28 **Abstract.** The increase in the temperature of surface waters has been studied for many decades,  
29 and various methods have been used to predict the most probable scenarios. The present study  
30 was undertaken to test the following research hypothesis: the warming of surface waters in  
31 winter (caused by the inflow of geothermal water) significantly modifies the dynamics,  
32 significance and type of relationships in zooplankton communities colonizing mine pit  
33 reservoirs. These relationships were examined with the use of network graph analysis for three  
34 thermal variants: warm winters (WW), moderate winters (MW), and cold winters (CW). The  
35 CW network was most cohesive, and it was controlled by eutrophic Rotifera (*Trichocerca*  
36 *pusilla*, *Pompholyx sulcata*, *Keratella tecta*) and Copepoda, with an equivalent number of  
37 positive and negative interspecific relationships. An increase in water temperature in winter led  
38 to a decrease in primary production, a decrease in the values of centrality attributes in MW and  
39 WW networks, and an increase in the significance of species that communicated with the  
40 highest number of species across sub-networks. Moderate winters increased the role of  
41 ecologically and functionally diverse species, which contributed to the heterogeneity of the MW  
42 network. The WW network was least cohesive, and it was controlled by small-sized  
43 psammophilous and phytophilous rotifers (*Monommata maculata*, *Cephalodella* spp.) and  
44 littoral cladocerans *Alona* spp. Adults Copepoda were not identified in the network, and the  
45 significance of antagonistic relationships decreased, which indicates that the WW network  
46 structure was weak and unstable.

47 The results of the impact of warm winters and the flattening of the annual water temperature  
48 amplitude on the zooplankton network may be a projection of the expected global changes.  
49 These effects are particularly important in water reservoirs exposed to anthropogenic pressure  
50 and where changes in the thermal regime can influence future ecosystem services.

51

52

## 53 **1 Introduction**

54 Research on variations in water temperature and their impact on the structure, stability and  
55 functions of ecosystems in an era of global warming has been growing in importance in recent  
56 years. Temperature is one of the key factors that regulate life processes in the aquatic  
57 environment, and it affects gas exchange, saturation levels, and the rates of nutrient and organic  
58 matter cycling in water (Lampert and Sommer, 1999, Wrzesiński et al., 2015). Water  
59 temperature gradients lead to changes in biocenosis composition and the structure of the food  
60 chain (Lewandowska et al., 2014 a; Gutierrez, 2016). In the temperate climate, water bodies are  
61 affected by seasonal changes in air temperature and insolation which create diverse thermal  
62 regimes (Lampert and Sommer, 1999). Shallow water bodies are particularly susceptible to  
63 atmospheric fluctuations because air temperature and the mechanical effects of wind induce  
64 frequent changes in thermic and oxygen profiles (Williamson et al., 2009).

65 The fluctuations and/or permanent changes in the thermal profile of surface waters have  
66 been largely associated with the discharge of industrial cooling water (Capuzzo, 1980; Ejsmont-  
67 Karabin and Wągleńska, 1988; Zargar and Ghosh, 2006; Vandysh, 2009; Ejsmont-Karabin,  
68 2011). The effects of local geothermal sources have been less frequently investigated, mostly  
69 focusing on their local use for therapeutic purposes (balneotherapy) or as tourist attractions  
70 (Samsudin et al., 1997; Beriatos and Papageorgiou, 2009; Boekstein, 2014; Menkshi et al.,  
71 2019). There is a general scarcity of research on the hydrobiological impact of geothermal water  
72 that reaches water bodies, and the few available studies have focused mostly on the tropical  
73 regions (Sellami et al., 2009; Dash et al., 2012; Baksir et al., 2022). In recent decades, climatic  
74 factors associated with a rise in global temperature, in particular in northern latitudes, have been  
75 recognized as an additional driver of changes in the thermal profile of surface water bodies  
76 (EEA, 2014; Ptak et al., 2018; IPCC, 2021). A growing temperature gradient can significantly  
77 affect the structure and functioning of aquatic biocenoses in the temperate climate, and the

78 sensitivity of aquatic organisms results from evolutionary adaptations to specific thermal  
 79 regimes (Moore et al., 1996; Richardson, 2008; Wagner and Adrian, 2009; Evans et al., 2020).

80         Zooplankton support important processes in aquatic ecosystems. They play the key role  
 81 in the food web by integrating primary producers with consumers at higher trophic levels (fish)  
 82 (Lampert, 1997; Sotton et al., 2014; St-Gelais, 2017). Planktonic animals are the main link in  
 83 microbial carbon cycling (Bowszys et al., 2020), and they are sensitive bioindicators of changes  
 84 in abiotic factors (Goździewska et al., 2016; Zhou et al., 2018; Wang et al., 2021). Due to  
 85 their taxonomic and functional diversity, different ecological strategies, phylogenetic  
 86 distinctness, as well as passive and broad dispersion in the environment, zooplankton are highly  
 87 useful for the development of ecosystem models/forecasts, including in the context of global  
 88 warming (Richardson, 2008; Chou, 2012; Arlic, et al. 2013; Feitosa et al., 2019; Kruk et al.,  
 89 2020, 2021; Goździewska and Kruk 2022). Zooplankton respond directly to water  
 90 temperature at the physiological (by regulating metabolic, growth and development processes)  
 91 (Gillooly, 2000; Lewandowska et al., 2014 b) and behavioral level (changes in distribution,  
 92 population size, species composition and phenology) (Ejsmont-Karabin and Wągleńska, 1988;  
 93 Carter and Schindler, 2012; Ejsmont-Karabin et al., 2020). In turn, the water temperature  
 94 indirectly affects the zooplankton communities by determining the availability and quality of  
 95 food resources (mainly phytoplankton) and the intensity of fish predation (Evans et al., 2020;  
 96 Wang et al., 2021).

97         Previous research has demonstrated that an increase in mean seasonal/annual water  
 98 temperature induces similar responses in freshwater zooplankton to accelerated eutrophication,  
 99 and it involves an increase in total density and biomass, changes in species composition  
 100 (Williamson et al., 2002; Visconti, 2008; Vandysh, 2009; Arlic et al., 2013), elimination of  
 101 seasonal succession, including a decrease in the proportion of cold-water species in spring  
 102 rotifer communities (Ejsmont- Karabin et al., 2020), an increase in the proportion of Copepoda

larvae, and accelerated growth of crustaceans characterized by small body size/low biomass (Daufresne et al., 2009; Gutierrez, 2016; Evans et al., 2020; Zhou, 2020). Seasonal shifting caused by, among others, early water warming in spring speeds up the development of thermophilic species and often disrupts their natural life cycle (Edwards and Richardson, 2004; Thackeray et al., 2008; Carter and Schindler, 2012). Particular attention has been paid to phenological changes in temperate ecosystems because the date on which temperatures begin to increase determines reproductive success, emergence from resting stages, generation time, and food availability (Adrian et al., 2006; Costello et al., 2006; Lewandowska et al., 2014 b). Therefore, species-specific responses to changes in the thermal regime are directly reflected by the taxonomic structure and functional attributes of zooplankton communities (Costello et al., 2006; Wagner and Adrian, 2011; Evans et al., 2020). These factors affect the organization of interspecific relationships in zooplankton networks, which involve mostly competition and predation, and they influence successive trophic levels (Hart, 1988; Gliwicz and Pijanowska, 1989; Carter et al., 2017). An analysis of the interactions between changing temperatures and the attributes of zooplankton communities provides valuable information for evaluating the condition of aquatic ecosystems and predicting future changes.

This study proposes a new, structural approach to describing zooplankton's responses to water temperature. Interspecific interactions were examined with the use of the network graph analysis. A network graph model supports the identification and assessment of relationships between species, based on mutualism or neutral coexistence of species in ecological guilds (positive mathematical interactions) or limitation (negative correlations) resulting from predation or competition (Allesina et al., 2005, D'Alelio et al., 2016, Kruk and Paturej, 2020; Goździewska and Kruk, 2022).

Zooplankton were sampled from three artificial reservoirs in the Bełchatów-Szczerców coal strip mine (central Poland) that are supplied with water from various depths, including

128 from geothermal sources. As a result, feedwater differs in temperature. In the studied geological  
129 region, the availability of geothermal water is determined by Early Jurassic deposits, where the  
130 water table has a stable temperature of ~40-50 °C (Jasnós et al., 2012). As a result, the studied  
131 reservoirs differ significantly in mean annual temperature and the annual temperature gradient,  
132 in particular in winter. The structures of plankton communities could be compared *in situ* across  
133 various thermal conditions, because the examined ecosystems have similar limnological and  
134 hydrological parameters and are used in a controlled manner. Zooplankton networks were  
135 analyzed between 2014 and 2016 based on the biomass parameters of crustacean, rotifer, and  
136 protozoan species. Based on Krebs (2009), we assumed that positive interactions between two  
137 taxa are correlated with an increase in their biomass as the effect of consumer guilds, where  
138 independent species share resources. In turn, negative interactions between species (their  
139 biomass) are indicative of grazing on phytoplankton, predation or interference competition.

140 We hypothesized that water temperature gradient considerably affects food availability,  
141 thus influencing the growth and competitive equilibrium of zooplankton species, i.e. the  
142 significance of individual taxa and their interactions that determine network cohesion. We  
143 assumed that the significance and strength of the interactions between zooplankton species,  
144 involving an equal number of positive and antagonistic biocenotic relationships, should be  
145 highest in unmodified thermal regimes (cold winters), where zooplankton taxa should form a  
146 cohesive central network. In turn, higher water temperatures in winter and the flattening of the  
147 annual temperature gradient should be correlated with network decentralization and  
148 fragmentation, and it should weaken the interactions between zooplankton species, and the role  
149 of crustaceans.

150 The examined reservoirs were created more than 20 years ago, and they are supplied  
151 with water with relatively stable physical and chemical parameters (including temperature). The  
152 above implies that feedwater influences planktonic biocenoses by acting as a permanent

153 environmental filter, rather than a temporary disturbance. Therefore, the extent to which  
154 zooplankton networks are influenced by the water temperature gradient in the compared  
155 reservoirs should be examined, and the results can be used to predict changes in aquatic  
156 biocenoses resulting from surface water warming under the influence of global climate change.  
157 Global warming will affect not only mean temperatures, but it will also increase the frequency,  
158 intensity and duration of warm spells, which is why the impact of thermal variations on the  
159 structure, stability, and functions of ecological communities is an important consideration  
160 (Tuck and Romanuk, 2012, EEA, 2014). A better understanding of the responses of  
161 zooplankton communities to long-term environmental changes is vital for predicting the  
162 responses of freshwater ecosystems to global climate change.

163

## 164 **2 Material and methods**

### 165 **2.1 Study area**

166 The study was conducted in three artificial reservoirs (CH1, PN, WI) located in the vicinity of  
167 the Bełchatów brown coal strip mine in Central Poland (51°24'43.6"N; 19°26'32.9"E). The  
168 reservoirs act as dewatering ponds for the open-pit coal mines in Bełchatów and Szczerców  
169 (Fig. 1). Their main function is to reduce suspended matter through sedimentation  
170 (Goździewska et al., 2018, 2019). These flow-through reservoirs (with an estimated retention  
171 time of 16 h) have a similar structure, shape, area (7.1-8.2 ha), and depth (1.7-2.7 m)  
172 (Goździewska et al., 2018, 2020). Feedwater originates from various depths and differs in  
173 temperature. Reservoir CH1 is filled with atmospheric water, meltwater, and capillary water  
174 with temperature similar to air temperature. Therefore, reservoir CH1 represents natural  
175 seasonal variations in the temperature of shallow water bodies in the temperate climate (Fig. 2).  
176 Reservoir WI is supplied with water from a deep dewatering well (up to 350 m) with a stable  
177 temperature of >30 °C which is characteristic of geothermal sources (Jasnos et al., 2012;

178 Macuda et al., 2018). Reservoir PN is supplied mainly by deep dewatering wells as well as  
 179 surface runoffs from a coal yard. Therefore, the temperature of feedwater in reservoir PN  
 180 corresponds to the mid-range of values describing feedwater in reservoirs CH1 and WI. Water  
 181 is transported to reservoirs by open concrete channels with a length of 1-1.5 km, which reduces  
 182 differences in water and air temperature. Despite this, water carried to the warmest reservoir  
 183 (WI) has a temperature of around 16-18 °C in winter (when air temperature is around 0-4 °C),  
 184 which results difference between the compared reservoirs is greatest in the coldest season of  
 185 the year (Fig. 2). In addition, during mild winters, the growing season of aquatic macrophytes  
 186 is prolonged in reservoir WI, and macrophytic vegetation colonizes the littoral zone as well as  
 187 well as large portions of the water surface (mainly *Nuphar lutea*), all the year.

188 The influence of water temperature on the interactions between zooplankton species was  
 189 analyzed in three winter temperature scenarios: cold winters (CW < 6 °C) – reservoir CH1,  
 190 moderate winters (MW = 6 – 10 °C) – reservoir PN, and warm winters (WW > 10 °C) –  
 191 reservoir WI.

192

## 193 **2.2 Sampling and analytical procedure**

194 Zooplankton were sampled monthly, between January and December in 2014 and 2015, and  
 195 between June and September in 2016. In each reservoir, samples were collected in three sites  
 196 located in the center, in the coastal zone, and in the vicinity of the filter zone. Samples were  
 197 collected with a 5 l Patalas trap at an estimated depth of 1 m below the surface. A total of 252  
 198 zooplankton samples (84 samples from each of the three reservoirs) were collected during the  
 199 experiment. The sampled material (20 l) was filtered through a plankton net with 30 µm mesh  
 200 size, preserved with a 4 % formalin solution. Zooplankton were identified under a Zeiss AXIO  
 201 Imager microscope to the lowest possible taxonomic level (with the exception of Copepoda  
 202 juvenile stages) using the methods described by von Flössner (1972), Koste (1978), Ejsmont-

203 Karabin et al. (2004), Rybak and Błędzki (2010), and Błędzki and Rybak (2016). Zooplankton  
 204 abundance (ind l<sup>-1</sup>) was determined with a Sedgewick-Rafter counting chamber in quantitative  
 205 analyses. Zooplankton biomass (mg l<sup>-1</sup>) was determined according to the methods proposed by  
 206 Bottrell et al. (1976) and Ejsmont-Karabin (1998). The diversity (Shannon's index,  $H'$ ), species  
 207 evenness (Pielou's index,  $J'$ ), and similarity of zooplankton communities (Jaccard's coefficient,  
 208  $P'$ ) were analyzed with the use of MVSP 3.22 software (Kovach, 2015).

209 The physical and chemical parameters of water were analyzed in a single site in the  
 210 center of each reservoir, during each sampling event. Water temperature (°C), pH, and dissolved  
 211 oxygen (DO, mg l<sup>-1</sup>) were measured with the YSI 6600 V2 Multi-Parameter Water Quality  
 212 Sonde. Water transparency (SDT, m) was measured with a Secchi Disk. In the laboratory, water  
 213 samples were analyzed for color (Hazen scale), turbidity (NTU), total nitrogen (TN, mg l<sup>-1</sup>),  
 214 total phosphorous (TP, mg l<sup>-1</sup>), total organic carbon (TOC, mg l<sup>-1</sup>), chlorophyll *a* (Chl *a*, µg l<sup>-1</sup>),  
 215 total suspended matter (Tot susp, mg l<sup>-1</sup>), and iron (Fe, mg l<sup>-1</sup>) concentrations.  
 216 Hydrochemical analyses were conducted in accordance with APHA guidelines (1999) (Table  
 217 1).

218

### 219 **2.3 Statistical and network analyses**

220 The overall differences in the physical and chemical parameters of water and zooplankton  
 221 across the analyzed thermal classes were determined by one-way ANOVA ( $f$ ,  $P \leq 0.05$ ) and  
 222 Tukey's HSD test. The Kruskal–Wallis non-parametric test ( $H$ ,  $P \leq 0.05$ ) was used to determine  
 223 differences in zooplankton biomass between thermal classes (Statistica 13.0 for Windows,  
 224 Statsoft, Tulsa).

225 The graph theory was applied to compare the parameters of the zooplankton network in  
 226 three thermal classes and to determine the significance of individual species and interspecific  
 227 interactions in these networks. The interactions between zooplankton species in three thermal

228 classes were analyzed in the Cytoscape platform (<http://www.cytoscape.org/>) with the use of  
 229 MetScape and NetworkAnalyzer applications to determine the correlations between data points.  
 230 Data were normalized by autoscaling. The correlation matrix was computed in the Correlation  
 231 Calculator 1.01 program (University of Michigan).  
 232 In graph theory, the connections (edges) between species (nodes) are examined by analyzing  
 233 the parameters of the entire network and determining the extent to which the attributes of  
 234 individual nodes and edges affect the network and centrality measures (Borgatti, 2005). An  
 235 undirected graph was created to identify all positive and negative interactions between  
 236 zooplankton species in three thermal classes. Positive interactions denoted co-occurrence  
 237 patterns or mutualistic relationships between the biomass of zooplankton taxa, whereas  
 238 negative interactions denoted predatory or competitive relationships (Kruk and Paturej, 2020;  
 239 Goździewska and Kruk, 2022). The ranges of correlation coefficient values for the edges were  
 240 set to ensure that they were significant at  $P \leq 0.05$  for sample size in each thermal class. The  
 241 edge-weighted spring embedded layout was used with correlation coefficients as weights and  
 242 weight-based heuristics. The absolute values of the correlation coefficients between nodes were  
 243 used as weights. In weighted graphs, the distance between nodes is defined as the sum of  
 244 weights (Kamada and Kawai, 1989). The zooplankton network in three thermal classes was  
 245 compared based on the key network attributes that are applied in ecological studies, including  
 246 the number of neighbors, closest path, clustering coefficient, network centralization, network  
 247 density, and network heterogeneity (Pavlopoulos et al., 2011, Kruk and Paturej, 2020;  
 248 Goździewska and Kruk, 2022). Four popular node centrality attributes were used to determine  
 249 the significance of zooplankton taxa in three thermal classes: node degree centrality (NDC)  
 250 (Pavlopoulos et al., 2011), node closeness centrality (NCC) (Newman, 2005), node betweenness  
 251 centrality (NBC) (Brandes, 2001), and the clustering coefficient (CCF). The NCC is a measure  
 252 of how fast information, defined here by significant correlations among taxa, spreads from a

given species to other one in the network (Girvan and Newman, 2002). The higher the closeness centrality, the more important the zooplankton species biomass to organizing other interactions in the biocenosis network (Scardoni et al., 2009). NBC denotes the extent to which a given taxon contributes to the network's cohesion by communicating with other clusters (subnets). The global network clustering coefficient measures the degree to which the nodes (species) in the graph tend to cluster together. Each taxon has an individual (local) clustering coefficient (CCF) which denotes the ratio of the actual number of links between a given taxon and its closest neighbors to the possible number of links in a full graph if all possible links (100%) are present in a given cluster (Watts and Strogatz, 1998).

## 3 Results

### 3.1 Environmental variables and zooplankton distribution along the thermal gradient

Significant differences in the physical parameters of water were noted between the three thermal classes. The analyzed reservoirs differed significantly ( $P < 0.05$ ) in mean annual temperature and mean winter temperature, but significant variations were also observed in DO, chlorophyll *a*, TOC, TN, and the parameters describing suspended solids (turbidity, color, SDT, Tot susp) (Table 1). Water temperature significantly influenced oxygen concentration, which was confirmed by a significant negative correlation between temperature and DO ( $r = -0.555$ ,  $P < 0.05$ ).

The temperature gradient exerted a significant effect on zooplankton species richness. Species diversity was highest in WW ( $H' = 2.31$ ;  $J' = 0.824$ ), and it was significantly lower in MW and CW ( $H' = 1.62$  and  $1.66$ ;  $J' = 0.634$  and  $0.605$ , respectively; Table 1). The zooplankton community comprised 89 taxa in WW, 74 taxa in MW, and 61 taxa in CW. Rotifera dominated in all thermal classes, accounting for 67 % (CW) to 75 % (MW) of total zooplankton species. Greater differences were noted in the taxonomic structure of Crustacea, with a predominance

278 of cladocerans in WW (15%; 6-10.5 % in the remaining groups) and a predominance of  
 279 copepods in CW (19 %; 9 % in MW, and 6.5 % in WW). All thermal classes shared 33 (26 %)  
 280 common taxa and forms, with a predominance of juvenile nauplii and copepodites (100 % CW  
 281 – 92 % WW and 100 % CW – 50 % MW, respectively), and *Keratella cochlearis* (100 % CW  
 282 – 50 % MW) (Table S1). The greatest similarities between zooplankton communities, measured  
 283 by the Jaccard index, were determined between MW and WW (47.8 %). The zooplankton  
 284 communities in CW and WW were least similar (33.9 %) (Fig. S1).

285 The temperature gradient induced significant differences in the biomass distribution of  
 286 23 (18 %) zooplankton taxa (Kruskal-Wallis test,  $P < 0.05$ ), including 15 Rotifera, 2 Cladocera,  
 287 2 Copepoda, and 4 Protozoa. Most of the remaining zooplankton taxa (77 %) were not  
 288 represented in each thermal class (Table S1). The above led to significant differences in the  
 289 mean biomass and abundance of zooplankton across thermal classes. These parameters were  
 290 determined at 28.35 mg/L (CW), 0.73 mg l<sup>-1</sup> (MW), and 0.094 mg l<sup>-1</sup> (WW), and at 3903 ind.  
 291 l<sup>-1</sup> (CW), 563 ind. l<sup>-1</sup> (MW) and 45 ind. l<sup>-1</sup> (WW), respectively (Table 1).

292

### 293 3.2 Network structure

294 The compared thermal classes differed in the key metrics describing the structure of the  
 295 zooplankton species interaction network. The CW network was characterized by the highest  
 296 cohesion expressed by clustering (0.462), centrality metrics (0.248), the shortest paths (1406),  
 297 as well as the highest average number of neighbors (6.32) per species (node), i.e. the number  
 298 of interspecific interactions (Table 2; Fig. 3). Density (0.191) and heterogeneity (0.617) were  
 299 highest in MW, which suggests that this network was most diverse (Table 2; Fig. 4). The WW  
 300 network was characterized by the lowest centrality (0.165) and density (0.095) metrics and the  
 301 lowest parameters of communication paths between taxa, i.e. the shortest total sum of paths

(1056) and the longest characteristic path length (3.42), which denote the presence of taxa communicating with the lowest number of species (Table 2; Figs. 5 and 6).

304

### 305 3.3 Interspecific interactions in zooplankton networks

Node Degree Centrality (NDC), defined as the number of direct links incident on a taxon (node), is a significant indicator of interspecific relationships. The highest NDC values (more than 10 direct links per taxon) were noted in CW (*Trichocerca pusilla*, *Pompholyx sulcata*, *K. tecta*, and copepod nauplii) and MW (*Brachionus calyciflorus*, *Keratella tecta*, *Ascomorpha ovalis*, *Synchaeta* spp., *Keratella testudo*, *Filinia longiseta*, cladoceran *Bosmina longirostris*, and protozoan *Codonella cratera*). In WW, cladoceran *Alona quadrangularis* (8), protozoan *Centropyxis aculeata* (8), and rotifer *Trichocerca intermedia* (6) (Table 3) formed the highest number of interspecific relationships.

The strongest and the most numerous interspecific relationships were formed in MW. Positive relationships with the highest values of the correlation coefficient were established between *Polyarthra longiremis* and *Trichocerca tigris* (0.961), *Bosmina longirostris* and *Ascomorpha ovalis* (0.932), and *Asplanchna priodonta* and *Keratella valga* (0.907), whereas negative relationships were formed between *Brachionus calyciflorus* and *Synchaeta* spp. (-0.821), *Brachionus calyciflorus* and *K. valga* (-0.754), and *B. longirostris* and *K. testudo* (-0.701). Under extreme conditions, both positive and negative correlations were somewhat weaker, and they were observed between *A. ovalis* and *Notholca squamula* (0.837; CW), *Brachionus angularis* and *Polyarthra vulgaris* (0.779; WW), *Brachionus calyciflorus* and *K. tecta* (-0.671; CW), and *Cephalodella* spp. and *P. vulgaris* (-0.582; WW) (Figs. 3, 4, 5; Table S2).

Node closeness centrality (NCC), which ranks nodes based on their distance to other nodes and identifies nodes whose effect rapidly spreads to most nodes in the network, decreased with a

327 rise in temperature (CW – NCC >0.5; MW– NCC >0.4; WW – NCC >0.3). The number of taxa  
 328 with the above NCC values was similar in each thermal class (8, 8, and 9, respectively), but the  
 329 species composition of these groups differed in 75-88 % (Table 3). The rotifers *Trichocerca*  
 330 *pusilla* and *Pompholyx sulcata* were characterized by the highest centrality attribute values in  
 331 CW (Fig. 3). The highest centrality attribute values were observed for *Ascomorpha ovalis* and  
 332 *Keratella testudo* in MW, and for cladoceran *Alona quadrangularis* and rotifer *Trichocerca*  
 333 *intermedia* in WW (Figs. 4, 5).

334 The taxa in the WW network played a more important role in network cohesion,  
 335 measured by node betweenness centrality (NBC), than the taxa in other thermal classes because  
 336 this attribute favors taxa that connect with sub-networks (clusters). Thus, when a network is  
 337 less cohesive and more fragmented, taxa (nodes) that communicate with other network clusters  
 338 play a more important role than the taxa within the network. The phytophilous taxa of  
 339 *Cephalodella* spp. and *Monommata maculata* were characterized by the highest values of NBC  
 340 (>0.250) in the WW network, but high betweenness centrality (>0.200) values were also noted  
 341 for *Alona quadrangularis*, *Brachionus angularis*, and *T. intermedia*. The most cohesive and  
 342 centralized network (CW) favored mostly *Trichocerca pusilla* (0.253), whereas the most  
 343 heterogeneous network (MW) favored mostly *Ascomorpha ovalis* (0.205) (Table 3).

344 The MW network was most heterogeneous, and it contained taxa with a high tendency  
 345 to form clusters. These taxa were bound by the highest number of links with neighbors (CCF  
 346 >0.9), and they represented all higher-rank groups: Rotifera (*Notholca acuminata*, *K. valga*,  
 347 *Asplanchna priodonta*), Cladocera (*Daphnia cucullata*), Copepoda (Harpacticoida), and  
 348 Protozoa (*Arcella discoides*). Taxa with the smallest number of links also formed a large cluster  
 349 (CCF <0.2) (Figs. 4, 7).

350 The CW network was most centralized, and it contained a much higher number of  
 351 interspecific links with moderate values and no links with extreme values (CCF = 0 or 1) (Fig.

352 8). The CW network was characterized by the highest CCF value and the highest cohesiveness  
 353 (Table 2; Fig. 3).

#### 354 **4 Discussion**

355 Various methodologies and research hypotheses have been proposed for investigating and  
 356 predicting changes in plankton biocenoses under the influence of rising water temperatures  
 357 (Hessen et al., 2007; Tuck and Romanuk, 2012; Ingleton and McMinn, 2012; Ejsmont-Karabin  
 358 et al., 2020). Graph theory opens new possibilities for analyzing the structure of zooplankton  
 359 networks across temperature gradients by focusing on biomass distribution as an indicator of  
 360 interspecific interactions. In ecosystem ecology, all interspecific relationships are associated  
 361 with the flow of energy (biomass), and the type and strength of these processes are largely  
 362 dependent on changes in temperature and insolation (Currie, 1991). Temperature is a physical  
 363 factor that modifies the energy of water, and the thermal gradient determines the intensity and  
 364 direction of these processes (Lampert and Sommer, 1999; Hessen et al., 2007).

365 The studied reservoirs differed mainly in winter water temperature (the difference  
 366 between CW and WW = 9.7 °C), which significantly affects the annual temperature gradient  
 367 (Fig. 2). In the coldest reservoir (CW), more energy was needed to heat water to a similar  
 368 temperature within the same period of time (winter – summer), which led to changes in the rate  
 369 of physical and chemical (element cycling) processes and biomass accumulation. As a result,  
 370 organic matter cycling was rapidly intensified due to an increase in water temperature after  
 371 winter (by 19.2 °C in CW), when heat energy was absorbed by the surface layer and distributed  
 372 to the bottom (the examined reservoirs are shallow) by convection or mechanical motion. The  
 373 above contributed to rapid phytoplankton growth. However, when the water temperature  
 374 gradient is flattened (water temperature increased by 13.1 °C in MW and 9.2 °C in WW;  
 375 therefore, less energy was generated), phytoplankton is produced at a slower rate and algal  
 376 blooms are less frequent (Wollrab et al., 2021). When the accumulated matter is continuously,

377 but less rapidly cycled in heated reservoirs (in particular in WW), surface water can be  
 378 colonized by macrophytes that effectively utilize the available nutrients (TN and TOC levels  
 379 decreased in WM and WW) and compete for food with phytoplankton (Vanderstukken et al.,  
 380 2011). These energy transformations create trophic conditions which exert the greatest  
 381 influence on species composition and function, as well as biomass and the type and strength of  
 382 interspecific interactions in zooplankton communities (Kruk et al., 2021; Goździewska and  
 383 Kruk, 2022).

384       The natural, for temperate climate, thermal regime of surface waters (CW) promoted  
 385 the development of the most cohesive zooplankton network with an equal number of strong  
 386 positive and negative interspecific relationships. These relationships (node centrality;  $NCC >$   
 387 0.5) were formed mainly by rotifers with a diverse food base, i.e. detritophagous and  
 388 bacteriophagous *Pompholyx sulcata* and *Brachionus angularis*, phytophagous *Keratella tecta*  
 389 and *K. valga* (Ejsmont-Karabin et al., 2004), as well as raptorial *Polyarthra vulgaris* and  
 390 *Trichocerca pusilla*. In the CW network, these species formed numerous ( $NDC > 10$ ) and strong  
 391 relationships with other taxa, mostly copepods. In the CW network, the above Rotifera node  
 392 species were characterized by higher biomass than in warmer classes, and these taxa could be  
 393 regarded as effective bioindicators (Ejsmont-Karabin, 2012; Goździewska et al., 2018) of  
 394 good food conditions (eutrophic) in class CW. The above observation was confirmed by the  
 395 highest values of primary productivity (Chl *a*), organic carbon (TOC), and nitrogen in CW in  
 396 comparison with the remaining thermal classes. In the CW network, total zooplankton biomass  
 397 was more than 40 and 300 higher than in MW and WW, respectively. This result differs from  
 398 the predictions based on the correlations between increasing water temperature and biomass  
 399 accumulation in the food chain (Visconti et al., 2008; Vandysh, 2009), but it confirms that  
 400 energy processes in ecosystems (their significance and effects) are related to the amplitude of  
 401 water temperature.

402           In the coldest reservoir (CW), an increase in trophic levels probably also contributed to  
403   a higher content of mineral suspensions. Suspended particles form a substrate that is readily  
404   colonized by algae, bacteria and protozoa, and they contribute to the accumulation of organic  
405   matter (greater availability of food resources) and its effective cycling (Boenigk and Novarino,  
406   2016; Goździewska et al., 2019; Goździewska and Kruk, 2022). According to Bonecker et  
407   al. (2013), the concentration of mineral suspensions is highly correlated with the concentration  
408   of chlorophyll *a* which is an important predictor of increased rotifer biomass and copepod  
409   diversity in lotic ecosystems. The results of the present study confirm the above observation  
410   because copepods were represented by diverse species characteristic of astatic habitats and  
411   small water bodies (*Microcyclops varicans*, *Cryptocyclops bicolor*), eurytopic species (*Cyclops*  
412   *vicinus*, *C. strenuus*, *Thermocyclops crassus*) as well as benthic Harpacticoida (Błędzki and  
413   Rybak, 2016). These species were characterized by low values of centrality attributes in CW,  
414   but they contributed to the formation of valuable antagonistic (predator-prey) relationships.  
415   According to Currie (1991) and Schmitz and Trussell (2016), predatory behavior is crucial for  
416   maintaining high interspecific cohesion because it prevents competitive exclusion and loss of  
417   biodiversity.

418           The abundance and diversity of food resources in CW were responsible not only for the  
419   strength, but also for the closeness of interspecific relationships which was expressed by the  
420   highest number of the shortest communication paths between taxa. A similar dependency  
421   between high primary production (organic matter), high total zooplankton biomass, short path  
422   length, and high network cohesion was reported by Goździewska and Kruk (2022) in a study  
423   of environmental gradients (turbidity). Kruk et al. (2021) also found that network cohesion and  
424   the strength of interspecific interactions increased with a rise in salinity which was correlated  
425   with trophic levels in coastal lakes.

426 In the present study, an increase in water temperature led to changes in the species  
 427 composition of zooplankton communities, including that with the highest centrality attribute  
 428 values, and similar observations were made by Richardson (2008), Arlic et al. (2013), and  
 429 Carter et al. (2017). Similarly to CW, Rotifera made the greatest contribution to network  
 430 centrality also in warmer reservoirs (MW and MM), but their ecological and functional structure  
 431 was clearly modified. Only a few studies have investigated Rotifers' responses to changes in  
 432 water temperature, pointing to their lower sensitivity, i.e. tolerance of a wider range of  
 433 temperatures (Bērziņš and Pejler, 1989), and a correlation between their lower reactivity vs.  
 434 lower biomass and lower activity, compared with crustaceans (Xu et al., 2008). Most rotifers  
 435 are eurythermal species, therefore the results of studies analyzing species-specific responses,  
 436 such as migration patterns in vertical temperature and food gradients in deep lakes (Obertegger  
 437 and Flaim, 2018; Goździewska et al., 2021), cannot be used to formulate far-reaching  
 438 conclusions about global changes in the environment. According to Obertegger and Flaim  
 439 (2018), changes in water temperature affect the structure of the relationships between rotifer  
 440 species that are based on feeding and predation, which is consistent with the present findings.

441 In the MW network, raptorial rotifers (*Ascomorpha ovalis* and *Synchaeta* spp.), rotifers  
 442 grazing on selected algae (*Keratella testudo*, *K. quadrata* and *Brachionus calyciflorus*), and  
 443 predatory rotifers (*Asplanchna priodonta*) were characterized by the highest values of network  
 444 centrality attributes (Moreira et al. 2016; Obertegger and Flaim 2018). At the same time, these  
 445 species established the highest number of strong positive and antagonistic relationships,  
 446 predominantly with the cladoceran *Bosmina longirostris*. These observations point to lower  
 447 trophic levels in MW (resulting from the energy transfer described above), including lower  
 448 phytoplankton production and lower food availability (Goździewska et al. 2018). In a study  
 449 by Goździewska et al. (2018), the chemical parameters of sediments in reservoir PN  
 450 (represented by class MW in the present study), resulted phosphorus concentration decrease in

451 water. Lower phosphorus levels inhibited the development of more demanding phytoplankton  
 452 groups and led to the dominance of diatoms, including large *Pennales* species. Due to the  
 453 specificity of the available food resources, only consumer species with functionally specialized  
 454 roles (*Notholca* spp., *A. ovalis*, *K. testudo*) and species relying on other food resources, such as  
 455 animal protein (*A. priodonta*), were able to maintain high biomass (May, 1980; Ejsmont-  
 456 Karabin et al., 2004). The MW network was highly fragmented (divided into sub-networks), as  
 457 demonstrated by the highest values of opposing attributes – density and heterogeneity (i.e. the  
 458 tendency to form concentrating nodes - clusters). Loosening of the network structure, i.e. a  
 459 decrease in the values of centrality attributes, increased the significance and number of taxa  
 460 communicating with two sub-networks (NBC; Table 3, Fig. 4). The heterogeneity of the MW  
 461 network was manifested by high fragmentation and the formation of large groups with the  
 462 highest and lowest number of interspecific relationships (Fig. 7). The largest clusters (CCF ~  
 463 1) with many positive and negative relationships contained effective filter feeders, including  
 464 cladoceran *Bosmina longirostris* and *Daphnia cucullata*, predatory benthic copepods of the  
 465 order Harpacticoida, phytophilous rotifers *K. valga* and *Notholca acuminata*, and protozoan  
 466 *Arcella discoides*. These observations point to the dynamic character of zooplankton  
 467 communities in MW, which can be attributed to their taxonomic and functional diversity  
 468 (feeding strategy, habitat ecology). Taxa with high CCF values (>0.5) played a crucial role  
 469 because they formed numerous antagonistic relationships (correlation coefficient > -0.5; Table  
 470 S2) which were important for maintaining this rich, but unstable (due to a very weak second  
 471 sub-network) network structure (Schmitz and Trussell 2016).

472 Warm winters and small differences in water temperature between seasons significantly  
 473 affected the rate of physical (decrease in saturation) and biochemical processes  
 474 (accumulation/immobilization of organic matter in macrophyte tissues) and decreased  
 475 phytoplankton production in the warmest reservoir (WW). The above weakened interspecific

476 interactions, including negative relationships, and compromised the cohesiveness of the  
 477 zooplankton network relative to colder reservoirs (CW and MW). Network attributes (NCC and  
 478 NBC) were determined by phytophilous and psammophilous rotifers *Cephadella* spp.,  
 479 *Monommata maculata*, and *Trichocerca intermedia* (Ejsmont-Karabin et al., 2004), littoral  
 480 cladocerans *Alona* spp., small eurytopic *Chydorus sphaericus* and *Bosmina longirostris*  
 481 (Błędzki and Rybak, 2016), and protozoa. Therefore, zooplankton species characterized by  
 482 smaller size, lower weight and lower nutritional requirements contributed to an increase in  
 483 biomass. Ejsmont-Karabin et al. (2020) also reported a positive correlation between  
 484 psammophilous-epiphytic Rotifera and an increased and stable water temperature in heated  
 485 lakes. Other authors observed that the growth of small crustacean species was accelerated by  
 486 an increase in water temperature (Daufresne et al. 2009, Gutierrez 2016, Evans et al. 2020,  
 487 Zhou 2020). In the present study, zooplankton growth was also promoted by the development  
 488 of macrophytes which colonized a large part of reservoir WW and created a supportive  
 489 habitat/refugium for the diverse group of Cladocera.

490 Small littoral cladocerans *Alona* spp. were characterized by the highest values of NCC  
 491 and NBC (Figs. 5, 6), and were responsible for the highest number of individual links (NDC),  
 492 mostly negative competitive interactions (Table S2). According to Martín González et al.  
 493 (2010), species with high NCC and NBC values play a special role in zooplankton networks  
 494 because network structure disintegrates more rapidly when these species are selectively  
 495 eliminated. The ratio of positive to antagonistic relationships also plays an important role  
 496 (Schmitz and Trussell 2016), and this parameter was not optimal in the WW network. Despite  
 497 the above, the WW network was characterized by the co-existence of the highest number of  
 498 rotifer and cladoceran taxa, as well as the highest taxonomic diversity of zooplankton relative  
 499 to colder reservoirs. Macrophyte habitats probably played an important role in this process.

500 Macrophytes promote microbial carbon cycling and increase the bioavailability of carbon for  
 501 small zooplankton species when phytoplankton resources are scarce (Bowszys et al. 2020).

502 In warmer reservoirs, a decrease in copepod biomass was followed by the disappearance  
 503 of most taxa noted in CW. Smaller differences in temperature and low food availability in warm  
 504 reservoirs induced long-term disruptions in Copepoda phenology. The absence of clear seasonal  
 505 fluctuations in the temperature of warmer reservoirs could have disrupted the life cycle of  
 506 copepods (no diapause), which decreased the body size and biomass of adult individuals  
 507 (Adrian et al. 2006; Costello et al. 2006; Rybak and Błędzki 2010). According to Santer and  
 508 Hansen (2006), when algal food resources are scarce, Copepoda can skip diapause and develop  
 509 directly into adults. This observation was validated by the present study where a decrease in  
 510 copepod biomass weakened the WW network because Copepoda play an important role in  
 511 predatory interspecific relationships.

## 512 **5 Conclusions**

513 The network graph analysis enabled a comprehensive visualization of the changes in plankton  
 514 communities induced by a rise in the temperature of surface water reservoirs. The applied  
 515 method elucidated the position and role of taxa in the biocenotic network and the ecological  
 516 mechanisms that are usually difficult to identify and interpret with the application of  
 517 conventional structural and multidimensional analyses, especially in *in situ* studies.

518 In the natural thermal regime (cold winters), the network of interspecific interactions  
 519 was characterized by the highest cohesion and the highest centrality attributes of taxa utilizing  
 520 shared and abundant food resources. The network featured an equal number of positive and  
 521 negative relationships that were controlled by eutrophic rotifers, with very high values of  
 522 centrality attributes ( $NCC > 0.5$ ). An increase in water temperature in winter and the flattening  
 523 of the annual temperature gradient decreased primary production and affected the availability  
 524 of food resources for zooplankton. The values of centrality attributes decreased, which led to

525 the disintegration of MW and WW networks into clusters (sub-networks). In MW, diverse  
 526 ecological and functional groups of rotifers (raptorials, phytophiles and predators) made the  
 527 greatest contribution to the network's cohesion and interspecific communication. In the  
 528 warmest environment (WW) colonized by macrophytes, small littoral cladocerans and small  
 529 psammophilous-epiphytic rotifers formed a network with the lowest values of centrality  
 530 attributes. Warm winters disrupted the phenology of Copepoda and diminished their importance  
 531 in the biocenosis, leading to a decrease in their biomass and in the number of antagonistic  
 532 relationships responsible for the network's functionality.

## 808 **Acknowledgements**

809 Project financially supported by Minister of Education and Science the range of the program  
 810 entitled “Regional Initiative of Excellence” for years 2019–2022, project No. 010/RID/2018/19,  
 811 amount funding 12.000.000 PLN. This research was substantially funded by the PGE  
 812 Gornictwo i Enegetyka Konwencyjna SA Oddział KWB Bełchatow (agreement No.  
 813 LPU/1225/2011) and University of Warmia and Mazury in Olsztyn (18.610.010-110).

## 814 **Author contributions**

815  
 816 A.M.G. designed the research, conducted fieldwork, analyzed the zooplankton samples and  
 817 water samples, planned and wrote the main manuscript text and prepared Figs. 1, 2 and S1.  
 818 M.K. prepared network graph analysis of zooplankton structure, interpreted results and  
 819 prepared Figs. 3 - 8.

## 821 **Competing interests**

822 The authors declare that they have no conflict of interest.

823

825 **Figure 1.** Location of the study area. Abbreviations: O-MB – opencast mine in Bełchatów, O-  
 826 MS – opencast mine in Szczerców; reservoir CH1 represents CW class, reservoir PN represents  
 827 MW class; reservoir WI represents the WW class. Modified, see Goździewska and Kruk  
 828 (2022).

829 **Figure 2.** Mean monthly water temperature in the analyzed thermal classes in 2014-2016.

830 **Figure 3.** Network graph analysis of the interactions between zooplankton species in the CW  
 831 network with an analysis of node closeness centrality (NCC), node betweenness centrality  
 832 (NBC), and edge betweenness centrality (EBC) values. Node size is proportional to the NCC  
 833 measure, node color on the blue (dark) – orange (bright) color scale is proportional to the NBC  
 834 measure, and edge thickness is proportional to the EBC measure. Sign of the relationship: bright  
 835 orange edges denote positive relationships between nodes, whereas dark blue edges denote  
 836 negative relationships.

837 **Figure 4.** Network graph analysis of the interactions between the zooplankton species in the  
 838 MW network with an analysis of node closeness centrality (NCC), node betweenness centrality  
 839 (NBC), and edge betweenness centrality (EBC) values. Refer to the legend and explanations in  
 840 Fig. 3 (CW).

841 **Figure 5.** Network graph analysis of the interactions between the zooplankton species in the  
 842 WW network with an analysis of node closeness centrality (NCC), node betweenness centrality  
 843 (NBC) and edge betweenness centrality (EBC) values. Refer to the legend and explanations in  
 844 Fig. 3 (CW).

845 **Figure 6.** Clustering coefficient distribution in the WW zooplankton network. Node size is  
 846 proportional to the Clustering coefficient measure in the range 0 – 1, showed by arrows. For  
 847 node and edges color explanations see the legend in Fig. 3.

848 **Figure 7.** Clustering coefficient distribution in the MW zooplankton network. Node size is  
 849 proportional to the Clustering coefficient measure in the range 0 – 1, showed by arrows. For  
 850 node and edges color explanations see the legend in Fig. 3.

851 **Figure 8.** Clustering coefficient distribution in the CW zooplankton network. Node size is  
 852 proportional to the Clustering coefficient measure in the range 0 – 1, showed by arrows. For  
 853 node and edges color explanations see the legend in Fig. 3.

## TABLES

Table 1 Water quality and zooplankton parameters across the studied thermal classes (mean  $\pm$  SD). Abbreviations: DO – dissolved oxygen, Chl *a* – chlorophyll *a*, TOC – total organic carbon, TP – total phosphorus, TN – total nitrogen, SDT – Secchi depth transparency, Tot susp – total suspended solids, Fe – iron. Differences in the analyzed parameters were determined by ANOVA ( $P \leq 0.05$ ); values with different superscripts differ significantly across reservoirs in Tukey's HSD test.

	CW		MW		WW		ANOVA <i>P</i>
