

Dear Prof. Lu,

Attached are our responses to the Anonymous Referees, along with a copy of the new manuscript with changes tracked. We have listed the referee comments in blue for easier comparison.

Please let us know if we can do anything else to assist during the review process.

Thank you,
Anthony, Max, Rihui, Lili, and Zhu

Response to Anonymous Referee #1:

In this paper, the authors extensively tested the multifidelity Monte Carlo (MFMC) method for accurately catching some quantities of interest in climate-related modeling. Compared to the widely used Monte Carlo (MC) method, they demonstrated that MFMC has superior properties over MC on this subject via three benchmark problems in the ocean, atmosphere, and ice sheet modeling. Since uncertainties exist almost everywhere in climate modeling and prediction, I think MFMC would greatly impact this area, especially in reducing the number of costly large-scale simulations in very fine resolutions. Hence, I would highly recommend the publication of this manuscript in GMD after the authors address the following minor issues.

Thank you for your helpful comments and for your interest in our work. Below are responses to your specific comments

- 1. In line 67 on page 3, the statement is somehow confusing. The authors declare that they don't consider any possible alternate sampling schemes at the beginning. But their goal is to use a nontraditional MC sampling strategy. Doesn't the sampling strategy belong to the "alternate sampling schemes"?*

By “alternate sampling strategies” we mean that a user might be using (or may want to use) some other sampling scheme besides traditional MC for the truth model, e.g., Latin hypercube sampling, quasi-MC sampling, or sparse grid sampling, as doing so often results in lower costs for a given accuracy tolerance. Therefore, the choice of sampling scheme is determined by how we want to sample the truth model and its surrogates. While we use MC sampling in this work, other choices are possible and would produce analogues to the MFMC method, e.g., MFLH, MFQMC, or MFSG.

- 2. In Algorithm A, it mentions that F^k is removed from the list of surrogates if the second requirement is not satisfied. Will there be such a case all F^k will be removed from the estimation? Secondly, will it obtain less accuracy compared to the MC method with all F^k included?*

Note that all F^k will never be removed according to our criterion; in the most extreme case, at least the high-fidelity model F^1 will remain. On the other hand, if this occurs, we obtain the useful information that none of the surrogates F^2, \dots, F^k are effective at increasing estimation accuracy or reducing computational costs, i.e., we are stuck using MC on its own and should look for other, more informative, surrogates. To address the other question, there should never be a loss of accuracy relative to MC regardless of the model set. The worst-case scenario is if all the surrogates fail the second test, in which case we are left with traditional MC using F^1 . Hence, there is no loss of accuracy

in MFMC; its worst-case accuracy is simply equal to that of MC using the truth model. However, if at least one surrogate survives the second test, then the MFMC method guarantees that costs are reduced without compromising accuracy.

3. For Figures 3 and 6, it is better to point out that the blue shading is the standard deviation of the MC prediction and the melon for MFMC. Moreover, being included in the blue shading indicates a smaller standard deviation.

We agree that it is a good idea to mention this explicitly. Any future versions of the manuscript will include this change.

This change has been reflected in the new manuscript in the captions of Figures 3 and 6.

Response to Anonymous Referee #2:

The authors describe a "multi-fidelity" Monte Carlo method for expected value estimation that is shown to improve convergence/efficiency compared to traditional Monte Carlo methods. This multi-fidelity approach is different to existing techniques in that expected values are computed using simulations run at differing resolutions and/or incorporating various levels of dynamical approximation. The test cases presented here employ hierarchies of progressively coarsened meshes to provide low-cost estimators, as well as an interpolation-based approach. The authors present results for two shallow-water benchmarks and one ice-sheet test-case, and demonstrate significant speed-ups compared to the traditional MC scheme for various maximum-value estimation problems. The speed-ups demonstrated for the MFMC method are very attractive, especially in the context of climate-model estimators which are often extremely expensive to obtain. There are a number of questions I have relating MFMC performance to problem nonlinearity though, in addition to various minor corrections.

Thank you for your helpful comments and for your interest in our work. Below are responses to your specific comments.

- The three test-cases analysed appear to involve estimators evaluated after relatively short integration periods, and, rather than fully nonlinear flows/dynamics, the response of the system may be relatively linear over these short horizons as a result --- is this expected to influence the effectiveness of the MFMC results presented? For example, TC5 from Williamson does not become strongly nonlinear until approx. 20-days, with 50-days being the typical analysis window at which turbulence is fully developed. The SOMA case described in Wolfram (2015) is typically spun-up over several years, and then analysed over 30-day windows. In this work, it appears the TC5 case is analysed after 10 days, and the barotropic-gyre-version-of-SOMA after 3-days (restarted from a 15-day spin-up). Are the MFMC results robust when the duration/nonlinearity of the test-cases is increased?

Based on our experience with prior work on MC-based estimation, we do not expect the linearity (or lack thereof) of the model solution to affect the performance of the MFMC estimation procedure.

- Is it possible to estimate the relative "multi-fidelity" contributions to the accuracy of the MFMC estimator? For example, is the overall accuracy governed more by the small number of high resolution runs, the large number of low resolution runs, or something in-between? Considering the more linear (or at least non-turbulent) nature of solutions studied, how would a conventional MC estimator compare if run only using lower-resolution simulations? In other words, is the good performance of the MFMC method due to the solution being well-resolved even on the coarser meshes, or is the multi-resolution hierarchy effective in

estimating behaviour resolvable only at high-resolution? If it is the former, I wonder whether the problems studied are sufficiently nonlinear at the grid-scale. If it is the latter, this may be a nice result to highlight further.

A goal of MFMC estimation is to achieve (using very few samples of the high-fidelity mode) the same accuracy as obtained by an MC estimator (that exclusively uses many samples of that model). Certainly, at least one high-fidelity model evaluation is necessary to eliminate bias in the MFMC estimator. Moreover, we find practically that the high-fidelity samples used to “steer” this estimator in an accurate direction, while the low-fidelity samples are used to shrink its variance around the true solution. Note that the dynamics of the example systems are not particularly well resolved by the low-fidelity models relative to the high-fidelity ones; particularly in the case of the barotropic gyre (SOMA) case, there is a noticeable visual difference between the 32km solution and the 8km solution.

- I believe the gradient terms in the shallow-water system (12) should be $\text{grad}(1/2|u|^2) + g*\text{grad}(h + h_b)$ rather than the $\text{grad}(\rho)$ included currently. Here $p = \rho_0*g*h$ is used to simplify the linear $1/\rho_0 * \text{grad}(p)$ shallow-water pressure gradient, consistent with e.g. Ringler et al (2010).*

This has now been corrected. Thank you for your attention.

This change is reflected in equation (12) in the new manuscript.

- The SWE runtimes noted in 3.1.1 and 3.2.1 appear to be quite slow --- requiring 100's of seconds to advance a single time-step using relatively small $O(\leq 100,000)$ cell meshes? Are these runtimes for the full multi-day simulations instead, or for all ensemble members perhaps?

These were the wall-clock times observed when the relevant system was implemented in MATLAB and run on a 2015 MacBook laptop. Therefore, neither the implementation nor the hardware was optimized for computational efficiency.

- While the MFMC methods presented here are clearly different in that they leverage varying resolution simulations, is it fair to compare against only the "historical" MC method, which is known to be uncompetitive in terms of efficiency? Significant work on alternative MC methods has been conducted by various authors in which a variety of accelerated techniques have been proposed. Are the large gains reported for MFMC expected to be replicated compared to e.g. MCMC (Markov Chain Monte Carlo) approaches more frequently used in climate model estimation?

A primary benefit of MFMC over other modern estimation methods such as MCMC is its ability to leverage low-fidelity information to effect cost-savings without sacrificing estimator accuracy. In our experience with MFMC in other settings, this benefit translates to much larger cost savings for a given accuracy tolerance when compared to MCMC as well as other MC-related sampling schemes (e.g., variance reduction MC, importance sampling).

Minor comments:

- The SOMA test case (Simulating Ocean Mesoscale Activity) typically refers to simulations using the multi-layer primitive equations, in which mesoscale eddies form due to 3d interactions between the momentum, density and forcing tendencies. In this shallow-water configuration with $\rho = \text{const.}$, it appears to be a wind-driven barotropic gyre that's studied instead, which is typically less turbulent, as per the smooth flow features in fig. 2. If so, it's suggested to label this test case as a wind-driven gyre.

We agree with this reasoning and have changed the name globally throughout the manuscript.

This change is reflected throughout Section 3.1 in the new manuscript.

- Wallis (2012) reference appears to be missing.

This has been fixed, thank you for your attention.

This change is reflected in lines 185, 200-205, and 554 in the new manuscript.

*- In 76: Is saying "no guesswork involved" too strong a statement? The systematic nature of the MFMC approach is attractive, but is it **the** provably optimal sampling strategy, or more of an effective heuristic?*

It can be shown that the MFMC method presented here is the provably optimal solution (up to rounding) to a particular constrained optimization problem (see Gruber et al 2022, "A multifidelity Monte Carlo method for realistic computational budgets", for a formal statement). Therefore, we do not think it is a stretch to say there is "no guesswork involved" in this context.

- In 72: ...also uses cheaper to obtain...

- fig. 3 labelling: left-right vs top-bottom.

These have been fixed, thank you for your attention.

These changes are reflected in (resp.) line 73 and the caption to Figure 3.

- In 308: Is this an expression for the free surface height or the layer thickness --- h appears to be thickness in the shallow-water system (12).

This is an expression for the fluid thickness. We have clarified this globally throughout the manuscript.

This change is reflected in Sections 3.1 and 3.2 of the new manuscript.

- The Gruber (2022) paper referenced here appears to be an arXiv preprint, that in-turn references this GMD submission??

This is true. The referenced preprint (to appear in J. Sci. Comput.) establishes the particular MFMC algorithm which has been applied to climate-related examples in this paper. Therefore, we refer interested readers to that manuscript for a more detailed description of the MFMC method. Conversely, we write in that preprint that "Forthcoming work will investigate applications of the present MFMC method to complex systems governed by partial differential equations, particularly in the context of climate modeling.", and provide an empty citation with title and relevant authors. The mentioned work has since become this GMD submission.

Since this has caused confusion, we intend to remove the offending citation from the J. Sci. Comput. paper during the proofing stage.

Multifidelity Monte Carlo Estimation for Efficient Uncertainty Quantification in Climate-Related Modeling

Abstract. Uncertainties in an output of interest that depends on the solution of a complex system (e.g., of partial differential equations with random inputs) are often, if not nearly ubiquitously, determined in practice using Monte Carlo (MC) estimation. While simple to implement, MC estimation fails to provide reliable information about statistical quantities (such as the expected value of the output of interest) in application settings such as climate modeling for which obtaining a single realization of the output of interest is a costly endeavor. Specifically, the dilemma encountered is that many samples of the output of interest have to be collected in order to obtain an MC estimator having sufficient accuracy; so many, in fact, that the available computational budget is not large enough to effect the number of samples needed. To circumvent this dilemma, we consider using multifidelity Monte Carlo (MFMC) estimation which leverages the use of less costly and less accurate surrogate models (such as coarser grids, reduced-order models, simplified physics, interpolants, etc.) to achieve, for the same computational budget, higher accuracy compared to that obtained by an MC estimator or, looking at it another way, an MFMC estimator obtains the same accuracy as the MC estimator at lower computational cost. The key to the efficacy of MFMC estimation is the fact that most of the required computational budget is loaded onto the less costly surrogate models, so that very few samples are taken of the more expensive model of interest. We first provide a more detailed discussion about the need to consider an alternate to MC estimation for uncertainty quantification. Subsequently, we present a review, in an abstract setting, of the MFMC approach along with its application to three climate-related benchmark problems as a proof-of-concept exercise.

1 Introduction

In many application settings — climate modeling being a prominent one — large computational costs are incurred when solutions to a given model are approximated to within an acceptable accuracy tolerance. In fact, this cost can be prohibitively large when one has to obtain the results of multiple simulations, as is the case for, e.g., uncertainty quantification, control and optimization, to name a few. Thus, there is often a need for compromise between the accuracy of simulation algorithms and the number of simulations needed to obtain, say, in the uncertainty quantification setting, accurate statistical information.

For example, consider the following case which represents the focus of this paper. Suppose one has a complex system, say, a system of discretized partial differential equations, for which the input data depends on a vector of randomly distributed parameters \mathbf{z} . Letting $\mathbf{u}(\mathbf{z})$ denote the solution of the discretized partial differential equations, we define an output of interest

25 $F(\mathbf{u}(\mathbf{z})) = F(\mathbf{z})$ that depends on $\mathbf{u}(\mathbf{z})$ so that, of course, it also depends on the choice of \mathbf{z} . Next, suppose we wish to use Monte Carlo sampling to estimate the expected value $Q = \mathbb{E}[F(\mathbf{z})]$ of the output of interest $F(\mathbf{z})$, i.e., we have the Monte Carlo estimator of Q given by

$$Q^{MC} = \frac{1}{M} \sum_{m=1}^M F(\mathbf{z}_m) = \frac{1}{M} \sum_{m=1}^M F(\mathbf{u}(\mathbf{z}_m)) \approx \mathbb{E}[F(\mathbf{z})] = Q, \quad (1)$$

where $\{\mathbf{z}_m\}_{m=1}^M$ denotes a set of M independent and identically distributed samples of the random vector \mathbf{z} . This is a common task in uncertainty quantification which provides useful statistical information in both predictive and inferential applications.

On the other hand, Monte Carlo estimation is not without its drawbacks. Consider the following scenario. Let $\delta < 1$ denote a measure of the spatial grid size used to discretize the PDE system in question, and suppose that δ is normalized by the diameter of the domain in which that system is posed. Then, we have that the error in the approximate solution is of $\mathcal{O}(\delta^{\nu_d})$ for some $\nu_d > 0$ and that the cost (e.g., measured in seconds, or days, or weeks) of a simulation which obtains the approximate solution is of $\mathcal{O}(\delta^{-\nu_c})$ for some $\nu_c > 0$. Neglecting any additional costs connected with the evaluation of $F(\mathbf{z}) = F(\mathbf{u}(\mathbf{z}))$ (for any given \mathbf{z}) once $\mathbf{u}(\mathbf{z})$ is obtained, it is clear that the cost C incurred when obtaining the Monte Carlo estimator Q^{MC} is of $\mathcal{O}(M\delta^{-\nu_c})$. Of course, it is well known that the accuracy of a Monte Carlo estimator is of $\mathcal{O}(1/\sqrt{M})$ so that in order for the accuracy of the estimator to be commensurate with the discretization error, we must have that $1/\sqrt{M} \propto \mathcal{O}(\delta^{\nu_d})$. Therefore, the needed number of samples is proportional to $M \propto \delta^{-2\nu_d}$, and the total cost CM incurred when determining the Monte Carlo estimator Q^{MC} is of $\mathcal{O}(\delta^{-2\nu_d-\nu_c})$.

The cost CM can quickly get out of control when dealing with large-scale problems. For example, suppose that the approximate solution of the PDE system is second-order accurate, i.e., $\nu_d = 2$, and that a single simulation incurs a cost of $\mathcal{O}(\delta^{-3})$ (i.e., $\nu_c = 3$) which is the best-case scenario in three dimensions. We then have that the number of samples needed is $M \propto \delta^{-4}$ and the total cost $CM \propto \delta^{-7}$. Thus, with even a modest grid size of $\delta = 0.01$ we have that number of samples needed $M \propto 10^8$ and the total cost $CM \propto 10^{14}$, which is too high for practical use. Turning things around, suppose instead that the available computational budget allows for at most ten thousand simulations, i.e., $M = 10^4$, so that the resulting accuracy of the Monte Carlo simulator is of $\mathcal{O}(10^{-2})$. Here, the estimator error and approximation error are already commensurate when $\delta = 0.1$, making the choice of a smaller delta redundant if not infeasible. In fact, in this case there is no way to achieve the four digits of accuracy sought by choosing $\delta = 0.01$, since the best we can do with the available budget is on the order of $\mathcal{O}(10^{-2})$. Note that the situation becomes even worse when the PDE system in question is time dependent, as a single simulation incurs an even larger cost when one accounts for the number of time steps used in the simulation.

Given that the cost of MC estimation is at times prohibitively expensive, it comes as no surprise that many alternatives or run-arounds to such estimation have been proposed. One approach in this direction has led to the development of many different random parameter sampling schemes, e.g., quasi-Monte Carlo sampling, sparse-grid sampling, importance sampling, Latin hypercube sampling, lattice sampling, compressed sensing, to name just a few, for which the estimation error is guaranteed to be smaller than its Monte Carlo equivalent; see, e.g., Addcock et. al. (2022); Evans and Swartz (2000); Gunzburger et. al. (2014); Nierderreiter (1992); Sloan (1994); Smith (2013). On the other hand, some of these alternate approaches require

smoothness of solutions to achieve better accuracy. Furthermore, most, if not all, of these methods are superior to Monte Carlo sampling only for moderate dimension of the parameter vector \mathbf{z} ; see the references just cited.

60 A second approach towards reducing the cost of Monte Carlo (and for that matter for any type of) uncertainty estimation is to use approximate solutions of the PDE system that are less costly to obtain compared to the cost of obtaining the approximation of actual interest. For example, using simulations obtained using coarser grids or using reduced-order models such as reduced-basis or proper orthogonal decomposition methods are less costly as are interpolation and support vector machine approximations; see, e.g., Cristianini and Shawe-Taylor (2000); Fritzen and Ryckelynck (2019); Keiper et. al. (2018); Quarteroni and Rozza (2014); Quarteroni et. al. (2016); Steinwart and Christmann (2008). However, such approaches, by definition, result in less accurate approximations compared to the accuracy that one wants to achieve.

In this paper we do not consider any of the possible alternate sampling schemes nor do we exclusively consider using less costly and less accurate approximate solutions of the PDE system. Instead, because of the near ubiquity of its use in practice, *our goal is to outperform traditional Monte Carlo estimation by using a nontraditional Monte Carlo sampling strategy and*
70 *in so doing refrain from incurring any loss of accuracy.* To meet this goal, we invoke *multifidelity Monte Carlo estimation* which, *in addition to the expensive and accurate PDE system approximation of interest* (hereafter referred to as the “truth” approximation) *also uses ~~cheaper-to-obtain~~ cheaper-to-obtain and less accurate approximations* (which are referred to as the “surrogates”). The bottom line is that multifidelity Monte Carlo estimation meets our goal by leveraging increased sampling of the less accurate/less costly approximations alongside low sampling of the more expensive/more accurate truth approximation.
75 The multifidelity Monte Carlo algorithm systematically determines the number of samples taken from each surrogate (i.e., there is no guess work involved) and systematically (i.e., again no guess work involved) combines the samples of the surrogates to obtain the desired estimator. We note that multifidelity Monte Carlo estimation has already been shown to outperform Monte Carlo estimation in a variety of application settings; see, e.g., Clare et. al. (2022); Dimarco et. al. (2022); Konrad (2019); Law et. al. (2022); Modderman (2021); Quick et. al. (2019); Rezaeiravesh et. al. (2020); Romer et. al. (2020); Valero et. al. (2022)
80 for some examples.

In Section 2, we review how the Monte Carlo and multifidelity Monte Carlo estimators are constructed in an abstract setting; here we follow the expositions in Peherstorfer et. al. (2016) and also in Gruber et. al. (2022). Then, in Sections 3 and 4 we demonstrate the effectiveness of multifidelity Monte Carlo estimation using three well-known climate-related benchmarks. Sections 3.1 and 3.2 are respectively devoted to single layer shallow-water equations ~~model for~~ models based on the SOMA
85 Test Case of Wolfram et. al. (2015) and Test Case 5 of Williamson et. al. (1992). Section 4 is devoted to a benchmark case for the first-order model for ice sheets; see Blatter (1995); Pattyn (2003); Perego et. al. (2012); Tezaur et. al. (2015). We close by providing some concluding remarks in Section 5.

2 Monte Carlo and multifidelity Monte Carlo estimators

An abstraction of the specific settings considered in Sections 3 and 4 involves first

90 – having in hand a (*discretized*) *partial differential equation* (PDE) system for which the solution $\mathbf{u}(\mathbf{z})$ depends on a random vector of parameters $\mathbf{z} \in \Gamma$, where Γ denotes a parameter domain.

Note that the input data to this PDE system, e.g., forcing terms, initial conditions, coefficients, etc., could depend on one or more of the components of the random vector \mathbf{z} . Moreover,

– we are interested in situations such that, *for any* $\mathbf{z} \in \Gamma$, *obtaining* $\mathbf{u}(\mathbf{z})$ *is a costly endeavor*.

95 In addition,

– we define a scalar *output of interest* (OoI) $F^1(\mathbf{z}) = F^1(\mathbf{u}(\mathbf{z}))$ that depends on the solution $\mathbf{u}(\mathbf{z})$ of the (discretized) PDE system; of course, if obtaining $\mathbf{u}(\mathbf{z})$ is costly, then so is obtaining $F^1(\mathbf{z})$.

While they are not considered in this work, vector-valued outputs of interest can also be treated with multifidelity Monte Carlo techniques. OoIs could be, e.g., averages or extremal values of the energy, etc., associated with the solution $\mathbf{u}(\mathbf{z})$.

100 Having defined an OoI $F^1(\mathbf{z})$,

– we let $Q_1 = \mathbb{E}[F^1]$ denote the *quantity of interest* (QoI) corresponding to the $F^1(\mathbf{z})$,

where $\mathbb{E}[\cdot]$ denotes the expected value with respect to \mathbf{z} . Because the estimation of $Q_1 = \mathbb{E}[F^1]$ is the central goal of this paper,

– we refer to $F^1(\mathbf{z})$ as the “*truth*” *output of interest*.

105 Commonly, even ubiquitously,

– a Monte Carlo (MC) sampling method is used to (approximately) quantify the uncertainty in the chosen OoI $F^1(\mathbf{z})$.

Specifically,

– MC sampling is used to estimate the quantity of interest $Q_1 = \mathbb{E}[F^1]$ corresponding to $F^1(\mathbf{z})$,

i.e., we have that

110 – the MC estimator of the QoI $Q_1 = \mathbb{E}[F^1]$ is given by

$$Q_1^{MC} = \frac{1}{M_1} \sum_{m=1}^{M_1} F^1(\mathbf{z}_m) \approx Q_1 = \mathbb{E}[F^1], \quad (2)$$

where $\{\mathbf{z}_m\}_{m=1}^{M_1}$ denotes a set of M_1 randomly selected points in the parameter domain Γ .

We are then faced with the following dilemma: on the one hand,

– obtaining an acceptably accurate MC estimator Q_1^{MC} of the QoI Q_1 requires obtaining the solution $\mathbf{u}(\mathbf{z})$ of the discretized

115 PDE system at many randomly selected points $\mathbf{z} \in \Gamma$,

and, on the other hand,

– each of those approximate solutions $\mathbf{u}(\mathbf{z})$ are computationally costly to obtain.

Quantifying uncertainties in climate system settings are victimized by this two-headed dilemma to the extent that, e.g., accurate long-time integrations can often not be realized in practice.

120 Due to the issue of prohibitive computational cost, we turn to *multifidelity Monte Carlo* (MFMC) methods for uncertainty quantification. MFMC methods leverage the availability of surrogate outputs of interest $F^k(\mathbf{z})$, $k = 2, \dots, K$, which have smaller computational complexity compared to that of the truth OoI $F^1(\mathbf{z})$. As mentioned in Section 1, there are many types

of surrogates that can be used for this purpose, e.g., discretized PDEs with coarser spatial grids and larger time steps, reduced-basis and proper orthogonal decomposition-based reduced-order models, and interpolants of $F^1(\mathbf{z})$, to name just a few.

125 For the truth and the $K - 1$ surrogate OoIs, Monte Carlo (MC) sampling yields the K unbiased estimators

$$Q_k^{MC} = \frac{1}{M_k} \sum_{m=1}^{M_k} F^k(\mathbf{z}_m) \approx \mathbb{E}[F^k] = Q_k \quad \text{for } k = 1, \dots, K, \quad (3)$$

where $\mathbf{z}_1, \dots, \mathbf{z}_{M_k}$ denote M_k i.i.d. samples of $\mathbf{z} \in \Gamma$. The goal of an MFMC method is using an appropriate linear combination of the K MC estimators Q_k^{MC} in (3) to estimate the QoI $Q_1 = \mathbb{E}[F^1]$. Specifically, we define the MFMC estimator as

$$Q^{MFMC} = Q_1^{MC} + \sum_{k=2}^K \alpha_k (Q_k^{MC} - Q_{k-1}^{MC}) \approx Q_1 = \mathbb{E}[F^1], \quad (4)$$

130 where $\{\alpha_k\}_{k=2}^K$ denotes a sequence of scalar weights and $\{M_k\}_{k=1}^K$ denotes a nondecreasing sequence of integers defining the numbers of samples.

Letting C_k denote the cost of evaluating the k^{th} output of interest F^k , the costs of computing the respective MC and MFMC estimators are given as

$$C_k^{MC} = C_k M_k \quad \text{for } k = 1, \dots, K \quad \text{and} \quad C^{MFMC} = \sum_{k=1}^K C_k^{MC} = \mathbf{C} \cdot \mathbf{M},$$

135 where $\mathbf{C} = \{C_k\}_{k=1}^K$ and $\mathbf{M} = \{M_k\}_{k=1}^K$ denote K -vectors formed from the previously introduced sequences.

The variance σ_k^2 of the k^{th} output of interest F^k and the correlation $\zeta_{k,k'}$ between the outputs of interest F^k and $F^{k'}$ are given by, for $k', k = 1, \dots, K$,

$$\sigma_k^2 = \text{Var}[F^k(\mathbf{z})] \quad \text{and} \quad \zeta_{k,k'} = \frac{\text{Cov}[F^k(\mathbf{z}), F^{k'}(\mathbf{z})]}{\sigma_k \sigma_{k'}},$$

respectively, where $\text{Cov}[\cdot, \cdot]$ denotes the statistical covariance. We then have that the *mean-squared error* (MSE) incurred by

140 the MC estimator Q_k^{MC} of the QoI Q_k is given by

$$\begin{aligned} e(Q_k^{MC}) &= \mathbb{E}[(Q_k - Q_k^{MC})^2] = \mathbb{E}[(\mathbb{E}[F^k(\mathbf{z})] - Q_k^{MC})^2] \\ &= \mathbb{E}[F^k(\mathbf{z})^2] - \mathbb{E}[F^k(\mathbf{z})]^2 = \frac{\sigma_k^2}{M_k} \quad \text{for } k = 1, \dots, K \end{aligned} \quad (5)$$

whereas the MSE incurred by the Q^{MFMC} estimator of the QoI Q_1 is given by (see Peherstorfer et. al. (2016))

$$e(Q^{MFMC}) = \frac{\sigma_1^2}{M_1} + \sum_{k=2}^K \left(\frac{1}{M_{k-1}} - \frac{1}{M_k} \right) (\alpha_k^2 \sigma_k^2 - 2\alpha_k \sigma_k \sigma_1 \zeta_{1,k}). \quad (6)$$

Note that it can be shown (see e.g. Peherstorfer et. al. (2016)) that the MSE for Q^{MFMC} is lower than that for Q_1^{MC} if and

145 only if

$$\sqrt{\frac{e(Q^{MFMC})}{e(Q_1^{MC})}} = \sum_{k=1}^{K-1} \sqrt{\frac{C_k}{C_1} (\zeta_{1,k}^2 - \zeta_{1,k+1}^2)} < 1. \quad (7)$$

Given a fixed computational budget B , MFMC aims to construct an optimal sampling strategy $\mathbf{M} = \{M_k\}_{k=1}^K$ along with an optimal set of weights $\boldsymbol{\alpha} = \{\alpha_k\}_{k=2}^K$ so that the MSE (6) of the multifidelity estimator Q^{MFMC} is lower than the MSE (5) of the Monte Carlo estimator Q_1^{MC} . Viewed differently, this means that an appropriate estimator Q^{MFMC} can achieve a fixed MSE $\varepsilon > 0$ at a smaller computational cost compared to that incurred for the Monte Carlo estimator Q_1^{MC} achieving MSE ε .

In Peherstorfer et. al. (2016, 2018), unique optimal values of $\mathbf{M} = \{M_k\}_{k=1}^K$ and $\boldsymbol{\alpha} = \{\alpha_k\}_{k=2}^K$ are analytically obtained by minimizing the MSE (6) of the Q^{MFMC} estimator (4) over the real numbers. However, the values \mathbf{M} must certainly be integers for practical use, and the heuristic of Peherstorfer et. al. (2016) which determines the optimal values can result in either a biased estimator of the expectation or (with naïve modification) a violation of the given budget B . For “small” computational budgets, the consequences of this can be quite severe as illustrated in Gruber et. al. (2022).

Because “small” computational budgets are of high interest for climate modeling, here, instead of using the MFMC method of Peherstorfer et. al. (2016, 2018), we use the modified MFMC method of Gruber et. al. (2022) which guarantees that the optimal sampling numbers are integers and that the computational budget is not exceeded. In that method, instead of simply minimizing the MSE $e(Q^{MFMC})$ defined in (6), the modified MFMC estimator is determined through the use of at least some of the sequential minimization problems given by

for $k = 1, 2, \dots, K$ and, if $k > 1$, for given $M_{1,1}, \dots, M_{k-1,k-1}$, minimize the functional

$$\mathcal{L}^k(\mathbf{M}_k, \boldsymbol{\alpha}_k; \lambda_k, \boldsymbol{\mu}_k, \xi_k) = e(Q^{MFMC}) + \lambda_k \left(\sum_{k'=k}^K C_{k'} M_{k',k} - \left(B - \sum_{k'=1}^{k-1} C_{k'} \right) \right) + \sum_{k'=k+1}^K \mu_{k',k} (M_{k',k} - M_{k'-1,k}) - \xi_k M_{k,k} \quad (8)$$

where $\mu_{k',k}$ for $k' = k+1, \dots, K$, λ_k , and $\xi_k > 0$ are Lagrange multipliers.

In (8), the first term added to the MSE $e(Q^{MFMC})$ enforces the budget constraint, or, more precisely, for each k , enforces that the remaining available budget suffices to not exceed the given budget B after that budget has been depleted by the sampling already effected for the OoIs $F^{k'}$, $k' = 1, \dots, k-1$, where, of course, for $k = 1$ the whole budget B is available. The second term added in (8) enforces the monotone non-decrease in the numbers of samples $M_{k',k}$ for $k' > k$. The third term added to the MSE enforces the positivity of $M_{k,k}$.

Repeating the arguments made in Peherstorfer et. al. (2016) concerning optimal choices for the sample numbers and weights, the results given in the box A below are proved in Gruber et. al. (2022).

Remark 2.1. It is clear from (11) that the weights $\alpha_{k',k}^*$ depend only on input data, specifically on the variances and correlations of the OoIs $\{F^{k'}\}_{k'=1}^K$. As such the value of $\alpha_{k',k}^*$ is independent of k so that

$$\alpha_{k',k}^* = \frac{\zeta_{1,k'} \sigma_1}{\sigma_{k'}} = \alpha_{k',1}^* \quad \text{for all } k = 1, \dots, K \text{ and all } k' = k+1, \dots, K.$$

Thus, the set of weights $\{\alpha_{k',1}^*\}_{k'=2}^K$ determined from the minimization of \mathcal{L}^1 suffices to determine $\alpha_{k',k}^*$ for all such k' and k , i.e., all $\alpha_{k',k}^*$ for all k' and k are determined once and for all by the minimization of \mathcal{L}^1 . \square

A. Optimal non-integer sampling numbers for the modified MFMC method; see Gruber et. al. (2022)

- Let $\{F^k\}_{k=1}^K$ denote the set of computational outputs of interest with correlation coefficients $\{\zeta_{1,k}\}_{k=2}^K$ and computational costs $\{C_k\}_{k=1}^K$ that respectively satisfy

$$|\zeta_{1,k-1}| > |\zeta_{1,k}| \quad \text{and} \quad \frac{C_{k-1}}{C_k} > \frac{\zeta_{1,k-1}^2 - \zeta_{1,k}^2}{\zeta_{1,k}^2 - \zeta_{1,k+1}^2}, \quad k = 2, \dots, K. \quad (9)$$

The first requirement is easily satisfied by a reordering of the of the surrogate outputs of interest F^2, \dots, F^K . If after that reordering, the second requirement is not satisfied for some $k \in \{2, \dots, K\}$, then that F^k is removed from the list of surrogates.

- Let $M_{1,1}, \dots, M_{k-1,k-1}$ be given which are all positive by construction.
- Also let $\mathbf{M}_k^* = \{M_{k',k}^*\}_{k'=k}^K$ and $\boldsymbol{\alpha}_k^* = \{\alpha_{k',k}^*\}_{k'=k+1}^K$ and let

$$r_{k',k}^* = \frac{M_{k',k}^*}{M_{k,k}^*} = \sqrt{\frac{C_k}{C_{k'}} \left(\frac{\zeta_{1,k'}^2 - \zeta_{1,k'+1}^2}{\zeta_{1,k}^2 - \zeta_{1,k+1}^2} \right)}, \quad k' = k, \dots, K.$$

- Then, for each $k = 1, \dots, K$, the *unique global minimizer* $(\mathbf{M}_k^*, \boldsymbol{\alpha}_k^*)$ of the functional \mathcal{L}^k is given by

$$M_{k,k}^* = \frac{B - \sum_{k'=1}^{k-1} C_{k'}}{\sum_{k'=k}^K C_{k'} r_{k',k}^*}, \quad (10)$$

and

$$M_{k',k}^* = M_{k,k}^* r_{k',k}^* \quad \text{and} \quad \alpha_{k',k}^* = \frac{\zeta_{1,k'} \sigma_1}{\sigma_{k'}}, \quad k' = k+1, \dots, K. \quad (11)$$

175 Unfortunately, as was the case in Peherstorfer et. al. (2016, 2018), the results given in box **A** do not immediately lead to a practical MFMC method because the sample numbers $M_{k',k}^*$ given in (10) and (11) are not, in general, integers. Moreover, as was also the case in Peherstorfer et. al. (2016, 2018), the first and perhaps even the first few sampling numbers at stage $k' = 1$ may be < 1 in addition to being noninteger. In those papers, a rounding procedure is implemented, i.e., the sample numbers $M_{k',1}$ are replaced by integers, though this is unsuitable for scenarios where $M_{1,1} < 1$ as the choice $M_{1,1} = 0$ leads to a biased estimator while the choice $M_{1,1} = 1$ exceeds the computational budget. On the other hand, the modified MFMC method in
 180 box **B** below is constructed to avoid these issues while preserving the optimality of the original solution (up to some amount of rounding). Note that in that box and elsewhere, $\lfloor \cdot \rfloor$ denotes rounding downwards to the nearest integer.

B. Practical near-optimal integer sampling numbers for the modified MFMC method; see Gruber et. al. (2022)

For $k = 1, 2, \dots$,

Ia. if the minimization of the Lagrangian functional \mathcal{L}^k constrained by $M_{1,1} = M_{2,2} = \dots = M_{k-1,k-1} = 1$ results in all $K - k + 1$ members of the set $\{M_{k',k}\}_{k'=k}^K$ satisfying $M_{k',k} \geq 1, k' = k, \dots, K$.

Then,

Ib. simply rounding downwards to the nearest integer produces integer sample numbers $M_{k',k}^* \rightarrow \lfloor M_{k',k}^* \rfloor, k' = k, \dots, K$, so that the final set $\{M_{k',k'} = 1\}_{k'=1}^{k-1} \cup \{\lfloor M_{k',k}^* \rfloor\}_{k'=k}^K$, of sampling number optimal under the constraint $M_{1,1} = \dots = M_{k',k'} = 1$ and *preserves the computational budget*. We then set $\hat{K} = k - 1$ and exit to step **IV**.

Otherwise,

IIa. if $M_{k,k}^* < 1$, then it is rounded upwards $M_{k,k}^* \rightarrow 1$ and the function \mathcal{L}^{k+1} is minimized to obtain the remaining $K - k$ components of $M_{k',k}^*, k' = k + 1, \dots, K$.

This yields

IIb. a new set $\{M_{1,1}^* = 1, M_{2,2}^* = 1, \dots, M_{k,k}^* = 1\} \cup \{M_{k',k}^*\}_{k'=k+1}^K$ which may or may not contain entries less than 1. If it does not, the model evaluation vector becomes $\mathbf{M}^* = \{M_{k',k'} = 1\}_{k'=1}^k \cup \{\lfloor M_{k',k}^* \rfloor\}_{k'=k+1}^K$. We then set $\hat{K} = k$ and exit to step **IV**.

Otherwise,

III. we increment $k \rightarrow k + 1$ and return to step **Ia**.

IV. The process terminates and the final set of sample numbers is given by $\{M_{1,1}^* = 1, M_{2,2}^* = 1, \dots, M_{\hat{K},\hat{K}}^* = 1\} \cup \{M_{k',\hat{K}+1}^*\}_{k'=\hat{K}+1}^K$.

3 Tests for the single-layer rotating shallow-water equations

Consider the single-layer rotating shallow-water equations (RSWEs) posed on the domain $\Gamma \times [0, T]$ and given by (see [Vallis \(2012\)](#))

185 [Vallis \(2012\)](#)

$$\begin{aligned} \frac{\partial h}{\partial t} + \nabla \cdot (h\mathbf{u}) &= 0, \\ \frac{\partial \mathbf{u}}{\partial t} + (\mathbf{k} \cdot \nabla \times \mathbf{u} + f)(\mathbf{k} \times \mathbf{u}) + \nabla \left(\frac{|\mathbf{u}|^2}{2} + g(h + h_b) \right) &= G(h, \mathbf{u}), \end{aligned} \tag{12}$$

where

Γ denotes the surface of a sphere or a subset of that surface,

$[0, T]$ denotes a time interval,

190 \mathbf{k} denotes a unit vector perpendicular to the surface of the sphere,

$h(\mathbf{x}, t)$ denotes the fluid thickness,

$\mathbf{u}(\mathbf{x}, t)$ denotes the vector velocity field tangential to the surface of the sphere,

$G(h, \mathbf{u})$ denotes the a forcing term that depends on the specific setting,

f denotes the Coriolis parameter,

195 ~~ρ denotes the density,~~

$h_b(\mathbf{x}, t)$ denotes the bottom topography,

g denotes the (constant) acceleration due to gravity,

∇ denotes the tangential gradient, i.e., $\nabla f = Df - (Df \cdot \mathbf{k})\mathbf{k}$ where D is the derivative operator of \mathbb{R}^3 .

Note that the expression $(\mathbf{k} \cdot \nabla \times \mathbf{u} + f)/h$ appearing in the velocity equation is known as the potential vorticity; see [Vallis \(2012\)](#).
 200 Supplementing (12) are the initial conditions $h = h_0$ and $\mathbf{u} = \mathbf{u}_0$ at $t = 0$ and, if Γ is a strict subset of the surface of the sphere, the boundary condition $\mathbf{u} \cdot \mathbf{n} = 0$ on the boundary $\partial\Gamma$ of Γ , where \mathbf{n} denotes the unit vector tangent to the surface of the sphere and also (outward) perpendicular to $\partial\Omega$.

The RSWEs represent a useful simplification of the primitive equations ([Vallis \(2012\)](#)) which are commonly used in oceanic and atmospheric modeling and which are obtained by assuming a small ratio between the vertical and horizontal length scales.
 205 In this way, the single-layer RSWEs describe the motion of a thin layer of fluid which lies on a rigid surface, yielding conditions used extensively in the modeling of oceanic and atmospheric flows.

Spatial discretization of the system (12) is effected using the TRiSK scheme (Ringler et. al. (2010); Thuburn et. al. (2009)) which is a staggered C-grid mimetic finite difference/finite volume scheme that preserves desirable physical properties including conservation laws for mass, energy, and potential vorticity. TRiSK discretization involves the approximation h_ℓ of the
 210 ~~height thickness~~ h at the center of a grid cell P_ℓ , the approximation u_e of the normal to the edge component $\mathbf{u} \cdot \mathbf{n}$ of velocity at the centers of the edges of P_ℓ , and the approximation of the potential vorticity $(\mathbf{k} \cdot \nabla \times \mathbf{u} + f)/h$ at the vertices of P_ℓ . The necessary meshing is done using spherical centroidal Voronoi tessellation (SCVT) grids (Jacobsen et. al. (2013); Ringler et. al. (2008); Yang et. al. (2018)); examples of such grids are given in Sections 3.1 and 3.2 for the specific settings of those sections.

Temporal discretization of the system (12) is effected using an explicit 4^{th} -order Runge-Kutta method, although many
 215 alternative time-stepping schemes have also been proposed for this purpose; see, e.g., Leng et. al. (2019); Meng et. al. (2020); Trahan and Dawson (2012). We denote by $\{t_n\}_{n=0}^{N_t}$ with $t_0 = 0$ and $t_{N_t} = T$ the time instants used for temporal discretization.

3.1 A ~~SOMA~~ [wind-driven gyre](#) test case for the RSWE system

The specific setting considered here is [a modification of](#) the benchmark test case referred to as “simulating ocean mesoscale activity” (SOMA) (Wolfram et. al. (2015)) which involves a geodesic basin with radius 1250km centered at latitude/longitude
 220 $(35^\circ, 0^\circ)$ on the surface of the Earth. Inside the basin, the depth of fluid varies from 2500m at the center to 100m on the coastal shelf, creating a realistic topography which yields interesting dynamical behaviors which are useful for studying the propagation of fronts and eddies. [The present experiment considers this same setting with a constant density \$\rho\$, leading to a computational model for a wind-driven barotropic gyre.](#)

In (12),

$$225 \quad G(h, \mathbf{u}) = d_{\text{bottom}}(h, \mathbf{u}) + d_{\text{wind}}(h) \quad \text{with} \quad \begin{cases} d_{\text{bottom}}(h, \mathbf{u}) = -c_{\text{bottom}} \frac{|\mathbf{u}| \mathbf{u}}{\rho h} \\ d_{\text{wind}}(h) = \frac{\tau_{\text{wind}}}{\rho h} \end{cases}$$

with $f_{\text{bottom}}(h, \mathbf{u})$ denoting a forcing term due to the bottom drag and $f_{\text{wind}}(h)$ denoting a forcing term due to wind drag. Here, c_{bottom} denotes the bottom drag coefficient chosen to be 10^{-3} , ρ denotes the density, and τ_{wind} denotes the surface wind stress. See, e.g., Wolfram et. al. (2015) for a discussion of this choice for $G(h, \mathbf{u})$.

For constructing the MC and MFMC estimators, we use three SCVT grids of the SOMA domain Γ given by

grid resolution		number of cells	number of edges	number of vertices
8km	\Rightarrow	120,953	364,124	243,172
16km	\Rightarrow	30,217	91,285	61,069
32km	\Rightarrow	8,521	25,898	17,378

230

A representative SCVT meshing of Γ is illustrated in Figure 1. Note that for the SCVT grids used by the TRiSK scheme, the cells are almost all hexagonal, with a few pentagons and heptagons thrown in.

Figure 1. The 32km grid used for the [SOMA-wind-driven gyre](#) test case and a zoom-in on a portion of that mesh.

The *output of interest* we consider is the maximum [sea-surface-height-fluid layer thickness](#) which is a common benchmark in oceanic RSWE simulations and which is relevant to, e.g., the detection of phenomena such as flooding. In particular, we simulate the RSWE until the final time of $T = 3$ days using the finest grid (8km resolution) of 120,953 cells and then choose the OoI F_{soma}^1 given by F_{gyre}^1 given by

235

$$F_{\text{soma gyre}}^1 = \max_{\ell=1, \dots, 120,953} h_{\ell}, \quad (13)$$

where h_{ℓ} denotes the [sea-surface-height \(also called fluid thickness\)-fluid thickness](#) at the center of the cell P_{ℓ} at the final time $T = 3$.

240

The *quantity of interest* we choose considers the effect that perturbations of the initial velocity $\mathbf{u}_0 = \mathbf{u}(0)$ have on F_{soma}^1 and how that effect can be quantified using MC and MFMC estimation. To this end, consider random dilations $(1+z)\mathbf{u}_0$

of the initial velocity depending on the i.i.d. random variable z that is uniformly distributed over the interval $[-0.5, 0.5]$. Then, the OoI defined in (13) depends on the choice of z in that interval, i.e., we have that $F_{soma}^1 = F_{soma}^1(z)F_{gyre}^1 = F_{gyre}^1(z)$. In particular, we choose the QoI to be the expectation $Q_{1,soma} = \mathbb{E}[F_{soma}^1]$ $Q_{1,gyre} = \mathbb{E}[F_{gyre}^1]$ of the output of interest $F_{soma}^1(z)F_{gyre}^1(z)$ defined in (13).

Note that in practical RSWE simulations, as is the case for more sophisticated models such as the primitive equations, an approximation of the initial data \mathbf{u}_0 is often obtained from a pre-processing procedure in which the RSWE system is *spun-up* from rest, i.e., from a zero initial condition for \mathbf{u} , up to some specified time; see Anderson et. al. (1975); Bleck and Boudra (1986). This procedure is invoked so as to eliminate transient artifacts which are not present in the current ocean or atmosphere and produces an initial configuration which is closer to observed oceanic and atmospheric data. The outcome of the spin-up calculation over the spin-up time frame of 15 days is illustrated in Figure 2. The initial conditions \mathbf{u}_0 and h_0 that supplement (12) are then simply set to the outcome of this pre-processing step, i.e., to the sea-surface-height fluid thickness and velocity obtained at the end of the spin-up calculation.

Figure 2. For the setting of Section 3.1, the RSWE truth model solution (8km resolution) with thickness h (left) and velocity field \mathbf{u} (right) after integration of the system from rest for $T = 15$ days.

3.1.1 MC and MFMC estimators

The MC estimator $Q_{1,soma}^{MC}$ of $Q_{1,soma} = \mathbb{E}[F_{soma}^1]$ $Q_{1,gyre}^{MC}$ of $Q_{1,gyre} = \mathbb{E}[F_{gyre}^1]$ is given by (2). Unfortunately, obtaining acceptable accuracy using a MC estimator suffers from a double shortcoming. First, for any given z , obtaining $F_{soma}^1 F_{gyre}^1$ is a costly endeavor because it requires the solution of the discretized RSWE system to obtain the necessary 120,953 values of $h_\ell(z)$. Second, to obtain an MC estimator that is acceptable accuracy requires obtaining $F_{soma}^1 F_{gyre}^1$ for many sample values of z .

Naturally, to mitigate this double shortcoming, we turn to the MFMC estimator described in box **B** of Section 2. To do so, we define three surrogate OoIs $F_{soma}^2(z)$, $F_{soma}^3(z)$, and $F_{soma}^4(z)F_{gyre}^2(z)$, $F_{gyre}^3(z)$, and $F_{gyre}^4(z)$, all three of which are

less costly to obtain compared to that of $F_{soma}^1(z)F_{gyre}^1(z)$. Here, $F_{soma}^2(z)$ and $F_{soma}^3(z)F_{gyre}^2(z)$ and $F_{gyre}^3(z)$ are simply based on solving the discretized RSWE system using the coarser 16km and 32km grids, respectively. The third surrogate $F_{soma}^4(z)F_{gyre}^4(z)$ is the piecewise-linear interpolant based on the values of $F_{soma}^1(z)F_{gyre}^1(z)$ which is exact at the three points $z = \{-0.5, 0, 0.5\}$. These four OoIs constitute a reasonable multifidelity ensemble of models which are available during computational ocean studies, even more realistic ones such as primitive equation models. Moreover, all four OoIs can be leveraged for MFMC estimation whereas more traditional MC and multilevel MC estimators only make use of the first or the first three OoIs, respectively. Approximations of the costs and correlations for the four OoIs $\{F_{soma}^k(z)\}_{k=1}^4$ $\{F_{gyre}^k(z)\}_{k=1}^4$ are obtained by considering 100 uniform i.i.d. samples of $z \in [-0.5, 0.5]$. These are computed to be

$$270 \quad \mathbf{C} = \begin{pmatrix} C_1 \\ C_2 \\ C_3 \\ C_4 \end{pmatrix} = \begin{pmatrix} 101.1 \\ 12.83 \\ 1.714 \\ 0.05 \end{pmatrix} \quad \text{and} \quad \zeta_1 = \begin{pmatrix} \zeta_{1,1} \\ \zeta_{1,2} \\ \zeta_{1,3} \\ \zeta_{1,4} \end{pmatrix} = \begin{pmatrix} 1.00000000 \\ 0.99975045 \\ 0.99975920 \\ 0.99974835 \end{pmatrix}, \quad (14)$$

where C_k for $k = 1, 2, 3$ denote the average computation time (in wall-clock seconds) necessary to advance the relevant discretized RSWE system one time step, computed using 500 time steps for the simulation parameter $z = 0.001$. Note that the cost C_4 is assigned arbitrarily because the cost of evaluating the interpolant is negligible. These cost-correlation pairs are ideal for MFMC estimation, i.e., the surrogates are very well correlated with $F_{soma}^1(z)F_{gyre}^1(z)$ and are much less costly to obtain compared to $F_{soma}^1(z)F_{gyre}^1(z)$. Note that the 100 samples of z used to determine the data in (14) can be reused when determining the MC and MFMC estimators.

From (14), we observe that the more expensive surrogate $F_{soma}^2(z)F_{gyre}^2(z)$ is slightly less correlated to $F_{soma}^1(z)F_{gyre}^1(z)$ than is the cheaper surrogate $F_{soma}^3(z)F_{gyre}^3(z)$. So, to satisfy the first criteria in (9), the correlations should be ordered in the decreasing order $\zeta_{1,1}, \zeta_{1,3}, \zeta_{1,2}$, and $\zeta_{1,4}$. However, it turns out that then the second criteria in (9) for $k = 2$ is not satisfied so that the $F_{soma}^2(z)F_{gyre}^2(z)$ is removed from the list of surrogates when computing the MFMC estimator. That estimator is given by (4) with $K = 4$ and where $k = 2$ is excluded from the sum. This is an example which illustrates, as discussed in Section 2, that not all surrogates one chooses contribute to the efficiency of MFMC estimation and, on the other hand, their omission does no harm to the accuracy of that estimator.

As already alluded to, the goal is to compare, for the same budget, the MSEs of the approximations Q_{soma}^{MC} and Q_{soma}^{MFMC} to the exact QoI $Q_{1,soma} = \mathbb{E}[F^1]$ $Q_{1,gyre} = \mathbb{E}[F^1]$ produced by the MC and MFMC estimators. However, there is still an additional challenge to be dealt with, namely that it is unclear how to choose a reference QoI that one can use to determine these MSEs, as only limited data (200 high-fidelity samples) are available and an MC approximation Q_{gyre}^{MC} with 200 samples is not sufficient for an accurate estimate of the expectation $\mathbb{E}[F^1]$. Therefore, we choose Q_{soma}^{ref} Q_{gyre}^{ref} to denote the average of the MFMC approximation Q_{soma}^{MFMC} Q_{gyre}^{MFMC} at the highest budget $B = 128C_1$ taken over 250 runs which use samples z that are independently drawn from the interval $[-0.5, 0.5]$ except for the fact that the first M_3 (recall that M_2 is omitted) samples of each run are drawn from the pre-collected sampling set of size 200. The use of MFMC in defining Q_{soma}^{ref} Q_{gyre}^{ref} makes use of the fact that the MFMC method is at least as accurate as MC estimation, which can be

verified through the inequality (7). With this choice, the MSEs in the MFMC and MC estimators can be measured with respect to the “exact quantity” $Q_{soma}^{ref} Q_{gyre}^{ref}$.

295 The results of this procedure are given in Table 1 and Figure 3 from which it is evident that MFMC produces a much more precise estimate compared to that of MC. In addition to $MSE(e(Q_{soma}^{MFMC})e(Q_{gyre}^{MFMC}))$, we report the relative MSE defined as $e_{rel}(Q_{soma}^{MFMC}) = e(Q_{soma}^{MFMC}) / (Q_{soma}^{ref})^2$ $e_{rel}(Q_{gyre}^{MFMC}) = e(Q_{gyre}^{MFMC}) / (Q_{gyre}^{ref})^2$. It is interesting that most of the computational budget is loaded onto the very crude piecewise-linear interpolant approximation $F_{soma}^4(z) F_{gyre}^4(z)$, allowing MFMC to achieve not only a lower MSE but also an estimate with much smaller variance from run-to-run. Especially telling is
 300 the bottom plot in Figure 3 from which it is obvious that, for the same budget, MFMC estimation results in greater accuracy of 2 or 3 orders of magnitude compared to that MC estimation, or looking at it another way, for the same relative MSE, MFMC estimation requires a much smaller budget compared to MC estimation.

Table 1. Results of the SOMA-RSWE-wind-driven barotropic gyre test with perturbed initial velocities for budgets $B = 2^k C_1$ equivalent to 2^k highest-fidelity runs.

3.2 Test Case 5 for the RSWE system

We again consider the RSWE system (12) but now Ω denotes the whole surface of the sphere. Specifically, we consider the configuration of Test Case 5 defined in Williamson et. al. (1992), which is widely used as a benchmark and employed as a stepping stone towards more realistic atmospheric models; see, e.g., Leng et. al. (2019); Meng et. al. (2020); Ringler et. al. (2010); Williamson et. al. (1992). Note that for this example there are no additional forces acting on the system, so that $G(h, \mathbf{u}) = 0$ in (12).

Test Case 5 considers the flow over an isolated mountain centered at longitude $\lambda_c = \frac{3\pi}{2}$ and latitude $\theta_c = \frac{\pi}{6}$ with height

$$h_b(z_1) = z_1 \left(1 - \frac{r}{a}\right), \quad (15)$$

where $a = \frac{\pi}{9}$, $r^2 = \min\{a^2, (\lambda - \lambda_c)^2 + (\theta - \theta_c)^2\}$, and λ, θ denote longitude and latitude, respectively. In (15), z_1 denotes a random variable that is uniformly distributed over the interval [1km, 3km].

The initial tangential (to the sphere) velocity in the longitudinal and latitudinal directions is chosen to be $\mathbf{u}_0(z_2) = (z_2 \cos \theta, 0)$, where z_2 denotes a random variable that is uniformly distributed over the interval [15m/s, 25m/s]. The initial [sea-surface-height](#) [fluid thickness](#) h is chosen as

$$h_0(z_2) = \hat{h} - \frac{1}{g} \left(R\omega z_2 + \frac{z_2^2}{2} \right) \sin^2 \theta,$$

where $\hat{h} = 5.96\text{km}$, $R = 6371.22\text{km}$, and $\omega = 7.292 \times 10^{-5}\text{s}^{-1}$. With this, the solution $\mathbf{u}(\mathbf{z})$ and $h(\mathbf{z})$ of the RSWE system (12) depends on the random vector $\mathbf{z} = (z_1, z_2) \in [1\text{km}, 3\text{km}] \times [15\text{m/s}, 25\text{m/s}]$. In Figure 4 we provide an example of the initial thickness $h_0(z_2)$ and the thickness $h(z_1, z_2)$ after 10 days for specific values of z_1 and z_2 .

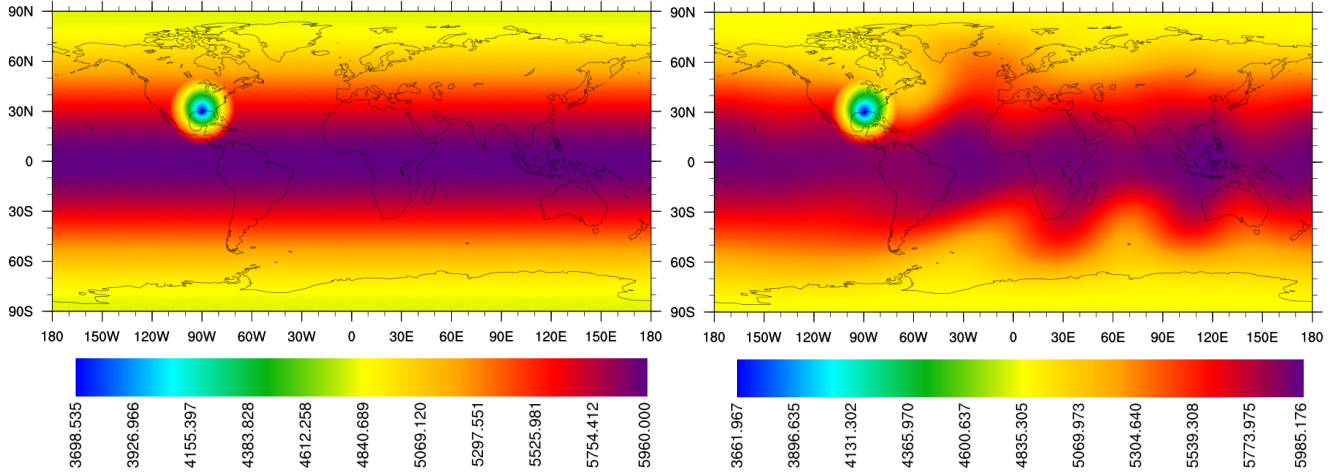

Figure 4. The initial thickness $h_0(z_2)$ with $z_2 = 23.82865\text{m}$ (top) and the thickness h after 10 days (bottom) with the mountain height $h_b(z_1)$ with $z_1 = 2023.78\text{m}$.

320 For the simulation results given in Figure 4 and for other results in this subsection, we use the TRiSK scheme for spatial discretization and a 4th-order explicit Runge-Kutta method for temporal discretization. SCVT uniform gridding is employed as in Section 3.1, although now the grid covers the whole surface of the sphere. A comparison of two such SVCT grids with 480 km and 240 km resolutions is provided in Figure 5. In constructing the MC and MFMC estimators, we use the three globally refined SCVT meshes of the whole sphere given by

325

grid resolution		number of cells	number of edges	number of vertices
120km	⇒	40,962	122,880	81,920
240km	⇒	10,242	30,720	20,480
480km	⇒	2,562	7,680	5,120

For the *output of interest*, we choose

$$F_{test5}^1(\mathbf{z}) = \frac{1}{N_\ell^1} \max_{\ell=1, \dots, N_\ell^1} |u_{e, \ell}(\mathbf{z})|,$$

where N_ℓ^1 denotes the number of cell edges for the finest resolution case of 120km and $u_{e, \ell}(\mathbf{z})$ denotes the value of the normal component of velocity u_e at the ℓ -th cell edge for any choice of the random vector $\mathbf{z} = (z_1, z_2) \in [1\text{km}, 3\text{km}] \times$
330 $[15\text{m/s}, 25\text{m/s}]$. We then have that the *quantity of interest* is given by

$$Q_{1, test5} = \mathbb{E} [F_{test5}^1(\mathbf{z})]. \quad (16)$$

Figure 5. Two global SCVT meshes of the sphere surface with different grid resolutions: 480 km (left) and 240 km (right).

3.2.1 MC and MFMC estimators

Similar to before, the goal is now to construct and compare, for the same computational budget, MC and MFMC estimators of the QoI defined in (16). The MC estimator $Q_{1,test5}^{MC}$ of the QoI $Q_{1,test5} = \mathbb{E}[F_{test5}^1]$ is given by (2). The MFMC estimator $Q_{1,test5}^{MFMC}$ of $Q_{1,test5} = \mathbb{E}[F_{test5}^1]$ makes use not only of the MC estimator $Q_{1,test5}^{MC}$ for the finest 120km grid, but also of the MC estimators $Q_{2,test5}^{MC} \approx \mathbb{E}[F_{test5}^1]$ and $Q_{3,test5}^{MC} \approx \mathbb{E}[F_{test5}^1]$ corresponding the coarser 240km and 480km grids, respectively.

In this case, 4500 uniform i.i.d. realizations of \mathbf{z} are drawn for pre-computation, of which all models share 1200 and models the two lower-fidelity surrogates share the entire 4500. Using 100 samples of the random variable \mathbf{z} , the costs and correlation coefficients of these models are respectively approximated by

$$340 \quad \mathbf{C} = \begin{pmatrix} C_1 \\ C_2 \\ C_3 \end{pmatrix} = \begin{pmatrix} 434.8 \\ 126.9 \\ 58.04 \end{pmatrix} \quad \text{and} \quad \zeta_1 = \begin{pmatrix} \zeta_{1,1} \\ \zeta_{1,2} \\ \zeta_{1,3} \end{pmatrix} = \begin{pmatrix} 1.00000000 \\ 0.99986604 \\ 0.99925882 \end{pmatrix},$$

where the costs C_1 , C_2 , and C_3 denote the computation time (in wall-clock seconds) necessary to advance the relevant discretized RSWE system one time step. As was the case for the [SOMA-wind-driven gyre](#) experiment, these cost-correlation pairs are ideal for MFMC estimation, i.e., the surrogates OoIs $F_{test5}^2(\mathbf{z})$ and $F_{test5}^3(\mathbf{z})$ are very well correlated with $F_{test5}^1(\mathbf{z})$ and are much less costly to obtain compared to $F_{test5}^1(\mathbf{z})$. Note the 100 samples of \mathbf{z} used to determine the data in (14) can be reused when determining the MC and MFMC estimators. From this point on, all other details about the construction and use of the MC and MFMC estimators are the same as for the [SOMA-wind-driven barotropic gyre](#) test case of Section 3.1.

The results provided in Table 2 and Figure 6 show that MFMC estimation produces a much more precise estimate compared to MC estimation. As was true for the [SOMA-wind-driven gyre](#) test case, especially telling is the bottom plot in Figure 6 from which it is obvious that, for the same budget, MFMC estimation results in an order of magnitude greater accuracy compared to

350 that MC estimation, or looking at it another way, for the same relative MSE, MFMC estimation requires a much smaller budget compared to MC estimation.

Table 2. Results of Test Case 5 with perturbed initial velocities for budgets $B = 2^k C_1$ equivalent to 2^k high-fidelity runs.

4 First-order ice sheet model

The next experiment we consider illustrates the effectiveness of MFMC estimation on a QoI important for the realistic modeling of ice sheets such as those found near, e.g., Greenland, Antarctica, and various glaciers.

Figure 6. Results over 250 runs of the RSWE system for the Test Case 5 experiment with quantity of interest given by 16. **Shading represents** Shaded regions represent the variance in the MC and MFMC predictions over the 250 runs, which are independent except for the fact that all random sampling employs the same pre-collected (random) set of parameters. Note that the melon region is contained in the blue region, indicating that the MFMC estimator has a smaller standard deviation than the MC estimator.

355 4.1 The first-order model for ice sheets

The dynamical behavior of ice sheets is commonly modeled by what is referred to as the *first-order model* or the *Blatter–Pattyn model*. Here, we provide a short review of that model; detailed descriptions are given in, e.g., Blatter (1995); Pattyn (2003) and also in Perego et. al. (2012); Tezaur et. al. (2015).

Let Ω denote the three-dimensional domain occupied by the ice sheet having boundary $\Gamma = \Gamma_s \cup \Gamma_b \cup \Gamma_\ell$ given by

$$\begin{aligned}
 \Gamma_s &\Leftarrow x_3 = s(x_1, x_2) \Rightarrow \text{top surface of the ice sheet} \\
 360 \quad \Gamma_b &\Leftarrow x_3 = b(x_1, x_2) \Rightarrow \text{bottom (or basal) surface of the ice sheet} \\
 \Gamma_\ell &\Leftarrow \ell(x_1, x_2) = 0 \Rightarrow \text{lateral boundary.}
 \end{aligned} \tag{17}$$

Figure 7 provides an illustration of the boundary segments defined in (17).

Figure 7. An (x_1, x_3) cross section of the three-dimensional domain Ω occupied by an ice sheet and the boundary segments defined in (17).

Also, let u_1 and u_2 denote the x_1 and x_2 components of the velocity vector $\mathbf{u} = (u_1 \ u_2 \ u_3)^\top$. Then, the first-order model equations for ice sheets is given by the partial differential equations

$$\begin{cases} -\nabla \cdot (2\mu\epsilon_1) + \rho g \frac{\partial s}{\partial x_1} = 0 \\ -\nabla \cdot (2\mu\epsilon_2) + \rho g \frac{\partial s}{\partial x_2} = 0 \end{cases} \quad \text{for } \mathbf{x} = (x_1 \ x_2 \ x_3)^\top \in \Omega, \quad (18)$$

365 where μ denotes the viscosity coefficient, g denotes the gravitational acceleration, and ρ denotes the density. In (18), the strain-rate tensor (ϵ_1, ϵ_2) is given by

$$\epsilon_1 = \begin{pmatrix} 2 \frac{\partial u_1}{\partial x_1} + \frac{\partial u_2}{\partial x_2} \\ \frac{1}{2} \left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1} \right) \\ \frac{1}{2} \frac{\partial u_1}{\partial x_3} \end{pmatrix} \quad \text{and} \quad \epsilon_2 = \begin{pmatrix} \frac{1}{2} \left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1} \right) \\ \frac{\partial u_1}{\partial x_1} + 2 \frac{\partial u_2}{\partial x_2} \\ \frac{1}{2} \frac{\partial u_2}{\partial x_3} \end{pmatrix}$$

and the nonlinear viscosity coefficient μ is given by the Glen flow law

$$\mu = \frac{1}{2} A^{-\frac{1}{n}} \epsilon_e^{\frac{1}{n}-1}$$

370 with $n = 3$ being the usual choice. The effective strain rate ϵ_e is given by

$$\epsilon_e^2 = \left(\frac{\partial u_1}{\partial x_1} \right)^2 + \left(\frac{\partial u_2}{\partial x_2} \right)^2 + \frac{\partial u_1}{\partial x_1} \frac{\partial u_2}{\partial x_2} + \frac{1}{4} \left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1} \right)^2 + \frac{1}{4} \left(\frac{\partial u_1}{\partial x_3} \right)^2 + \frac{1}{4} \left(\frac{\partial u_2}{\partial x_3} \right)^2,$$

and A is often chosen to obey the Arrhenius relation

$$A = A(T) = a \exp(-Q/RT),$$

where T denotes the absolute temperature measured in degrees Kelvin, R denotes the universal gas constant, Q denotes the
375 activation energy for creep, and a is an empirical flow constant often used as a tuning parameter.

The system (18) is supplemented by the boundary conditions

$$\begin{aligned} \epsilon_1 \cdot \mathbf{n} = 0 & \quad \text{and} \quad \epsilon_2 \cdot \mathbf{n} = 0 & \quad \text{on } \Gamma_s \\ 2\mu\epsilon_1 \cdot \mathbf{n} + \beta u = 0 & \quad \text{and} \quad 2\mu\epsilon_2 \cdot \mathbf{n} + \beta v = 0 & \quad \text{on } \Gamma_b \\ u = 0 & \quad \text{and} \quad v = 0 & \quad \text{on } \Gamma_\ell, \end{aligned} \quad (19)$$

where β denotes a basal friction parameter.

Once the horizontal components u_1 and u_2 of the velocity are determined, the vertical velocity component w is determined
380 by enforcing incompressibility, i.e., we have that

$$\frac{\partial w}{\partial x_3} = -\frac{\partial u_1}{\partial x_1} - \frac{\partial u_2}{\partial x_2} \quad \text{for } \mathbf{x} \in \Omega. \quad (20)$$

Because the right-hand side is known, this is an ordinary differential equation for w .

Of paramount interest in the modeling of ice sheets is the monitoring of the *temporal evolution* of the ice sheet domain Ω . However, one notices that there are no time derivatives of u_1 and u_2 appearing in (18), i.e., that system is a static one. The reasoning behind this curiosity is twofold. Firstly, we have that the system (18) is coupled to an equation for the temporal evolution of the temperature T within the ice sheet, and also coupled to an equation for the temporal evolution of the top surface of the ice-sheet which engenders changes in the ice-sheet domain Ω . Secondly, the time scale of changes in the temperature is much shorter (e.g., hourly) when compared to the time scale (e.g., at least many days) of changes in the ice sheet domain Ω .

Thus, in a computational model of ice-sheet dynamics, determination of the domain Ω is coupled to that of the velocity \mathbf{u} . Precisely, the temperature and top surface are first advanced from a given domain/velocity pair (Ω, \mathbf{u}) over several time steps, producing an evolution that prescribes a new domain/temperature pair (Ω, T) . Following this, the pair (Ω, T) are used to generate a new velocity \mathbf{u} by solving (18) and (20). While both stages of this process are important, the present experiment focuses on the computation of \mathbf{u} from Ω and T .

4.2 MC and MFMC estimation

The specific application setting we consider is based on Experiment C of the benchmark examples in Leng et. al. (2012); Pattyn et. al. (2008). Here, the ice domain is a rectangular parallelepiped having a square base with side length L and thickness H , which lies on a slanted bed with slope parameter θ . The upper surface boundary is given as

$$z_s(x_1, x_2) = -x_1 \tan \theta,$$

and the basal topography is given as

$$z_b(x_1, x_2) = z_s(x_1, x_2) - H.$$

For constructing the MC and MFMC estimators, we set the length $L = 80\text{km}$ and height $H = 1\text{km}$ and then use uniform tetrahedral grids of the ice domain Ω_t with 120, 60, and 30 grid intervals in each horizontal direction and, correspondingly, 20, 10, and 5 intervals in the vertical direction. As a result, we have that number of vertices, horizontal triangles, and tetrahedra are determined to be

	grid resolution		number of vertices	number of horizontal triangles	number of tetrahedra
405	$120 \times 120 \times 20$	\Rightarrow	307,461	28,800	1,728,000
	$60 \times 60 \times 10$	\Rightarrow	40,931	7,200	216,000
	$30 \times 30 \times 5$	\Rightarrow	5,766	1,800	27,000

The first-order ice-sheet model is discretized using the stabilized P1-P1 finite elements given in Zhang et. al. (2011). To solve the resulting nonlinear system of discrete equations, 15 Picard iteration steps are carried out after which a switch is made to a Newton iteration, up to a maximum of a total of 40 iterations. However, if the residual error decrease is less than 75% relative to the residual error of the previous step, the nonlinear iteration is switched back to a Picard iteration. An example

410 illustration of the discrete solution of this ice-sheet model for specific values of the parameters θ and β is provided in Figure 8 using the highest resolution grid.

Figure 8. A simulation of the ice-sheet model with $\theta = 0.7387$ and $\beta = 901.5232$, discretized at the highest grid resolution. The top two plots display contours of the velocity components u_1 and u_2 , respectively, on the top surface Γ_s . The third plot displays a contour plot of velocity component u_3 . The fourth plot displays a cutaway plot of the velocity magnitude $|\mathbf{u}|$ inside the sheet.

Because the cracking and melting of ice sheets is an important indicator of climate change (Clark et. al. (1999); Hanna et. al. (2013)), we consider the *the output of interest*

$$F_{ice}^1(\mathbf{z}) = \frac{1}{2N_1} \sum_{\ell=1}^{N_1} |\mathbf{u}_n(\mathbf{z})|^2,$$

415 where $N_1 = 307,461$ is the number of vertices of the finest $120 \times 120 \times 20$ grid, $\mathbf{u}_n(\mathbf{z})$ denotes the value of the discrete velocity \mathbf{u} at the n th vertex for any choice of the i.i.d. random vector $\mathbf{z} = (\theta, \beta) \in [0.2, 0.8] \times [800\text{m}, 1200\text{m}]$. This OoI provides a measurement of how energetic the ice sheet is depending on its slope and friction coefficient, and can be loosely related to how vigorously the ice will deform given a configuration specified by \mathbf{z} . We then choose the *quantity of interest* given by

$$Q_{1,ice} = \mathbb{E} [F_{ice}^1(\mathbf{z})]. \quad (21)$$

420 Two surrogates for the ice-sheet model

$$F_{ice}^2(\mathbf{z}) = \frac{1}{2N_2} \sum_{n=1}^{N_2} |\mathbf{u}_n(\mathbf{z})|^2 \quad \text{and} \quad F_{ice}^3(\mathbf{z}) = \frac{1}{2N_3} \sum_{n=1}^{N_3} |\mathbf{u}_n(\mathbf{z})|^2$$

are defined respectively using the coarser $60 \times 60 \times 10$ grid with $N_2 = 40,931$ and the even coarser $30 \times 30 \times 5$ grid with $N_3 = 5,766$. Then, from (3), we have the corresponding three Monte Carlo estimators $\{Q_{1,ice}^{MC}, Q_{2,ice}^{MC}, Q_{3,ice}^{MC}\}$ and, from (4), we have the MFMC estimator Q_{ice}^{MFMC} which makes use of these three MC estimators.

425 At this point, we proceed as was done in Section 3.2. For example, we now have that the approximate costs (measured in wall-clock seconds and averaged over 100 random samples) for computing $F_{ice}^1(\mathbf{z})$, $F_{ice}^2(\mathbf{z})$, and $F_{ice}^3(\mathbf{z})$, as well as the approximate correlations for the three OoIs are given by

$$\mathbf{C} = \begin{pmatrix} C_1 \\ C_2 \\ C_3 \end{pmatrix} = \begin{pmatrix} 285.5 \\ 23.05 \\ 2.690 \end{pmatrix} \quad \text{and} \quad \zeta_1 = \begin{pmatrix} \zeta_{1,1} \\ \zeta_{1,2} \\ \zeta_{1,3} \end{pmatrix} = \begin{pmatrix} 1.00000000 \\ 0.99999796 \\ 0.99996691 \end{pmatrix}.$$

The remaining experimental details are nearly identical to those of Section 3.2. As was the case for the oceanic simulations, 430 the computational expense of these models precludes the collection of unlimited data, so a total of 8000 uniform i.i.d. realizations of \mathbf{z} are drawn of which all models share 200 and the lower-fidelity surrogates share 1000. The results of carrying out MFMC and MC estimation over 250 “independent” runs using this common data set are provided in Table 3 and Figure 9. Here it is especially apparent that the budget-preserving modifications to MFMC that led to the algorithm in Box **B** were necessary, as $B \ll \mathbf{C} \cdot \mathbf{R}$ and only one high-fidelity run is ever selected by the algorithm.

435 Despite this, it is clear from Table 3 and the plots in Figure 9 that, at these small budgets, MFMC estimation produces an estimator which is much more accurate and precise than does MC estimation. This is not surprising because MFMC estimation has the flexibility to load most of its budget onto the cheaper lower-fidelity surrogate models, evaluating them many times in order to bring down the overall variance of their estimates. Again, this provides empirical validation for the use of MFMC estimation over MC estimation when estimating model statistics even in practical cases where data availability is low.

440 5 Concluding Remarks

This paper serves to introduce multifidelity Monte Carlo estimation as an alternative to standard Monte Carlo estimation for quantifying uncertainties in the outputs of climate system models, albeit in very simplified settings. Specifically, we consider benchmark problems for the single-layer shallow water equations relevant to ocean and atmosphere dynamics and we also consider a benchmark problem for the first-order model of ice sheet dynamics. The computational results presented here are 445 promising in that they amply demonstrate the superiority of MFMC estimation when compared to MC estimation on these examples. Furthermore, the use of MFMC as an estimation method will surely be even more efficacious when quantifying uncertainties in more realistic climate modeling settings for which the simulation costs are prohibitively large, e.g., for long-time climate simulations. Thus, our next goal is to apply MFMC estimation to more useful models of climate dynamics (such
