominant
 43 circulation feature, LCEs with a warm and salty core are shed irregularly from the LC through
 44 dynamic instability (e.g., Hurlburt & Thompson, 1980; Pichevin & Nof, 1997; Sturges &
 45 Leben, 2000; Yang et al., 2020). The shedding time of LCEs has been shown to be related to
 46 the seasonal winds in the GoM and the Caribbean Sea (CS) (Chang & Oey, 2012) and
 47 fluctuations from the CS (Chang & Oey, 2012, 2013; Murphy et al., 1999; Oey et al., 2003).
 48 LCEs have a diameter of 200 to 400 km, a surface swirling speed exceeding 0.5 m s^{-1} , and an
 49 average propagating speed of 2 to 5 km day^{-1} (e.g., Elliott, 1982; Kirwan et al., 1984; Kirwan
 50 et al., 1988; Vukovich & Crissman, 1986). After separating from the LC, LCEs bring warm
 51 and high-salinity water originating from the CS to the western GoM, and the LCE path occupies
 52 a broad band in the center of the basin with a mean west-southwest track (Hamilton et al.,
 53 1999). When LCEs travel to the western GoM and encounter the western boundary, companion
 54 cyclones can be generated (Frolov et al., 2004; Smith, 1986; Vidal et al., 1992). Besides the
 55 eddy-topography interaction, LCEs can be cleaved into two parts by interacting with deep
 56 water cyclones (Biggs et al., 1996).

57 In addition to LCEs, mesoscale cyclonic eddies (CEs) with relatively small diameters of 80 to
 58 150 km have also been detected in the GoM (Hamilton, 1992; Jouanno et al., 2016; Le Hénaff
 59 et al., 2014; Vukovich & Maul, 1985; Vukovich, 2007). The commonly seen CE in the eastern
 60 GoM are cold-core LCFEs that are formed on the LC's periphery as a result of the barotropic
 61 and baroclinic instabilities (e.g., Chérubin et al., 2006; Donohue et al., 2016a; Fratantoni et al.,
 62 1998; Jouanno et al., 2016; Maslo et al., 2020; Vukovich & Maul, 1985; Yang et al., 2020;
 63 Zavala-Hidalgo et al., 2003). The topographic vortex stretching can play a role in the
 64 intensification of LCFEs (Le Hénaff et al., 2012; Le Hénaff et al., 2014). Also, eddies with a
 65 median radius of 30 km have been observed on the northern GoM slope from drifter orbits and
 66 hydrographic surveys (e.g., Hamilton, 2007). The small-scale slope eddy activity was
 67 speculated to be related to the LC extension and LCE detachment. Some eddies on the northern
 68 GoM slope that are not likely related to the LC have also been observed (Hamilton, 1992;
 69 Hamilton et al., 2002). Besides, Caribbean eddies can squeeze into the GoM through the
 70 Yucatan Channel (Huang et al., 2013; Huang et al., 2021; Murphy et al., 1999), but the eddy
 71 number is relatively small.

72 Statistical and comprehensive analyses of eddies over the whole GoM using in situ data and
 73 satellite infrared or ocean color data are difficult (e.g., Vukovich, 2007). In situ data cannot
 74 give continuous monitoring over the whole GoM. The nearly uniform sea surface temperature

75 (SST) in summer and the extensive cloud cover hinder us from discerning eddies from the
 76 satellite infrared or ocean color maps (e.g., Sturges & Leben, 2000; Vukovich & Maul, 1985).
 77 In contrast, altimeter observed sea surface height (SSH) data are available in all weather
 78 conditions and are the most complete source of detecting mesoscale eddies. Although some
 79 temporal and spatial distributions of eddy characteristics have been obtained from the absolute
 80 dynamic topography (ADT) maps or along-track SSH anomalies, they are based on short-
 81 period altimeter data with record lengths of 2 to 4 years (Brokaw et al., 2020; Leben & Born,
 82 1993) or are focused on one specific type of eddy, such as the LCE (e.g., Leben, 2005; Hall
 83 and Leben, 2016) or LCFE (Le Hénaff et al., 2014). For example, by tracking SSH contour (17
 84 cm) and its breaking from the LC in the GoM, LCE separations have been determined over the
 85 first 12-year (Leben, 2005) and 20-year altimetry period (Hall and Leben, 2016). A significant
 86 peak in the timing of LCE separation in August and September and a less significant peak in
 87 February and March have been observed (Hall & Leben, 2016; Vukovich, 2012). An increasing
 88 number of LCEs in the decade 2001-2010 was also found (Lindo-Atichati et al., 2013;
 89 Vukovich, 2012).

90 The seasonal and interannual variabilities of mesoscale eddies are important and closely related
 91 to that of the large-scale circulation, from which eddies obtain energy (e.g., Yang et al., 2020).
 92 As the dominant circulation system in the eastern GoM, the LC has been shown to be more
 93 intrusive from January to July on the seasonal time scale (Hamilton et al., 2014) and from 2002
 94 to 2006 than in 1993 on the interannual time scale (Alvera-Azcárate et al., 2009). The climate
 95 variability in the GoM has been related to remote climate forcing such as El Niño-Southern
 96 Oscillation (ENSO) and North Atlantic Oscillation (NAO) (e.g., Rodriguez-Vera et al., 2019).
 97 Therefore, the eddy activity in the GoM could be affected by various climate modes, such as
 98 ENSO (e.g., Philander, 1990), NAO (e.g., Wallace & Gutzler, 1981), and Atlantic Meridional
 99 Mode (AMM) (e.g., Chiang & Vimont, 2004). However, characteristics of different types of
 100 eddies in the GoM, such as propagation, seasonal, and low-frequency (interannual to
 101 multidecadal) variability, are not clear and need more examination. Nowadays, with the
 102 satellite observed SSH data that span more than 26 years, we can conduct a more
 103 comprehensive analysis of the characteristics of mesoscale eddies in the GoM.

104 To detect and describe eddies, a variety of automatic eddy detection and tracking algorithms
 105 have been developed. Chelton et al. (2007) used the physical Okubo-Weiss (OW) parameter
 106 (Okubo, 1970; Weiss, 1991) to detect mesoscale eddies. Geometric properties, such as the
 107 closed SSH or streamline contours, have also been used to define eddy domains (e.g.,

108 Chaigneau et al., 2008; Chelton et al., 2011; Faghmous et al., 2015; Le Vu et al., 2018).
 109 Moreover, hybrid methods that combine the physical parameters and geometric properties have
 110 been proposed to discern mesoscale eddies (Halo et al., 2014; Kang & Curchitser, 2013). The
 111 17-cm SSH contour has also been widely used to define the LC front, and separation events of
 112 LCE are identified by breaking of the 17-cm tracking contour with no later reattachment
 113 (Leben, 2005; Hall and Leben, 2016). Different eddy detection algorithms have their
 114 advantages and drawbacks. For example, the OW method is sensitive to the noise in the SSH
 115 data, and the approaches that use geometrical properties are sensitive to the interval searching
 116 for closed contours (Le Vu et al., 2018; Lian et al., 2019). There is no best algorithm because
 117 the eddy definition is elastic among different studies (Kurian et al., 2011).
 118 In this study, to find eddies that are less sensitive to the eddy detection algorithms, a method
 119 that combines three previously used eddy detection algorithms is developed and applied to the
 120 26-year SSH maps in the GoM. Characteristics of robust eddies in the GoM are derived by
 121 examining the eddies detected with the new method. The paper is organized as follows: data
 122 and details of the eddy detection and tracking algorithms are presented in Sect. 2.
 123 Characteristics of the detected eddies, including eddy trajectories, basic eddy characteristics,
 124 seasonal and low-frequency variabilities of eddies are reported in Sect. 4. Conclusions and
 125 discussions are given in Sect. 5.

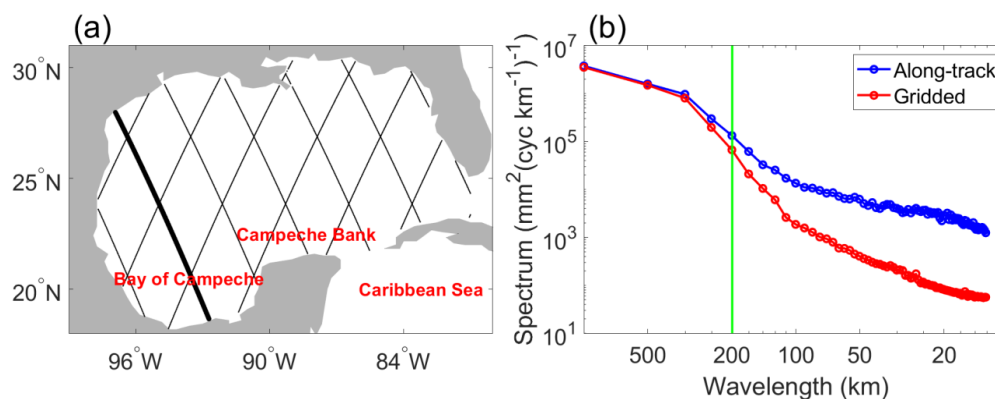

126 **2 Data and Methods**

127 **2.1 Data**

128 Delayed time 2018 (DT2018) gridded ADT data (Taburet et al., 2019) from two altimeter
 129 satellites (twosat product) provided by the Copernicus Climate Change Service (C3S) were
 130 used for eddy detection and the subsequent examination of eddy characteristics. DT2018
 131 gridded ADT data from multiple satellites (allsat product) provided by the Copernicus Marine
 132 Environment Monitoring Service (CMEMS) were also used for the discussion of the influence
 133 of satellite sampling on eddy detection. The ADT data span from 1 January 1993 to 13 May
 134 2019 with a daily time interval. ADT data rather than sea level anomalies (SLAs) were selected
 135 because artificial eddies could be identified in SLAs (e.g., Laxenaire et al., 2018; Pegliasco et
 136 al., 2021). Note that although the spatial resolution of the ADT provided is 0.25 degrees, its
 137 effective spatial resolution is controlled by many factors, such as the along-track smoothing
 138 and the spatial correlation scale (Pujol et al., 2016).

139 To examine the effective spatial resolution of the gridded ADT product in the GoM,
 140 TOPEX/Poseidon (T/P) along-track ADT data from 2 January 1996 to 3 December 1999 were
 141 compared with the twosat gridded ADT data (Fig. 1). Gridded ADT data were first linearly
 142 interpolated to the ground tracks shown in Fig 1a. The wavenumber spectra of the along-track
 143 and interpolated ADT data along one sample T/P track were then calculated and averaged over
 144 the selected T/P period (Fig. 1b). Compared to the along-track ADT, the spectrum of the
 145 gridded ADT decreases by 50% at the wavelength of 200 km, which represents the effective
 146 spatial resolution of the gridded ADT data in the GoM. This finding is consistent with the
 147 spatial correlation scales used in the gridded product processing (Pujol et al., 2016) and
 148 corresponds to an e-folding scale of about 37 km for an individual eddy (Chelton et al., 2011).
 149 The interpretation of filter cutoff wavelength in terms of the corresponding eddy scale is based
 150 on eddy shape that is approximated as an axially symmetric Gaussian structures (Chelton et al.,
 151 2011). Chelton et al. (2011) showed that a half-power point at a wavelength of 2° corresponds
 152 to a Gaussian feature in space with an e-folding scale of 0.37° . Therefore, the gridded ADT
 153 product in the GoM can only resolve eddies with a radius larger than 37 km, and eddies with a
 154 radius smaller than 37 km are not considered in this study. The gridded products cannot capture
 155 the small-scale eddies (Amores et al., 2018). It should be noted that eddies that lie in the
 156 "diamond-shaped" area between the satellite tracks cannot be fully resolved. The eddy
 157 amplitude could be underestimated due to the smoothing during the data generation process.
 158 We focus on the spatial and temporal variability when we examine the eddy amplitude.

159
 160 **Figure 1:** (a) Ground tracks of the TOPEX/Poseidon satellite in the GoM. The thick black line
 161 represents the track along which the wavenumber spectrum of ADT was estimated. (b)
 162 Wavenumber spectrum of along-track and gridded ADT along the track marked by the thick
 163 black line in (a). The vertical green line marks the wavelength of 200 km.

164

165 ADT data were further processed before they were used to detect eddies. First, since altimetry
 166 observations near the coast are less reliable (Castelao & He, 2013; Saraceno et al., 2008), ADT
 167 data at grid points that are 30 km or less away from the coast were discarded. Second, to make
 168 eddy features stand out from the large-scale background SSH field, a two-dimensional spatial
 169 filter with a cut-off wavelength of 1000 km was applied to the gridded ADT data. The spatial
 170 filtering removes the large-scale variability of SSH that is dominated by the seasonal steric
 171 height, which is similar to removing the daily spatial average ADT over the deep-water GoM.
 172 Third, because the LC has a shape of a loop, which is different from isolated mesoscale eddies
 173 but might be recognized as eddy by the eddy detection algorithms, the LC was isolated so that
 174 no eddy was considered within the LC. Leben (2005) used the 17-cm contour of ADT to define
 175 the LC front. As the mean reference SSH field in this study was different from that used in
 176 Leben (2005), we used the 25-cm contour of the SSH anomalies to define the LC front. Because
 177 we would like to eliminate the spatially uniform variability of SSH in the GoM, the SSH
 178 anomalies with the spatially mean SSH removed were used to find the LC front. The northern
 179 boundary of the LC obtained using the 25-cm contour of SSH anomalies shows similar
 180 variability as that reported in Leben (2005). Eddy detection and tracking algorithms were then
 181 applied to the high-passed ADT fields.

182 Other variables were also explored to explain some of the detected eddy characteristics. The
 183 global atlas of the first-mode Rossby radius of deformation (Chelton et al., 1998) was used to
 184 calculate the standard first-mode Rossby wave propagation velocity, $c = -\beta R^2$, where β is the
 185 meridional variation of the Coriolis parameter and R is the first-mode Rossby radius of
 186 deformation. Moreover, the multivariate ENSO index (MEI V2) (Zhang T. et al., 2019), NAO
 187 index (Hurrell, 1995), and AMM index (Chiang & Vimont, 2004) were used to examine
 188 possible relationships between the eddy activity in the GoM and climate modes.

189 2.2. Eddy detection and tracking algorithms

190 An approach that combines three eddy detection algorithms proposed by Faghmous et al.
 191 (2015), Le Vu et al. (2018), and Halo et al. (2014) was developed to detect robust mesoscale
 192 eddies in the GoM. The three algorithms represent different approaches of automatic eddy
 193 detection and hereafter are referred to as F15, L18, and H14, respectively. In the F15 algorithm,
 194 eddies are defined as features of closed-contour SSH with one extremum of SSH. The eddy
 195 center is at the location with extremum SSH. The H14 algorithm combines the OW parameter
 196 and geometrical properties of SSH. It identifies eddy as contained within a close loop of SSH

197 and dominated by vorticity with the negative OW parameter. The eddy center is the mean
 198 position of the identified eddy. The L18 algorithm is a hybrid method based on physical
 199 parameters and geometrical properties of the velocity field. The eddy is contained within closed
 200 streamlines around an eddy center with a local maximum normalized angular momentum. The
 201 differences between the three eddy detection algorithms are that closed SSH contours are used
 202 in F15 and H14, while closed streamlines are used in L18. The eddy center is defined differently
 203 in the three algorithms and is associated with the SSH extremum location, mean position of
 204 eddy, and the local maximum normalized angular momentum in F15, H14, and L18,
 205 respectively.

206 Due to the limited resolution of the gridded ADT field, a minimum of 9 pixels was used in the
 207 F15 algorithm and a minimum eddy radius of 37 km was used in the other two algorithms. The
 208 threshold value of nine pixels was selected in the F15 algorithm because it corresponds to a
 209 square area that is occupied by the smallest eddy with a radius of 37 km. Also, a minimum
 210 eddy amplitude of 2 cm was applied due to the accuracy of the SSH product (Pujol et al., 2016).

211 The three eddy detection algorithms were implemented to the high-passed ADT field, yielding
 212 daily mesoscale eddies. An example of the detected eddies on 20 March 1995, as marked by
 213 the black circles in Fig. 2a-c, shows that some eddies can be detected by one algorithm but
 214 cannot be detected by the others. The three algorithms, F15, L18, and H14, gave rise to a total
 215 of 67016, 65852, and 55309 anticyclonic eddies (AEs), and a total of 93054, 93118, and 86077
 216 CEs in the GoM over the examined period, respectively. The daily mean area occupied by AEs
 217 in F15, L18, and H14 is $1.91\text{e}5 \text{ km}^2$, $2.42\text{e}5 \text{ km}^2$, and $9.57\text{e}4 \text{ km}^2$, respectively; while the daily
 218 mean area occupied by CEs in F15, L18, and H14 is $2.1\text{e}5 \text{ km}^2$, $2.45\text{e}5 \text{ km}^2$, and $1.14\text{e}5 \text{ km}^2$,
 219 respectively. The H14 algorithm yields the smallest eddy size and the least eddy number,
 220 suggesting the H14 algorithm is more restrictive than the other two algorithms. Moreover, to
 221 examine the influence of the spatial filtering that removes the large-scale variability of SSH on
 222 eddy detection, we run the eddy detection algorithms on the unfiltered ADT field and compare
 223 the eddy numbers with those from the filtered ADT field. A total of 139867, 148309 and
 224 125886 eddies are found in F15, L18, and H14, respectively, which are less than 158970,
 225 160070 and 141386 eddies when the filtered ADT field is used. The differences of eddy
 226 numbers obtained from the filtered and unfiltered ADT fields are from 7% to 12% of the total
 227 eddy number. Therefore, the spatial filtering can make eddy features stand out from the large-
 228 scale background ADT field.

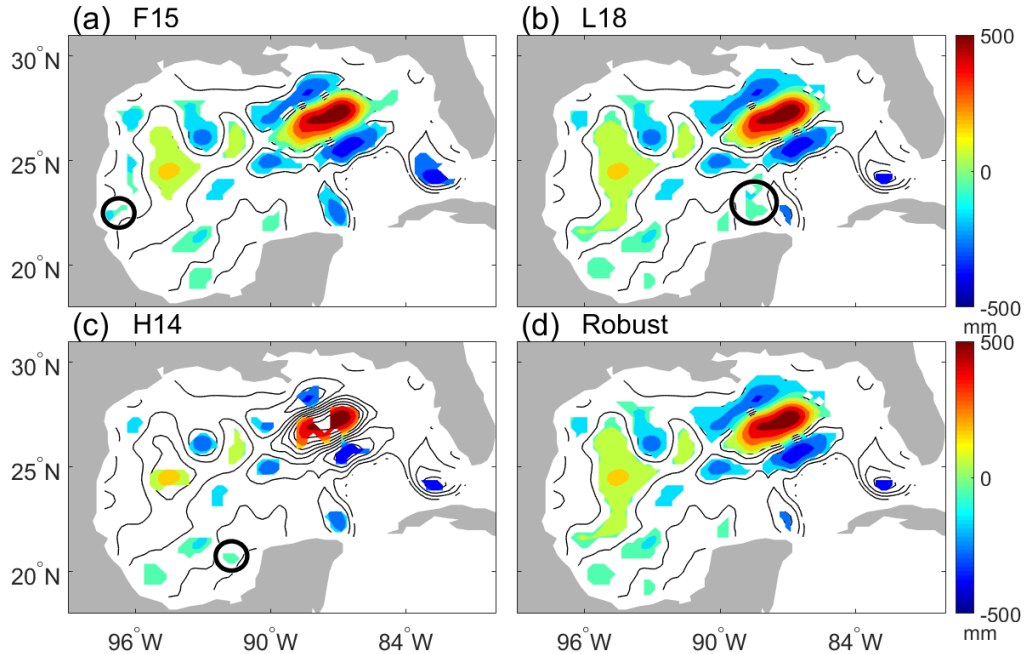

Figure 2: Snapshots of the high-passed ADT (contours) and detected eddies (color shading) on 20 March 1995. Eddies were detected by (a) F15 algorithm, (b) L18 algorithm, (c) H14 algorithm, and (d) robust detection algorithm. The black circle in (a), (b), and (c) encloses the eddy that was detected by one algorithm but not detected by the other two algorithms.

We focus on the mesoscale eddies that can be detected by at least two algorithms and define them as the robust eddies in the GoM. Eddies from the most recently developed L18 algorithm were used as basis eddies. For each basis eddy, if common eddy pixels were found in H14 or F15, the eddy was considered robust and kept for further processing. There are 10% of AEs and 7% of CEs detected by L18 that were removed based on the comparison of outputs of the three algorithms. Robust eddies are defined in this way so that we have more confidence in the detected eddies than that given by one algorithm, but they are less restrictive than those given by the H14 method. An example of robust eddies on 20 March 1995 is shown in Fig. 2d.

The resulting robust eddies were then tracked with an algorithm that was also used in Le Vu et al. (2018). First, each detected eddy e_i at the last time step t is associated with the closest eddy e_j of the same sign detected at the previous time step $t-dt$ in a given search area. The maximum search distance D_{ij} is then given by $D_{ij} = C(1 + dt)/2 + \langle R_{max} \rangle(j) + R_{max}(i)$, where $\langle R_{max} \rangle(j)$ is the mean speed-based radius of e_j averaged during the five preceding steps of

its track, while $R_{max}(i)$ is the speed-based radius of $e_i(t)$ that corresponds to the eddy radius with maximum mean azimuthal velocity. The speed parameter C is a constant value of 6.5 km/day that is one typical upper bound of eddy propagation speed used in the maximum search distance D_{ij} (Le Vu et al., 2018). When no eddies are found in the search area, $e_i(t)$ is identified as a new eddy. When several eddies are found in the search area, e_i will be associated with e_j , which minimizes one cost function:

$$\varepsilon_{ij} = \sqrt{\left[\frac{d_{ij}}{D_{ij}(T_c)}\right]^2 + \left[\frac{\Delta R}{\langle R \rangle(j) + R(i)}\right]^2 + \left[\frac{\Delta Ro}{\langle Ro \rangle(j) + Ro(i)}\right]^2} + \left(\frac{dt}{2T_c}\right)^2$$

where d_{ij} is the distance between e_i and e_j ; $D_{ij}(T_c)$ is the distance D_{ij} at the correlation time ($T_c=10$ days); ΔR and ΔRo are the radius and the Rossby number difference between e_i and e_j , respectively; $\langle R \rangle(j)$ and $\langle Ro \rangle(j)$ are the mean radius and the mean Rossby number of the eddy e_j averaged during the five preceding steps, respectively; the eddy radius is defined as the radius of the circle equivalent to the eddy area. The dimensionless coast function is used to compare physical similarity between eddy pairs. The terms under the root square represent the relative distance between eddy centers, the relative difference between eddy radius, the relative difference between the intensity characterized by Rossby number and the relative difference of temporal separation, respectively. Eddy merging and splitting due to eddy-eddy interactions are considered in this tracking algorithm. Because the temporal correlation scales of gridded ADT data are about 30 days at latitudes of the GoM (Pujol et al., 2016), only eddies with a lifetime greater than 30 days are examined in this study. Although there are eddies with lifetime shorter than 30 days, the gridded SSH data are not independent on timescales shorter than 30 days and are not sufficient to detect the short-lived eddies.

AEs were further grouped into LCEs and non-LCE AEs. LCEs are AEs that were generated east of 92°W, were dead west of 90°W, translated westward for more than 2 degrees, and had eddy amplitude at the birth time larger than 0.12 m and have a lifespan of more than 60 days. The eddy amplitude was defined as the difference between the SSH on the contour of maximum rotation speed and maximum or minimum SSH in the eddy. Because the LC may experience detachment and reattachment during the formation of LCE, the identified LCE may lose tracking and new eddies were identified. Therefore, AEs that were formed east of 92°W with amplitude larger than 0.2 m and with the distance between eddy center and the LC front being less than 250 km were considered as LCEs as well. The threshold values used in the definition of LCEs were chosen by comparing detected AEs with the SSH maps that show separations of LCEs from the LC. A total of 51 LCE trajectories were found. The larger number of LCE

trajectories than that reported in previous studies (e.g., Hall and Leben, 2016) is partially related to temporarily losing track. The separation dates of LCEs with industry names were compared with those reported by Hall and Leben (2016) (Table 1). Separation dates of 28 LCEs are less than 1 month different from those reported by Hall and Leben (2016) (Table 1). There are 376 non-LCE AE trajectories. CEs were further grouped into LCFEs and non-LCFE CEs. Based on the CE trajectories, LCFEs are CEs that have the distance between the eddy center and the LC front be less than 200 km in the first 20 days after the generation. LCFEs defined in this way propagate along the LC front during their lifetimes. Non-LCFEs are CEs that are not identified as LCFEs. There are 297 LCFE trajectories and 447 non-LCFE CE trajectories.

Number	Industry name	Separation date	Separation date (Hall and Leben,	Separation date
1	Whopper	7 July 1993	5 July 1993	2
2	Xtra	16 September	7 September 1993	9

289 Note: LCEs reported in Hall and Leben (2016) occurred from 1993 to 2015.

290 **Table 1:** Selected LCE events and their separation dates.

291

292 **3 Results**

293 **3.1 Eddy Trajectories and Propagation**

294 Figure 3 shows the percentages of months when eddy birth, death, and presence were observed
 295 over the observation period. LCEs were mostly generated in the northwestern tip of the LC
 296 (Fig. 3a), were mostly dissipated in the western GoM, and some of them could reach the
 297 western boundary of the GoM (Fig. 3b). They traveled from the east to the southwest in a broad
 298 meridional band (Fig. 4a), consistent with the broad paths of LCEs revealed in previous studies
 299 (e.g., Hamilton et al., 1999; Vukovich & Crissman, 1986; Vukovich, 2007). Therefore, it is
 300 more frequent to observe LCEs in the band from the east to the southwest (Fig. 3c).

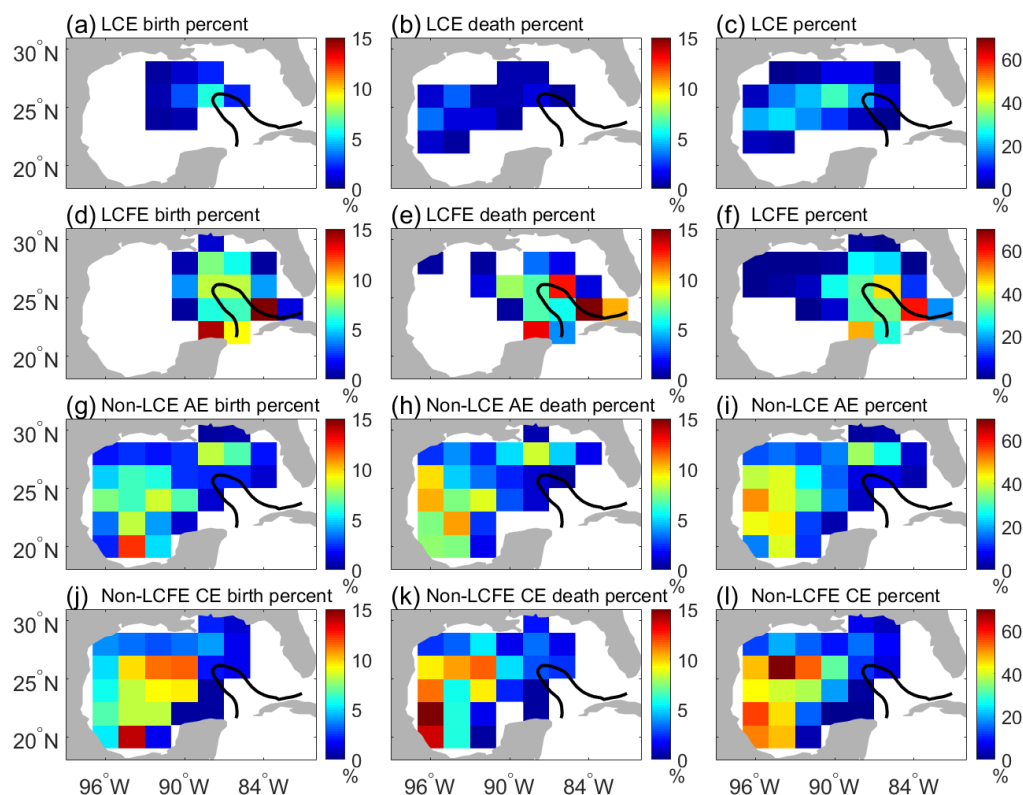

Figure 3: (a, d, g, j) The percentage of months when eddy birth was observed from January 1993 to April 2019. (b, e, h, k) The percentage of months when eddy death was observed. (c, f, i, l) The percentage of months when the presence of eddy was observed. LCEs, LCFEs, non-LCE AEs, non-LCFE CEs are shown in (a-c), (d-f), (g-i), and (j-l), respectively. The black line represents the 25-cm contour of temporal mean SSH anomalies from 1993 to 2019.

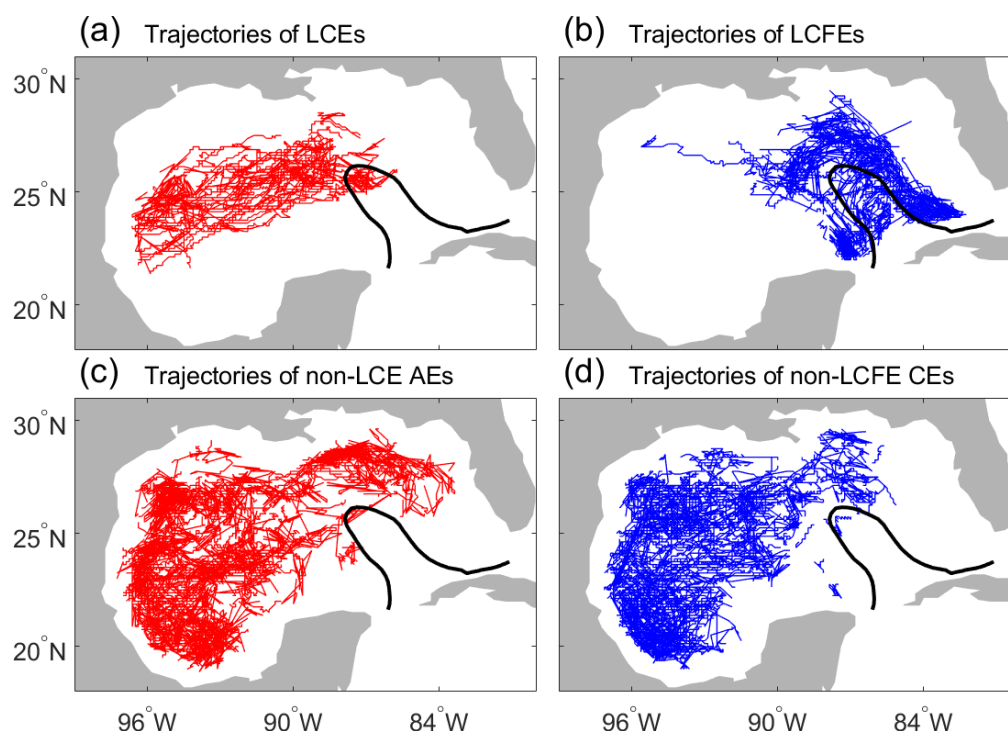

Figure 4: Trajectories of (a) LCEs, (b) LCFEs, (c) non-LCE AEs, and (d) non-LCFE CEs. The thick black line represents the 25-cm contour of temporal mean SSH anomalies from 1993 to 2019.

LCFEs were mostly generated east of Campeche Bank, in the northern and eastern LC (Fig. 3d), and they were more likely to dissipate in the eastern LC (Fig. 3e). LCFEs traveled mainly in the eastern GoM because they were closely tied to the LC (Fig. 4b). LCFEs generated around the Campeche Bank did not travel or lost tracks along the western part of the LC. In the eastern part of the LC, LCFEs traveled along the southward flowing LC. These are consistent with the previous conclusion that LCFE motions along the northern and eastern LC were decoupled from the LCFE motions along the southwestern LC (Donohue et al., 2016a; Donohue et al., 2016b; Hamilton et al., 2016; Walker et al., 2009). In consistence with the LCFE trajectories, LCFEs were most frequently found east of Campeche Bank and in the eastern LC (Fig. 3f). A large fraction of LCFEs has been reported on the eastern flank of the Campeche Bank (Le Hénaff et al., 2014; Jouanno et al., 2016; Zavala-Hidalgo et al., 2003).

324 In contrast to the LCEs and LCFEs that were directly related to the instability of the LC in the
 325 eastern GoM, non-LCE AEs and non-LCFE CEs were mostly generated in the western GoM,
 326 especially in the central-western GoM and in the Bay of Campeche (Fig. 3g and 3j). They were
 327 prone to dissipate along the western boundary of the GoM (Fig. 3h and 3k). The trajectories of
 328 non-LCE AEs and non-LCFE CEs are mostly in the western GoM and do not affect the eastern
 329 GoM (Fig. 4c-d). In line with the eddy trajectories, the presence frequencies of these eddies are
 330 also the highest west of 92°W (Figure 3i and 3l).

331 Although dynamic instabilities of large-scale currents have been reported to be important for
 332 the aforementioned spatial pattern of eddy generation (e.g., Chérubin et al., 2006; Donohue et
 333 al., 2016a; Jouanno et al., 2016; Maslo et al., 2020; Sturges & Leben, 2000; Yang et al., 2020;
 334 Zavala-Hidalgo et al., 2003), the eddy-topography interaction and eddy-eddy interaction could
 335 play a role in generating new eddies (Biggs et al., 1996; Frolov et al., 2004; Smith, 1986; Vidal
 336 et al., 1992). The eddy-eddy interaction including eddy splitting and merging was also
 337 considered in this study following Le Vu et al. (2018). New eddies due to splitting accounts
 338 for 15.4% of the total generated eddies. Only 2 LCEs and 16 LCFEs were generated by
 339 splitting. However, 80 non-LCE AEs and 82 non-LCFE CEs were generated by splitting and
 340 account for 7% of the total generated eddies, respectively. Most non-LCE AEs and non-LCFE
 341 CE due to eddy splitting were scattered in the western GoM (Fig. 5a). In addition to eddy
 342 splitting, LCEs could induce eddies along their periphery during the traveling period because
 343 of the relatively large current shear around LCEs or when they encounter the western boundary
 344 of the GoM. Figure 5b shows the center locations of eddies that were generated along LCE
 345 periphery. There are 14 non-LCE AEs and 118 non-LCFE CE (10% of the total generated
 346 eddies) that are likely related to LCEs, showing no particular pattern. Only a small number of
 347 CE were generated along the western boundary of GoM as LCEs arrived there, suggesting
 348 that the interaction between LCEs and topography plays a relatively small role in creating new
 349 eddies. The dominance of CE that are possibly induced by LCEs is consistent with the fact
 350 that the current shear along LCE periphery is mainly cyclonic.

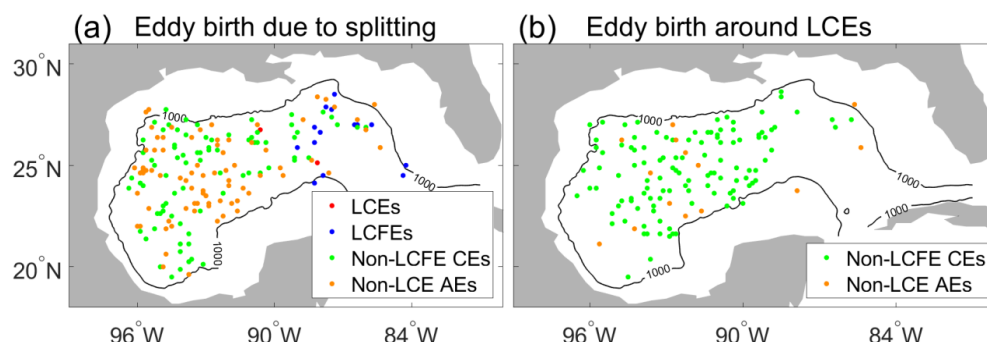

Figure 5: (a) Locations of generated eddies due to splitting. (b) Locations of generated eddies within LCE radius plus 100 km.

Moreover, eddy propagation velocities were estimated by least-squares fitting the positions of eddy centers as a function of time in overlapping 30-day segments of each eddy's trajectory. Figure 6 shows the mean eddy propagation speeds and directions. Mean eddy propagating speeds are highly variable in the GoM. Specifically, LCEs have large traveling speeds in the central-western GoM that can be as large as 5 km/day (Fig. 6a). The mean propagating direction of LCEs is southwestward in the central GoM and bifurcates north and south when LCEs encounter the western boundary of GoM. LCFEs propagate along the LC front and large propagation speeds are found in the eastern part of the LC (Fig. 6b) that are related to the advection of the LC. Non-LCE AEs and non-LCFE CEs have large propagation speeds in the southwest of the GoM and the dominant propagation direction of the two types of eddies is to the west (Fig. 6c-d). The eddy speeds in the western GoM have a similar magnitude as the first-mode Rossby wave propagation speeds (Chelton et al., 2011). However, it should be noted that eddy speeds larger than the first-mode Rossby wave propagation speeds by more than 1 km day⁻¹ were also found, which might be related to the background circulation, or in the case of CEs caused by the swirl velocities of a large LCE.

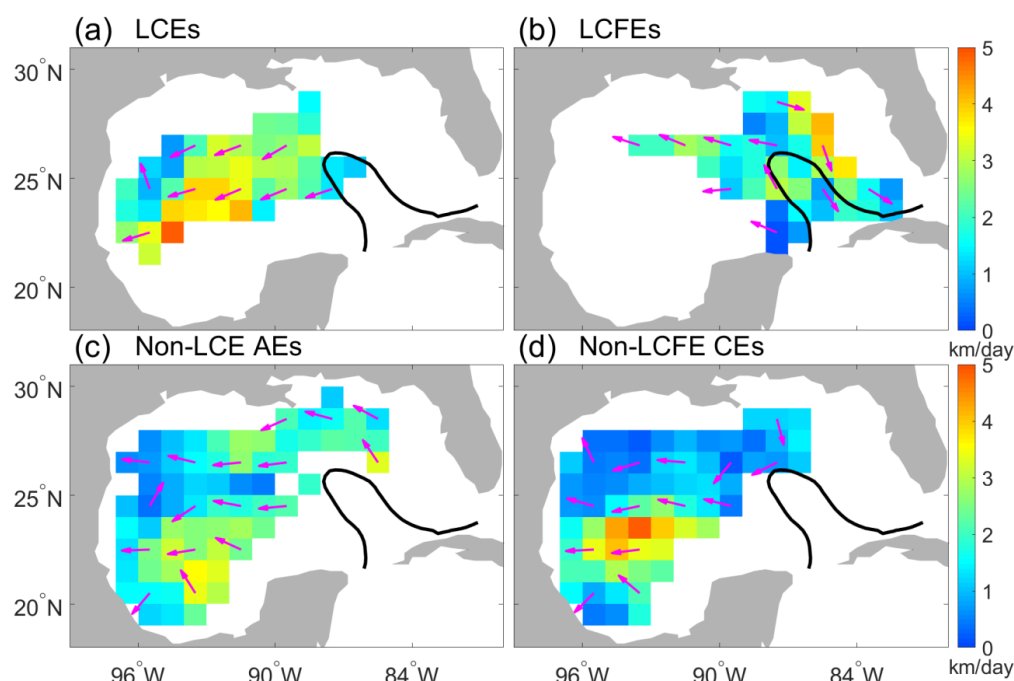

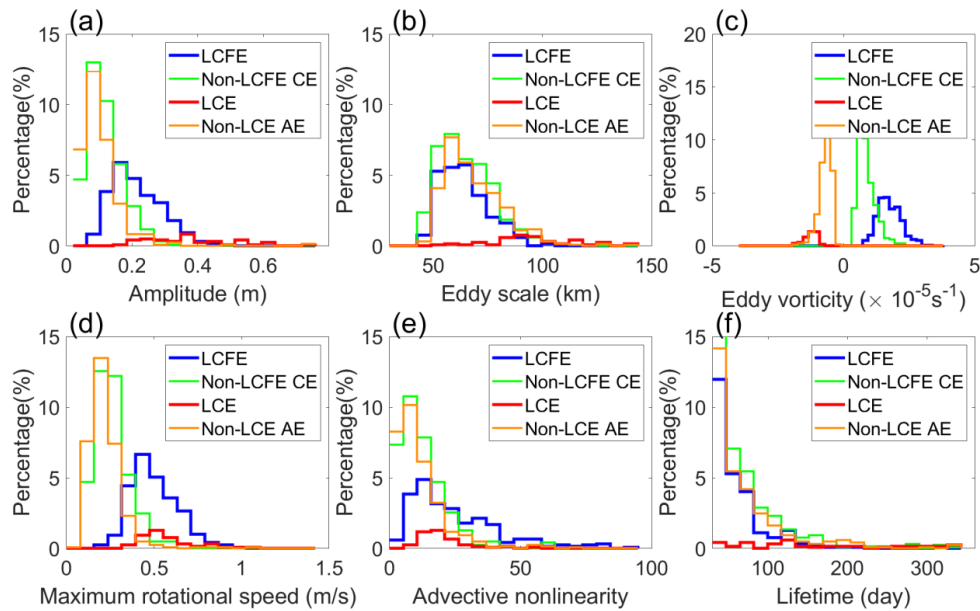

Figure 6: Mean eddy propagation speeds (color shading) and directions (magenta arrows) for (a) LCEs, (b) LCFEs, (c) non-LCE AEs, and (d) non-LCFE CEs. The thick black line represents the 25-cm contour of temporal mean SSH anomalies from 1993 to 2019.

3.2 Basic Eddy Characteristics

Distributions of some basic eddy characteristics derived from the mean values along eddy trajectories are presented in Fig. 7a-e, and the distribution of eddy lifetime is shown in Fig. 7f. Apparent differences between the four types of eddies appear in their amplitude, scale, relative vorticity, maximum rotational speed, and advective nonlinearity (Fig. 7a-e). LCEs have the largest mode values of eddy amplitude, LCFEs have a smaller eddy amplitude, and non-LCE AEs and non-LCFE CEs have the smallest mode values of eddy amplitude (Fig. 7a). The distributions of the eddy scale, defined as the radius with the maximum rotational speed (Chelton et al., 2011), show that LCEs have the largest scale and that the other three types of eddies have smaller and similar mode values of eddy scale (Fig. 7b). The distributions of the relative vorticity, maximum rotational speed, and advective nonlinearity show that LCEs and LCFEs have larger magnitudes of mode values than those of non-LCE AEs and non-LCFE CEs (Fig. 7c-e). The nonlinearity of eddy was assessed with the advective nonlinearity parameter,

388 U/C , where U is the maximum rotational speed and C is the translation speed of eddy. Eddies
 389 with $U/C > 1$ can advect trapped fluid within the eddy interior when they translate (Chelton et
 390 al., 2011; Flierl, 1981). All the nonlinearity parameters averaged over the eddy trajectories are
 391 larger than 1, confirming that eddies in the GoM are highly nonlinear. Nearly 25.1% of AEs
 392 have a lifetime longer than 100 days. About 16.7% of CEs can live longer than 100 days (Fig.
 393 7f).

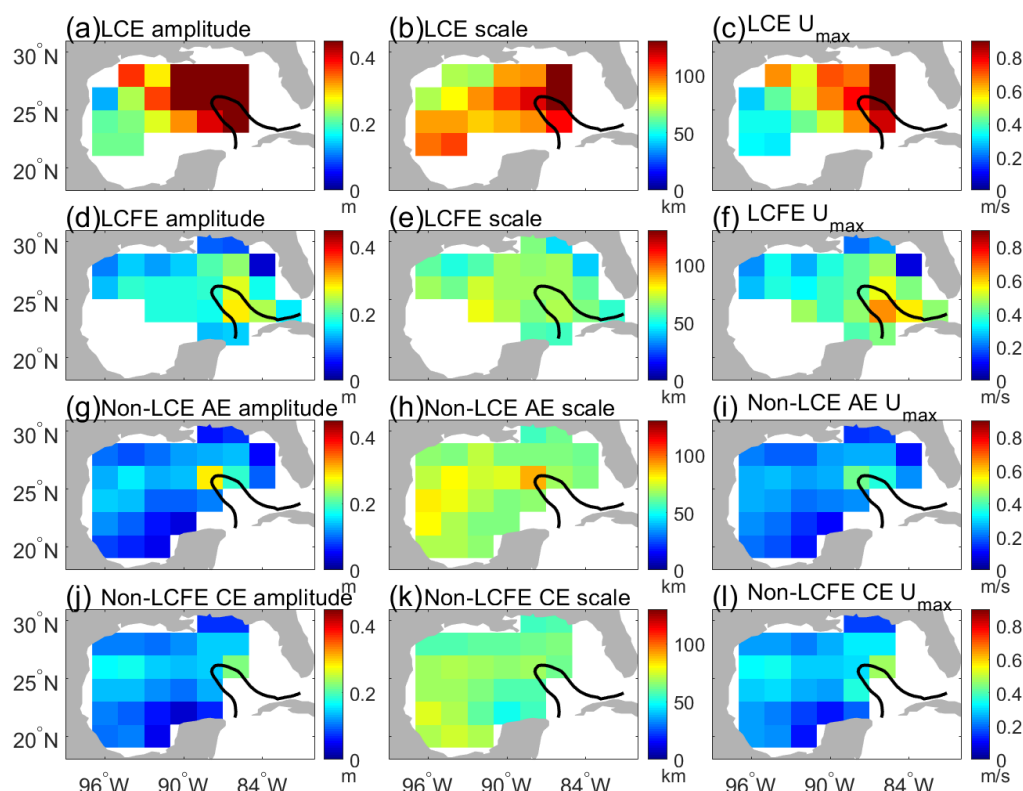

394 **Figure 7:** Histograms of basic eddy characteristics: (a) amplitude (m), (b) eddy scale (km), (c)
 395 eddy relative vorticity (s^{-1}), (d) maximum rotational speed (m/s), (e) advective nonlinearity
 396 (unitless), (f) lifetime (day).

398
 399 Because the temporal correlation scale of gridded ADT data is about 30 days, the obtained
 400 eddy amplitude, scale, and maximum rotational speed were mapped into monthly data on two-
 401 degree grids. To illustrate their spatial distributions, the temporal mean eddy characteristics on
 402 spatial grids are shown in Fig. 8. Eddy characteristics within the LC are not considered in this
 403 study because SSH fields within the LC region were removed. Mean values of the LCE
 404 amplitude, scale, and maximum rotational speed are large northwest of the LC where LCEs
 405 were shed from the LC (Fig. 8a-c) and are much larger than those of the other three types of
 406 eddies. The larger amplitude of LCEs is expected due to their larger size even with a rotational
 407 speed comparable to smaller eddies. LCFEs have relatively large amplitude and rotational

408 speed in the southeastern part of the LC (Fig. 8d and 8f), in agreement with previous estimates
 409 that LCFEs have larger amplitude and rotational speed in the northern and eastern side of the
 410 LC than on the western side (e.g., Le Hénaff et al., 2014). Compared to the eddy amplitude and
 411 rotational speed, the LCFE scale is relatively uniform (Fig. 8e). In contrast to LCEs and LCFEs,
 412 non-LCE AEs and non-LCFE CEs show relatively small spatial variations of amplitude, scale,
 413 and rotational speed (Fig. 8g-l). The spatial patterns of the eddy amplitude, scale, and
 414 maximum rotational speed are not likely related to the eddy number distributions (Figs. 3 and
 415 8).

416
 417 **Figure 8:** Eddy mean amplitude (m) for (a) LCEs, (d) LCFEs, (g) non-LCE AEs, and (j) non-
 418 LCFE CEs. Eddy mean scale (km) for (b) LCEs, (e) LCFEs, (h) non-LCE AEs, and (k) non-
 419 LCFE CEs. Eddy mean maximum rotational speed (m/s) for (c) LCEs, (f) LCFEs, (i) non-LCE
 420 AEs, and (l) non-LCFE CEs. The black line represents the 25-cm contour of temporal mean
 421 SSH anomalies from 1993 to 2019.

422

3.3 Monthly Climatology of Eddies

Monthly climatology of eddy number was obtained and expressed in percentage of the total generated eddies (Fig. 9). The seasonal peak of LCE birth in September and the secondary peak in February are observed (Fig. 9a), which are consistent with that reported by Hall and Leben (2016). The seasonal variation of LCEs is the smallest compared to the other three types of eddies and is not significant at the 95% confidence level. However, Hall and Leben (2016) showed that the seasonal peak of LCE separation in August and September is significant, which could be related to the seasonal variability of wind patterns in the Caribbean Sea and Gulf of Mexico (Chang & Oey, 2012, 2013). In this study, because LCEs show different birth number and date (Table 1) resulting from uncertainties due to the detachment, reattachment of LCEs and eddy splitting (Fig. 5a), the seasonality of LCE separation is not significant. The nonsignificant seasonal variability of LCE separation may be partially related to the physical processes that do not have apparent seasonal variability but can affect the LCE separation. For example, fluctuations such as mesoscale eddies from the Caribbean Sea (Huang et al., 2021; Murphy et al., 1999; Oey et al., 2003) can influence the LCE separation.

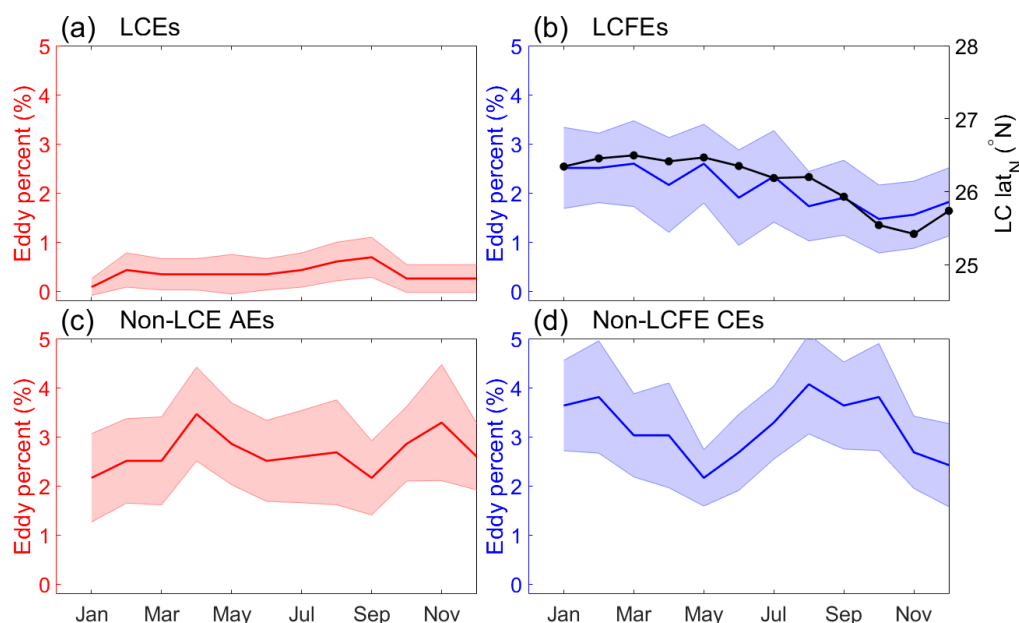

Figure 9: (a) The percentage of birth number of LCEs relative to the total eddy birth number. (b) The percentage of birth number of LCFEs relative to the total birth number. The black line in (b) represents the monthly climatology of the LC position. (c) The percentage of birth number of non-LCE AEs relative to the total birth number. (d) The percentage of birth number

443 of non-LCFE CEs relative to the total birth number. The shading denotes the 95% confidence
 444 level represented by two times standard deviation of eddy percentage in each month.

445

446 Compared to LCEs, more LCFEs are observed and the birth number of LCFEs is larger in
 447 January to July than in October to December (Fig. 9b). The magnitude of the seasonal variation
 448 of LCFEs is close to 1% of the total eddy birth number, but it is still not significant at the 95%
 449 confidence level. Because LCFEs are generated along the LC peripheral, the extent of northern
 450 penetration of the LC may be one important factor for the LCFE generation. The seasonal
 451 variation of the northern boundary of the LC is shown to have a similar variation as that of
 452 LCFEs (Fig. 9b). Hamilton et al. (2014) also showed that altimeter-derived LC northern-
 453 boundary latitude is relatively high from January through about July and low in September and
 454 October. The more northward the LC penetrates, the more LCFEs are generated.

455 The seasonal variations of non-LCE AEs and non-LCFE CEs are relatively large, but
 456 differences of eddy number between most months are not significant at the 95% confidence
 457 level due to large uncertainties (Fig. 9c-d). The number of non-LCFE CEs is small in May and
 458 December and is large in February and August (Fig. 9d), indicating a biannual variability.
 459 Compared to the non-LCFE CEs, the seasonal variation of non-LCE AEs has a different phase
 460 and a smaller amplitude (Fig. 9c). Both the background currents and eddy-eddy interaction
 461 might be important for the seasonality of the two types of eddies. Figure 10 shows the monthly
 462 climatology of the eddy numbers of non-LCE AEs and non-LCFE CEs that were induced by
 463 eddy splitting and LCEs. The seasonal variations of AEs and CEs induced by splitting and
 464 LCEs are small and are not significant at the 95% confidence level. It should be noted that their
 465 seasonal variations are much smaller and more random than those shown in Fig. 9c-d.
 466 Therefore, the seasonal variations of non-LCE AEs and non-LCFE CEs (Fig. 9c-d) are not
 467 related to eddy-eddy interaction represented by eddy splitting and the effect of LCEs and could
 468 be likely related to the background currents.

Figure 10: (a) The percentage of non-LCE AEs generated due to splitting relative to the total generated eddies. (b) The percentage of non-LCFE CEs generated due to splitting relative to the total generated eddies. (c) The percentage of non-LCE AEs generated within LCE radius plus 100 km relative to the total generated eddies. (d) The percentage of non-LCFE CEs generated within LCE radius plus 100 km relative to the total generated eddies. The shading denotes the 95% confidence level represented by two times standard deviation of eddy percentage in each month.

To further show spatial patterns of the monthly climatology of generated eddies, the locations of eddy centers were mapped on two-degree grids (Fig. 11). Figure 11a-d shows the generation locations of LCEs and the mean position of the LC in February, May, August, and November. The LC has a more northward penetration in February and May than in August and November but more LCEs are formed at the northwestern tip of the LC in August than in other months, suggesting no clear linkage between the generation of LCEs and the LC northern boundary can be built. However, more LCFEs can be found in the northern LC in February and May when the LC makes more penetration than in August and November when the LC makes less penetration (Fig. 11e-h). Therefore, a more northward penetration of the LC favors the generation of LCFEs.

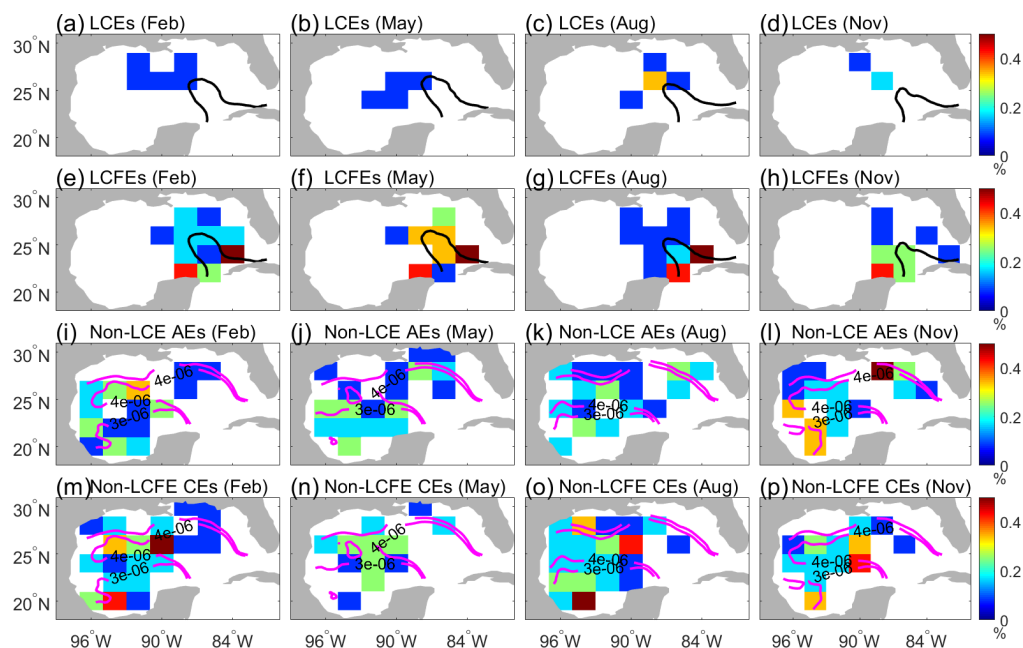

Figure 11: (a-d) LCE percentage relative to the total generated eddies in (a) February, (b) May, (c) August, and (d) November. (e-h) LCFE percentage relative to the total generated eddies in (e) February, (f) May, (g) August, and (h) November. (i-l) Non-LCE AE percentage relative to the total generated eddies in (i) February, (j) May, (k) August, and (l) November. (m-p) Non-LCFE CE percentage relative to the total generated eddies in (m) February, (n) May, (o) August, and (p) November. The black lines in (a-h) represent the mean position of the LC in February, May, August, and November, respectively. The magenta lines in (i-p) represent the monthly climatology of current speed gradient in February, May, August, and November, respectively.

Compared to LCEs and LCFEs that are closely related to the LC, the generation of non-LCE AEs and non-LCFE CEs is scattered over the whole GoM and is mainly in the western GoM (Fig. 11i-p). The contours of current speed gradient in Fig. 11i-p indicate the position of strong background currents. The generation locations of eddies tend to move with the seasonal movement of strong currents, from which eddies may obtain energy. However, non-LCE AEs do not show a significant change in the birth number between different months, which is also indicated in Fig. 9c. It is noted that the number of non-LCFE CEs is more likely related to the strength of the background currents (Fig. 11m-p). More non-LCFE CEs were generated along

the boundary of strong currents in February and August and fewer non-LCFE CEs were generated in May and November. Since most non-LCE AEs and non-LCFE CEs were generated in the western GoM, the current speeds and directions in the western GoM in the four months are highlighted and shown in Fig. 12. The background currents in western GoM are stronger in February and August than in May. The mean currents in the central western GoM flow westward approximately at 22-23°N and eastward at 25-27°N, forming an anticyclonic circulation pattern. It is noted that the currents change direction with season along the western boundary. Therefore, the non-LCFE CEs were more likely formed along the periphery of the strong anticyclonic circulation pattern in the western GoM. It is noted that the eddy generation location varies within the strong-current region and sometimes few eddies are generated. One possible reason is that the large-scale background current can influence the eddy generation but is not the only factor that determines the eddy generation location and other factors such as wind stress play some role.

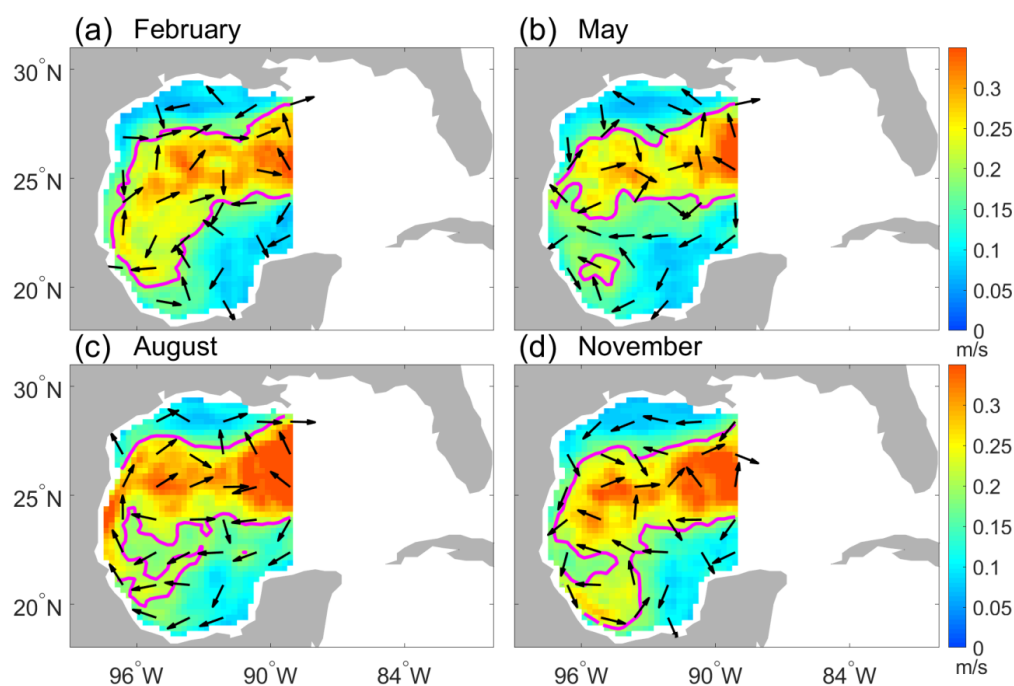

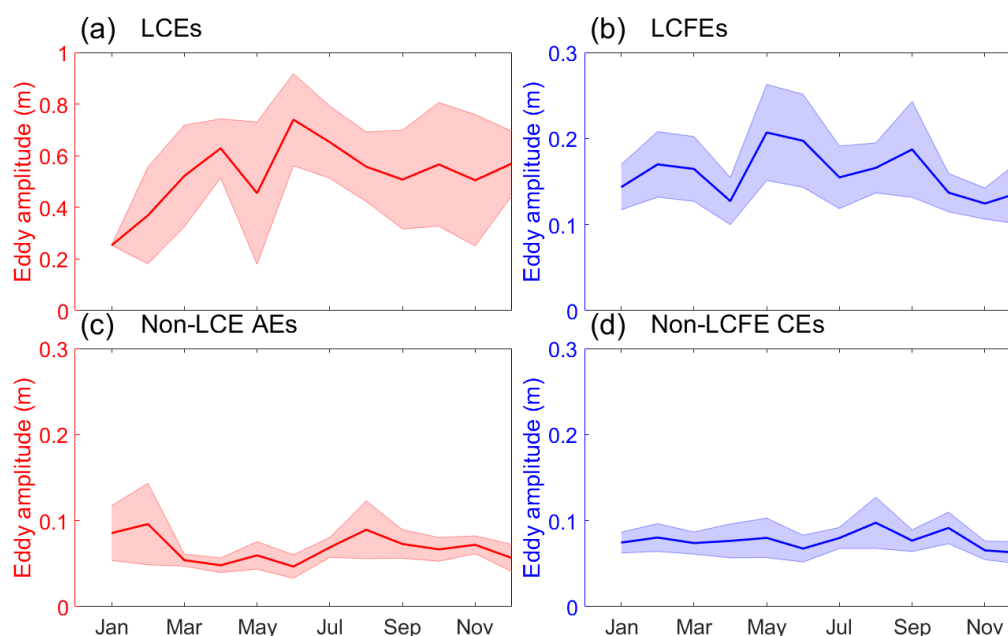

Figure 12: Current speeds (m/s, color shading) climatology and mean current direction (arrows) west of 89°W in the GoM in (a) February, (b) May, (c) August, and (d) November. The magenta contour denotes the current speed of 0.2 m/s.

525 In addition to the seasonality observed in the eddy birth number, the seasonal variability of
 526 eddy amplitude at the time of eddy birth was examined. The monthly climatology of median
 527 eddy amplitude is presented in Fig. 13. Since eddy amplitude is not normally distributed,
 528 median eddy amplitude was used to mitigate the potential influence of amplitude outliers.
 529 Compared to the seasonal variability of eddy number, the seasonal variability of eddy
 530 amplitude is less apparent. LCEs and LCFEs have relatively larger monthly variations and
 531 uncertainties than non-LCE AEs and non-LCFE CEs. It should be noted that the seasonal
 532 variation of LCE amplitude may not be reflected from the relatively short record because it was
 533 estimated from a relatively small number of LCEs that is less than 6 in most months.

534 **Figure 13:** Monthly climatology of eddy amplitude of (a) LCEs, (b) LCFEs, (c) non-LCE AEs,
 535 and (d) non-LCFE CEs when they were generated. The shading denotes the 95% confidence
 536 level represented by two times standard deviation of amplitude.
 537

538

539 3.4 Low-frequency Variability of Eddies

540 To examine the low-frequency variability of eddies, annual variations of eddy birth number
 541 and amplitude were obtained. Figure 14 shows the annual variations of the birth number of
 542 eddies. The generation of LCEs is relatively rare and shows a weak variability (Fig. 14a). The
 543 other three types of eddies indicate a larger variability. A linear regression model that includes

a linear trend, ENSO index, NAO index, and AMM index was applied to the annual eddy number. An increasing number of LCEs over 2001-2010 has been found in previous studies (Lindo-Atichati et al., 2013; Vukovich, 2012). Nevertheless, no long-term variability of other types of eddies has been reported. The linear trends of the annual birth number of LCEs, LCFEs, non-LCE AEs, and non-LCFE CEs from 1993 to 2018 are $3.5 \times 10^{-2} \pm 3.3 \times 10^{-2} (\pm 1\sigma)$ year⁻¹, $-0.2 \pm 0.17 (\pm 1\sigma)$ year⁻¹, $-0.06 \pm 0.11 (\pm 1\sigma)$ year⁻¹, and $0.05 \pm 0.11 (\pm 1\sigma)$ year⁻¹, respectively. These linear trends are not significant at the 95% confidence level. LCFEs have the largest decreasing trend that is not significant, which is likely related to the negative trend of the northern boundary of the LC that is $-1.7 \times 10^{-2} \pm 1.7 \times 10^{-2} (\pm 1\sigma)$ degree year⁻¹. Regression coefficients of the three climate indices are not significant as well. For the four types of eddies, the coefficients of determination of the three climate indices are less than 0.08. Therefore, only a small portion of eddy number variance can be explained by the three climate modes, indicating that the role of the remote climate variability in changing the eddy activity in the GoM is relatively small or cannot be detected from the linear model.

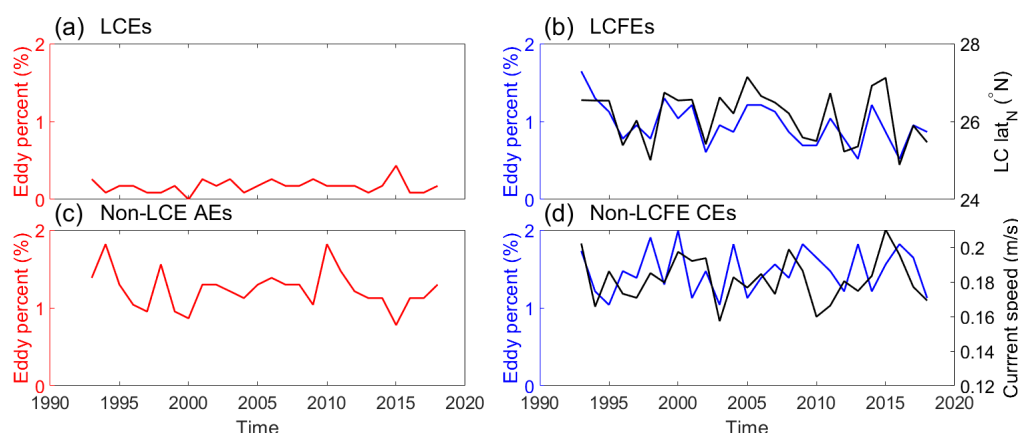

Figure 14: Annual number of generated (a) LCEs, (b) LCFEs, (c) non-LCE AEs and (d) non-LCFE CEs and is expressed as percentage of the total new eddy from 1993 to 2018. The black line represents the annual mean northern boundary (°N) of the LC in (b) and the annual mean current speed (m/s) in the western GoM in (d).

In the eastern GoM, the low-frequency variability of eddy number is likely related to that of the LC. Figure 14b shows the annual mean variation of the northern boundary position of the LC that particularly follows the variation of LCFEs. Correlation between the birth number of LCEs and the northern boundary position of the LC is small and not significant (Table 2),

therefore, the extent of LC penetration plays a relatively small role in the separation of LCEs. However, the LCFE number and the northern boundary position of the LC are correlated with a significant correlation of 0.76, indicating that the LCFE number increases with the northward penetration of the LC on the interannual to multidecadal time scale (Table 2). The extent of northward penetration of the LC is important for the LCFE generation although previous studies have shown that perturbations coming from the Caribbean Sea (Huang et al., 2013) and the topography of the northern Campeche (Chérubin et al., 2006) also contribute to the eddy activity along the western edge of the LC.

	LCE number	LCFE number	LCE amplitude	LCFE amplitude
LC northern boundary	0.38	0.76	-0.17	-0.26

Table 2: Correlations between the annual number and amplitude of LCEs and LCFEs with the annual mean northern boundary of the LC. The value in bold is significant at the 95% confidence level.

For the non-LCE AEs and non-LCFE CEs, the eddy numbers also show large annual mean variations (Fig. 14c-d). Since the background current strength could be important in affecting the low-frequency eddy activity (Chen et al., 2011), birth numbers of non-LCE AEs and non-LCFE CEs, which were mostly formed in the western GoM, were compared with the surface current speed averaged in the western GoM (Fig. 14d). The non-LCE AE number and the non-LCFE CE number are correlated and anticorrelated with the mean surface current speed in the western GoM respectively, but the correlation values are not significant at the 95% confidence level (Table 3).

	Non-LCE AE number	Non-LCFE CE number	Non-LCE AE amplitude	Non-LCFE CE amplitude
Current speed in WGOM	-0.42	0.33	0.47	0.47

Table 3: Correlations between the annual number and amplitude of non-LCE AEs and non-LCFE CEs with the annual mean current speed in the western GoM.

591 In addition to the influence of background currents, the eddy-eddy interaction that includes
 592 eddy splitting and eddy formation related to LCEs is considered as well. The annual mean
 593 variability of eddies due to eddy-eddy interaction is relatively weak. After removing the eddies
 594 induced by eddy splitting and LCEs, the correlations between non-LCE AE number, non-LCFE
 595 CE number, and the mean surface current speed in the western GoM are -0.38 and 0.32,
 596 respectively. Those numbers are similar to -0.42 and 0.33 shown in Table 3. The eddy-eddy
 597 interaction has little effect on the relationship between western eddies and the background
 598 flows. Since a much smaller number of eddies due to eddy splitting and LCEs are found along
 599 the western boundary (Fig. 5) where LCEs could interact with the topography (e.g., Vidal et
 600 al., 1992), the eddy-topography interaction is not important for the low-frequency variability
 601 of eddies.

602 The relationship between the eddy number and the strength of the circulation in the western
 603 GoM was further examined with composite analysis. The mean current speeds and flow
 604 directions in the western GoM during the periods with more non-LCFE CEs and fewer non-
 605 LCFE CEs are shown in Fig. 15. When the annual number of non-LCFE CEs is one standard
 606 deviation larger than the average eddy number, strong mean anticyclonic circulation is
 607 observed in the western GoM. When the annual number of non-LCFE CEs is one standard
 608 deviation smaller than the average eddy number, weak mean anticyclonic circulation is
 609 observed in the western GoM. However, over the period with more non-LCE AEs weak mean
 610 anticyclonic circulation is observed in the western GoM. Over the period with fewer non-LCE
 611 AEs strong mean anticyclonic circulation is observed in the western GoM. Therefore, the
 612 strength of the background circulation could play a role in influencing the low-frequency
 613 variability of eddy number.

614
 615 **Figure 15:** Composite of current speeds west of 89°W in the GoM (a) during the period with
 616 more generated non-LCFE CEs (annual number of non-LCFE CEs is larger than mean value

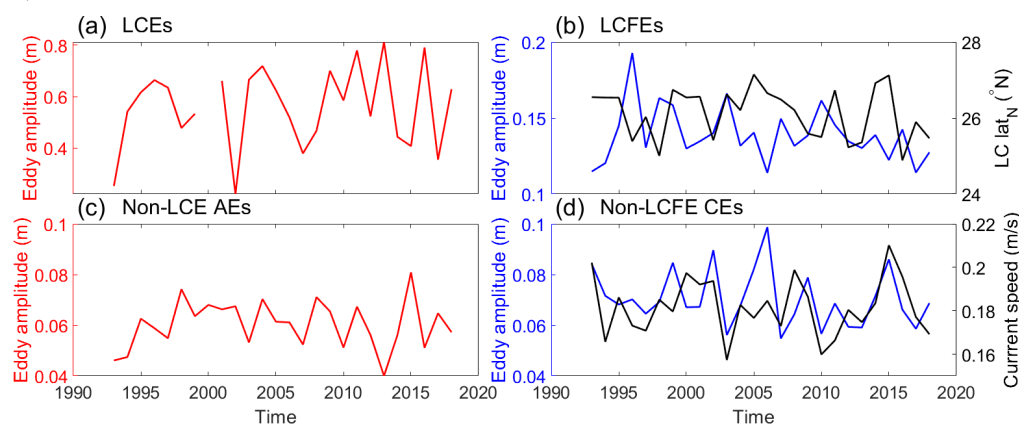

plus one standard deviation), and (b) during the period with fewer non-LCFE CEs (annual number of non-LCFE CEs is smaller than mean value minus one standard deviation). Arrows denote the mean current direction.

620

Eddy amplitude in the GoM exhibits low-frequency variability as well. To mitigate the potential influence of amplitude outliers, the median amplitude of eddies at the time of birth in each year was selected for the analysis of the low-frequency variability of eddy amplitude (Fig. 16). LCEs show the largest annual variation of eddy amplitude (Fig. 16a) that was obtained from a small number of LCEs (Fig. 14a). The amplitude variation of LCFEs is weaker than that of LCEs but is larger than those of non-LCE AEs and non-LCFE CEs (Fig. 16b). The variations of LCE and LCFE amplitude are not closely related to the northern boundary of the LC with small correlations (Table 2), suggesting the extent of the LC penetration is not an important factor for the eddy amplitude at the time of birth. For non-LCE AEs and non-LCFE CEs, the eddy amplitude at the time of birth seems to be related to the strength of background currents in the western GoM (Fig. 16c-d) but with a nonsignificant positive correlation of 0.47 (Table 3).

632

633

Figure 16. Annual median amplitude (m) of the (a) LCEs, (b) LCFEs, (c) non-LCE AEs and (d) non-LCFE CEs when they were generated. The black line represents the annual mean northern boundary ($^{\circ}$ N) of the LC in (b) and the annual mean current speed (m/s) in the western GoM in (d).

637

638

639 **4 Conclusions and Discussions**

640 In this study, we present characteristics of the robust mesoscale eddies in the GoM, including
 641 their spatial distributions, propagation features, seasonal and low-frequency variabilities. As
 642 expected, many eddy characteristics in the eastern GoM are closely related to the LC, which
 643 sheds large and strong LCEs and develops small-scale LCFEs (e.g., Brokaw et al., 2020; Le
 644 Hénaff et al., 2014). Compared to LCEs and LCFEs, non-LCE AEs and non-LCFE CEs are
 645 mainly formed in the central-western GoM, tend to dissipate along the western boundary, and
 646 have smaller amplitude, relative vorticity magnitude, rotational speed, and nonlinearity.
 647 Among LCEs, LCFEs, non-LCE AEs, and non-LCFE CEs, only LCEs can travel a long
 648 distance from the eastern to the western GoM, as observed from other datasets (e.g., Vukovich
 649 2007). Temporally mean propagation speeds are high in the eastern part of the LC and the
 650 southwestern GoM.

651 The temporal variability of eddy occurrence and amplitude, which is less reported in the
 652 literature, shows manifest spatial patterns and dramatic differences between LCEs, LCFEs,
 653 non-LCE AEs, and non-LCFE CEs. This study indicates a biannual variability of LCE
 654 separation with large uncertainties that is similar to that found in a shorter record by Hall &
 655 Leben (2016). However, the seasonality in LCE formation is not significant, while Hall and
 656 Leben (2016) suggested that the seasonal peak in LC eddy separation events in August and
 657 September was significant. The seasonal variabilities of birth numbers of the other three types
 658 of eddies are also not significant at the 95% confidence level. Nevertheless, LCFEs and non-
 659 LCFE CEs show more apparent seasonal patterns than LCEs and non-LCE AEs. More LCFEs
 660 are observed from January to July, while more non-LCFE CEs are found in February and
 661 August. Fewer LCFEs are observed from August to December, while fewer non-LCFE CEs
 662 are found in May and December. Moreover, the seasonal variability of eddy amplitude at the
 663 time of eddy birth is more random than that of eddy number. Similar to the temporal mean
 664 characteristics, the seasonal variability of eddy amplitude of LCEs and LCFEs at the time of
 665 eddy birth is much larger than that of non-LCE AEs and non-LCFE CEs. On the low-frequency
 666 time scale, although an increasing number of LCEs in the decade 2001-2010 has been found in
 667 previous studies (Lindo-Atichati et al., 2013; Vukovich, 2012), the linear trends of LCEs and
 668 other three types of eddies obtained in this study are not significant at the 95% confidence
 669 level.

670 The seasonal and low-frequency variabilities described above could be closely related to the
 671 large-scale background circulations such as the LC, eddy-eddy interaction, and eddy-

672 topography interaction. On the seasonal time scale, the extent of northward penetration of the
 673 LC is important for LCFE generation but not for their amplitude. The position and strength of
 674 background currents in the western GoM are likely important for the formation of non-LCFE
 675 CEs and non-LCE AEs that are mostly formed in the western GoM. On the low-frequency time
 676 scale (interannual to multidecadal), LCFE number is related to the extent of northward
 677 penetration of the LC in the eastern GoM. In the western GoM, the surface circulation strength
 678 could be important for the low-frequency variability of eddy occurrence and amplitude, which
 679 is also found in other oceans (e.g., Chen et al., 2011). In contrast, the eddy-eddy interaction
 680 that includes eddy splitting and the effect of LCEs and the eddy-topography interaction give
 681 rise to a relatively small number of eddies and play a small role in the temporal variability of
 682 eddies.

683 Although climate change and variability may be altering the oceanic conditions in the GoM
 684 (e.g., Rodriguez-Vera et al., 2019), the linear trend of eddy occurrence and the low-frequency
 685 variability related to climate modes such as NAO, AMM and ENSO are not significant in the
 686 current record.

687 Note that eddy characteristics obtained in this study may include uncertainties caused by
 688 drawbacks in eddy detection and tracking algorithms despite a combination of three different
 689 eddy detection algorithms. For instance, geometrical properties in detection algorithms are
 690 sensitive to interval searching for closed contours (Lian et al., 2019). With the increasing
 691 knowledge of mesoscale eddies and improved eddy detection and tracking algorithms, more
 692 robust eddies will be obtained in future studies. In addition to the limitation of eddy detection
 693 and tracking algorithms, satellite sampling could affect the detection of the mesoscale activity
 694 (Le Traon and Dibarboure, 1999) and the LC statistics (Dukhovskoy et al., 2015). The allsat
 695 ADT product was derived from a varying number of altimeters and was useful for examining
 696 the influence of satellite sampling on eddy detection. Mesoscale eddies were detected with the
 697 algorithm developed by Le Vu et al. (2018) from the allsat ADT product and were compared
 698 with those detected from the twosat ADT. From 1 January 1993 to 31 December 1999 when
 699 twosat and allsat ADT data were mainly derived from 2 altimeters, 41388 and 41343 eddies
 700 were detected from the twosat and allsat ADT data respectively, suggesting that 0.1% of eddies
 701 was less detected in allsat ADT than in twosat ADT. From 1 January 2000 to 13 May 2019
 702 when the allsat ADT data were mainly derived from 3 or more altimeters, 117582 and 117359
 703 eddies were detected from the twosat and allsat ADT data respectively, suggesting that 0.2%

704 of eddies was less detected in allsat ADT than in twosat ADT. The satellite sampling has a
 705 relatively small effect on the detection of eddies in the GoM.
 706 In this study, we focus on describing the characteristics of the robust mesoscale eddies in the
 707 GoM, and some characteristics such as the temporal and spatial patterns of eddies still need
 708 further dynamical explanations. Previous studies indicate that mesoscale eddies in the eastern
 709 GoM likely arise from dynamic instabilities, such as barotropic and baroclinic instabilities
 710 (e.g., Chérubin et al., 2006; Donohue et al., 2016a; Pichevin & Nof, 1997; Sturges & Leben,
 711 2000; Vukovich & Maul, 1985; Yang et al., 2020; Zavala-Hidalgo et al., 2003). In the future,
 712 dynamic analyses such as eddy energy may shed light on the detailed mechanisms of the
 713 temporal and spatial variability of mesoscale eddies in the GoM.

714

715 **Data Availability**

716 The daily DT2018 ADT data (Taburet et al., 2019) from two altimeter satellites used for eddy
 717 detection was provided by the C3S
 718 (<https://cds.climate.copernicus.eu/cdsapp#!/dataset/satellite-sea-level-global?tab=form>).
 719 Besides, the daily DT2018 ADT data from multi-mission altimeter satellites used to examine
 720 the influence of satellite sampling on eddy detection is
 721 SEALEVEL_GLO_PHY_L4_REP_OBSERVATIONS_008_047 that was produced and
 722 provided by CMEMS ([https://resources.marine.copernicus.eu/product-](https://resources.marine.copernicus.eu/product-detail/SEALEVEL_GLO_PHY_L4_MY_008_047/INFORMATION)
 723 [detail/SEALEVEL_GLO_PHY_L4_MY_008_047/INFORMATION](https://resources.marine.copernicus.eu/product-detail/SEALEVEL_GLO_PHY_L4_MY_008_047/INFORMATION)). TOPEX/Poseidon
 724 (T/P) along-track ADT data from 2 January 1996 to 3 December 1999 were used to examine
 725 the effective spatial resolution of the gridded ADT product in the GoM and were provided by
 726 CMEMS. Since the eddy traveling speeds were compared with the first-mode baroclinic
 727 Rossby wave speeds, the atlas of the first-baroclinic Rossby radius of deformation was also
 728 used and downloaded at https://ceoas.oregonstate.edu/rossby_radius (Chelton et al., 1998). The
 729 multivariate ENSO index (MEI V2) (e.g., Zhang T. et al., 2019) from National Oceanic and
 730 Atmospheric Administration (NOAA) Physical Sciences Laboratory, NAO index (Hurrell,
 731 1995) from NOAA Climate Prediction Center, and AMM index (Chiang & Vimont, 2004) from
 732 University of Wisconsin were used to examine possible relationships between the eddy activity
 733 in the GoM and climate modes. The MEI, NAO index, and AMM index were downloaded at
 734 <https://psl.noaa.gov/data/climateindices/list/>.

735

736 **Author contribution:** Yingli Zhu and Xinfeng Liang designed the experiments and Yingli
 737 Zhu carried them out. Yingli Zhu prepared the manuscript with contributions from all co-
 738 authors.

739

740 **Competing interests:** The authors declare that they have no conflict of interest.
