**Abstract:** Aspect-dependent landslide initiation is an interesting finding, and previous studies have attributed this to the mechanical effects of plant roots. In the present study, an overwhelming landslide probability on a south-facing slope over a north-facing slope was found in a localized area with only granite underneath and high cover of *Larix kaempferi*. These observations cannot be attributed to plant roots but may result from factors related to hillslope hydrology. Differential weathering associated with hillslope hydrology behaviors such as rainfall water storage and leakage, ~~pore-pore~~-water pressure, particle component, and hillslope stability fluctuation were used to examine these observations. Remote sensing interpretation using the high-resolution GeoEye-1 image~~-and~~, digitalized topography and field investigations showed that landslides on south-facing slopes have a higher probability, larger basal area, and shallower depth than those on a north-facing slope. The lower limits of the upslope contributing area and slope gradient condition for south-facing landslides were less than those for north-facing landslides. The higher basal areas of south-facing landslides than those of the north-facing landslides may be attributed to the high peak values and slow dissipation of ~~pore-pore~~-water pressure. The absorbed and drained water flow in a given time interval, together with the calculated water storage and leakage during the measured rainy season measured, demonstrate that the soil mass above the failure zone for south-facing slopes is more prone to pore-water pressure, which results in slope failures. In comparison, the two stability fluctuation results from the finite and infinite models further verified that landslides on south-facing slopes may fail under conditions of prolonged antecedent precipitation and intensive rainfall. Meanwhile, those on north-facing slopes may fail only in response to intensive rainfall. The results of this study will deepen our knowledge of aspect-dependent landslide initiation from both classical mechanics and the state of stress.

**Keywords:** Landslide; Pore-water pressure; suction stress; Hydraulic conductivity; Slope stability

## 1 Introduction

In some semi-arid environments of the Northern Hemisphere, aspect-dependent landslide initiation provides valuable insights into the relative importance of different factors in developing accurate landslide susceptibility models (Ebel, 2015; Rengers et al., 2016; Li et al., 2021; Deng et al., 2022). These events provide a thorough understanding of the amount of direct sunlight that translates into differences in vegetation communities, bedrock weathering, and soil development processes (Fu, 1983; Wang, 2008; Bierman and Montgomery, 2014). These earth surface processes indirectly affect hillslope hydrology and landscape dissection at the hillslope scale. Rainfall-induced shallow landslides are geomorphic agents at the hillslope scale and are governed by multiple factors, including hydrology, hillslope materials, bedrock, and vegetation (Birkeland, 1999; Geroy et al., 2011; Lu and Godt, 2013). Currently, the aspect-dependent landslide initiation observed has been predominantly attributed to the mechanical effect of plant roots. This is because the differences in vegetation on the south- and north-facing slopes are easier to examine and more pronounced than other factors (Li et al., 2021; Timilsina et al., 2021; Dai et al., 2022; Deng et al., 2022). However, vegetation succession takes place over substantially longer timescales than soil development and bedrock weathering (Watakabe and Matsushi, 2019). In most cases, the plant roots are not deep enough to ~~penetrate~~ intepenetrat the bedrock (Schwinning, 2010). Hypothesizing for a relatively localized area with the same ecosystem or plant species, aspect-dependent landslide initiation cannot be attributed to plant roots but may

43 result from differences in the properties of hillslope materials due to long-term differential weathering.

44 Aspect-dependent landslides in Frontal Colorado, USA and the Loess Plateau, China, have attracted interest  
45 because vegetation has a considerable influence on landslide distribution. The strong propensity for shallow landslide  
46 initiation on south-facing hillslopes in the two regions is closely related to the present-day tree density, regardless of  
47 the hillslope aspect (Ebel, 2015; Rengers et al., 2016; Deng et al., 2022). In the Colorado Frontal Range, field  
48 observations have shown that south-facing slopes lack thick tree cover and have an abundance of rock outcrops  
49 compared to north-facing slopes. In addition, the soil layer is thinner on south-facing slopes (Coe et al., 2014; Ebel  
50 et al., 2015). The cohesion supplied by the roots is responsible for the connection observed between landslide  
51 distribution and slope aspect (McGuire et al., 2016). On the Loess Plateau, vegetation recovery is one of the main  
52 ecological measures for mitigating sediment loss (Fu et al., 2009). Increased soil strength and hydraulic conductivity  
53 due to strong root networks may enhance the topographic initiation conditions (Montgomery and Dietrich, 1994;  
54 Wang et al., 2020). North- and westward moving storms may potentially produce more intense rainfall on the south-  
55 and east-facing slopes. This assumption may be invalid if an aspect-dependent landslide distribution is present in a  
56 localized catchment with a specific vegetation community. This study highlights the effect of the mechanical function  
57 of plants on landslides. If an aspect-dependent landslide exists in a localized area with vegetation cover comprising  
58 the same plant species alongside a high level of vegetation cover, the aspect-dependent landslide initiation observed  
59 cannot be attributed to the mechanical effect of plant roots.

60 To determine the relationship observed among vegetation, landslides, and slope aspect, the effects of the  
61 physical properties and strength of hillslope materials cannot be excluded. On the northern part of the Loess Plateau,  
62 China, as well as in many other semi-arid environments (Fu, 1983; Heimsath et al., 1997; Wang, 2008), different  
63 types and densities of vegetation and soils develop on north-facing versus south-facing convergent slopes (Fu, 1983;  
64 Heimsath et al., 1997; Wang, 2008). This is because systematic differences in the amount of direct sunlight translate  
65 into differences in physical and chemical weathering. North-facing convergent slopes have lower evaporation rates,  
66 retain snow cover longer in spring, and tend to hold soil moisture longer during the summer growing season. These  
67 differences may result in localized ecosystem communities in the presence of trees or shrubs on grass. South-facing  
68 slopes experience heavier and more frequent hydration, thermal expansion, or freeze-thaw cycles due to day warming  
69 and night cooling and tend to have stronger weathering throughout the year. These differences can result in local  
70 differences in the grain component, soil strength, and soil profile. This has indirect effects at the landslide scale  
71 through the mechanics of excessive pore-water pressure dissipation and sliding surface liquefaction (Terzaghi, 1950;  
72 Sassa, 1984), and hillslope hydrology behavior (Godt et al., 2009; Lee and Kim, 2019). Therefore, the physical  
73 properties of hillslope materials may be attributed to the aspect-dependent landslide initiation observed.

74 ~~All-s~~Shallow landslides are examples of debris flow initiation, which often enlarges their scale by multiple  
75 mechanics (Hung et al. 2005; Iverson et al. 2011). When the slope fails, the ~~pore-pore~~-water pressure abruptly  
76 increases within the shear zone (Iverson and LaHusen, 1989; Wang and Sassa, 2003). If the excessive ~~pore-pore~~-  
77 water pressure persists high over the static pressure for a relatively long duration, the displaced masses enlarge their  
78 volume by widespread liquefaction and transform into debris flows (Bogaard and Greco, 2016). The magnitude of  
79 the ~~pore-pore~~-water pressure is closely related to the scale of the shallow landslide. Therefore, the scale of shallow  
80 landslides can be determined by ~~the role of~~ excessive ~~pore-pore~~-water pressure during the failure process. However,  
81 the aspect-dependent landslide distribution in these two areas refers to the differences in landslide probability rather  
82 than the landslide scale.

83 In the present study, we used a combination of field soil moisture observation, strength measurement, hydraulic  
84 conductivity analysis of hillslope materials, and numerical modeling of slope stability to explain the high potential  
85 for landslide initiation on south-facing slopes relative to north-facing slopes with the same vegetation communities.  
86 Differences in landslide geometry and initiation conditions, in the form of the contributing area above the scar area

87 and the landslide gradient, were shown using field studies and high-resolution GeoEye-1 images. The differential  
 88 weathering-related physical properties and strength of the soil mass, including the dry unit weights, porosity, grain  
 89 size, effective cohesion, and inner friction angle were examined. We have also highlighted the importance of  
 90 excessive pore-pore-water pressure, hillslope hydrology, and stability in explaining the aspect-dependent landslide  
 91 initiation observed. The results of this work will deepen our understanding of aspect-dependent landslide distribution  
 92 in some mountainous areas of the Northern Hemisphere.

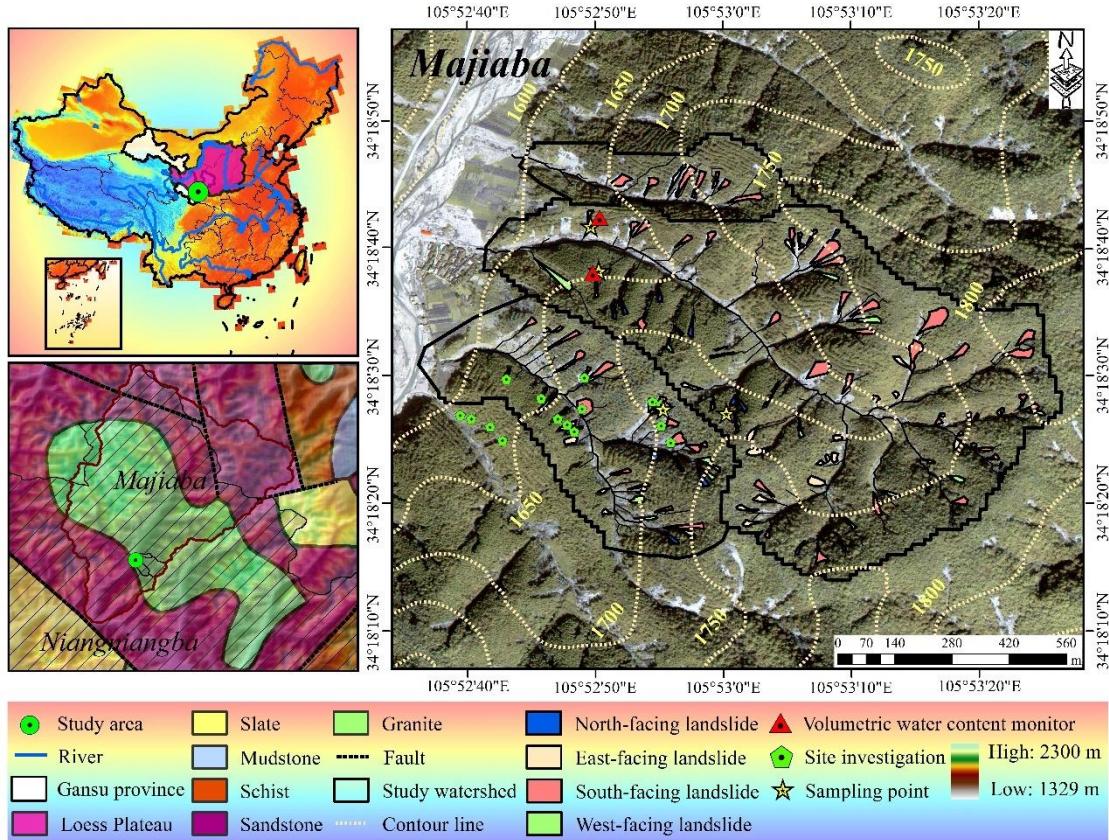

Fig. 1. Location, topography, and simplified lithology of the study area. All maps are created by the authors. The graph of Majiaba was taken using an Unmanned Aerial Vehicle. The territorial domain of China and simplified lithology map are from China Geological [Survey](#). Elevation legend refers to the mountain spanning Niangnianba and Majiaba.

## 2 Study area

The study area is in the mountainous region of Majiaba village, northeast of Niangnianba town, Tianshui City, Gansu Province, Central China. It is also close to the dividing crest of the Yellow and Yangtze Rivers and on the eastern part of the Loess Plateau. The elevation of the mountain near Niangnianba town in the mountain region of the study area ranges from 1329 m to 2300 m. Most of the hillslope is underlain by sandstone, and the stratigraphic units of granite, slate, schist and mudstone account for a smaller area. This area has four distinctive seasons and a semi-humid climate. The annual precipitation is approximately 491.6 mm and predominantly falls during June and August. One branch fault of the Tianshui-Lanzhou fault system runs through the area and has had no rupture records for the last few decades.

The shallow landslides in the study area and nearby surroundings were triggered by the prolonged antecedent precipitation during July 1–24 and the intensive rainstorm on July 25, 2013 (Yu et al., 2014; Guo et al., 2015). Most

shallow landslides in the entire storm spanned the mountain area with a gradient of 20–25 °, located on south-facing slopes and in areas with relatively sparse low-coverage vegetation (Li et al., 2021). Besides, some works found that plant roots may increase the topographical initiation threshold of landslides because of their positive effect on the strength and hydraulic conductivity of The strong root network may promote hydraulic conductivity of the soil–root composite and the landslide initiation condition of the upslope contributing area slope gradient, according to the landslide case studies from the *Larix kaempferi* and *Pinus tabulaeformis* forests (Dai et al., 2022). The three small catchment areas in the Majiaba Watershed are underlain by granite units. The total area is 0.88 km<sup>2</sup> with vegetation cover of over 90% (Fig. 1). The relative relief was approximately 200 m, and the mean hillslope gradient was 37°. The reason why the three catchments in the area were chosen is that the main plant species on the south- and north-facing slope is *Larix kaempferi*, which commonly have highly developed lateral roots with depth < 0.4 m. However, landslides in the three catchments still have a higher propensity for occurrence on south-facing slopes in comparison with the north-facing slopes. This finding differs from the results from Frontal Range, Colorado, USA, and the Central Loess Plateau, where landslides commonly occur in sparsely vegetated areas. Li et al. (2021) only addressed the relationship between landslide probability and vegetation cover at the regional scale, while excluding the importance of the properties of hillslope materials at a more localized scale. Therefore, we hypothesize that such observations in the study area may not be the result of the mechanical effect of plant roots but may be from the distinctive physical properties and strength of hillslope materials due to differential weathering.

### 3 Materials and methods

#### 3.1 Landslide information interpretation

The high resolution GeoEye-1 image (0.5 m × 0.5 m) on October 8, 2013 was orthorectified and the landslide boundary was visually interpreted using ENVI 5.1 and e-Cognition 8. An unmanned aerial vehicle (UAV) was used to obtain a digital elevation model (DEM) with a 5 m resolution. The GeoEye-1 orthographic image and DEM were spatially registered in ArcGIS 10.2 as a standard layer of orthoimage. The landslide initiation condition is represented by the competition between the slope gradient and upslope contribution area ( $A-S$ ):

$$S = kA^{-b} \quad (1)$$

where  $S$  is the local slope (m/m);  $A$  is the contribution area above the landslide head scar (m<sup>2</sup>);  $k$  is an empirical constant related to lithology, vegetation, and climate; and  $b$  is an empirically defined index.

Field studies were conducted to measure the depth of the head scar and sidewall area using tape, and the failure depth was taken as their average. The landslide volume could then be calculated using the interpreted scar area and failure depth measured. Detailed landside information including the landslide number and area probability, landslide volume and width, head scar and sidewall depth, and the upslope contributing area–slope gradient condition for the south- and north-facing slopes were compared.

#### 3.2 Field monitoring and soil sampling

To investigate the hillslope hydrology on south- and north-facing slopes, Frequency Domain Reflectometry (FDR) soil moisture sensors were used in this work to record the volumetric water content. To avoid the randomness of data caused by natural factors such as terrain and vegetation, a total of 16 shallow landslides were investigated to excavate soil profiles and take undisturbed soil samples. Sensors were installed at depths of 30 cm, 70 cm, and 110 cm on the south- and north-facing slopes to monitor the volumetric water content during June and September 2021. Soil moisture monitoring was implemented at two concave sites on the south- and north-facing slopes. The meteorological station was less than 3 km away from the study area to record the rainfall on a 30 min basis. During the sensor installation, undisturbed soil samples near the sensor location were taken for indoor tests, including the dry unit weight, porosity, grain size, shear strength, and hydraulic conductivity. The grain size was analyzed using a Malvern MS 3000 instrument (Malvern, England). In each layer, at least four samples were collected for the

153 consolidated undrained triaxial compression test (CU). Two samples were collected for unsaturated hydraulic  
 154 conductivity measurement using transient release and imbibition tests (Lu and Godt, 2013). Saturated hydraulic  
 155 conductivity was determined using the constant water head method (Table 1).

### 156 3.3 Pore-water pressure dissipation

157 CU tests were performed to obtain the effective cohesion, effective internal friction angle, and pore-water  
 158 pressure water dissipation curves. Soil samples with a diameter of 50 mm and height of 100 mm were first saturated  
 159 in a vacuum pump. They were then consolidated in the chamber of the GDS apparatus at 50, 100, 150, and 200 kPa  
 160 confining pressures and 10 kPa backpressure. During each test, the shearing rate was set to 0.1 mm/min, and the  
 161 device automatically recorded data every 10 s. Owing to the varied particle components and soil texture, the  
 162 increasing and dissipation ratios of pore-water pressure –differentiate a lotvaried. As a high excessive pore-water  
 163 pressure and slow dissipation ratio could cause widespread Coulomb failure within the shear zone, it will influence  
 164 theThis ratio is closely related to the widespread generation of excessive pore-water pressure, which increases the  
 165 landslide scale. A high excessive pore water pressure, rapid increase ratio, and slow dissipation ratio could cause  
 166 widespread Coulomb failure within the sliding zone. To demonstratecompare that the rate of rise and dissipation of  
 167 the pore-pore-water pressure during the CU test increases or dissipates, the ratio is expresses as

$$168 i = \frac{p_{t+\Delta t} - p_t}{\Delta t} \quad (2)$$

169 where  $i$  is the increase or dissipation ratio of the excessive pore-pore-water pressure, and  $p_t$  and  $p_{t+\Delta t}$  are the pore-  
 170 water pressures measured during the time interval of  $\Delta t$ . A higher  $i$  indicates that the pore-water within soil mass  
 171 drainage rapidly and the pore-water pressure will dissipate in a short time. In other words, the  $i$  is a proxy representing  
 172 the hydraulic conductivity.

### 173 3.3 Water storage and drainage

174 The unsaturated permeability of soil mass (diameter 61.8 mm, height 25.4 mm) was measured using the  
 175 Transient Release and Imbibition method (TRIM) (Lu and Godt, 2013). In this test, the water outflow mass was  
 176 measured on a 10 min basis. In each test, air pressures of 250 kPa and 0 kPa corresponded to the drying and wetting  
 177 processes, respectively. The Soil Water Characteristic Curve (SWCC) and Hydraulic Conductivity Function (HCF)  
 178 were obtained using Hydrus 1-D (Wayllace and Lu, 2012). Using the models proposed by Mualem (1976) and van  
 179 Genuchten (1980), the constitutive relations between the suction head ( $h$ ), water content ( $\theta$ ), and hydraulic  
 180 conductivity ( $K$ ) under drying and wetting states can be represented by the following equation:

$$181 \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[ \frac{1}{1 + (\alpha|h|)^n} \right]^{1-n} \quad (3)$$

182 and

$$183 K = K_s \frac{\left\{ 1 - (\alpha|h|)^{n-1} [1 + (\alpha|h|)^n]^{1-n} \right\}^2}{[1 + (\alpha|h|)^n]^{\frac{1}{2} - \frac{1}{2n}}} \quad (4)$$

184 where  $\theta_r$  is the residual moisture content (%),  $\theta_s$  is the saturated moisture content (%),  $\alpha$  and  $n$  are empirical  
 185 fitting parameters,  $\alpha$  is the inverse of the air-entry pressure head,  $n$  is the pore size distribution parameter, and  $K_s$   
 186 is the saturated hydraulic conductivity (cm/s).

187 The soil water storage ( $S_s$ ) and drainage ( $S_d$ ) during a rainfall event can be evaluated by the soil depth and the  
 188 difference between the maximum soil moisture and antecedent soil moisture:

$$189 S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} \quad (5)$$

$$190 S_s = S_e^w \Delta h \quad (6)$$

$$191 S_d = P - S_e^d \Delta h \quad (7)$$

192 where  $S_e$  is the degree of saturation,  $\theta$  is the volumetric moisture content measured (%),  $\Delta h$  is the average soil

193 thickness (400 mm in this study),  $S_e^w$  and  $S_e^d$  are the residual soil moisture in the wetting and drying processes  
 194 (%)  
 195 and  $P$  is the accumulated rainfall (mm).

### 3.4 Stability fluctuation

196 In this study, we applied a finite and infinite stability model to assess the slope stability fluctuation during the  
 197 rainy season as an attempt to examine aspect-dependent landslide initiation from the perspective of classical  
 198 mechanics and the state of stress (Schmidt et al., 2001). The finite-slope model evaluates the stability  $F_s' F_s$ :

$$199 \frac{F_s' F_s}{\tau} = \frac{c_l A_l + c_b A_b + A_b (\rho_s - \rho_w S_e) g z \cos^2 \beta \tan \varphi'}{A_b \rho_s g z \sin \beta \cos \beta} \quad (8)$$

200 where  $\beta$  is the topographic slope angle ( $^\circ$ ),  $A_l$  is the lateral area of side wall,  $\text{m}^2$ ,  $A_b$  is the basal area,  $\text{m}^2$ ,  $z$  is  
 201 the sliding depth (m),  $c_l$  is the sum of the effective soil cohesion and the root additional cohesion along the  
 202 sidewall perimeter (kPa) and adopts the cohesion of layer 1 and layer 2, in the actual calculation of  $c_l$ , according  
 203 to the composition ratio of root soil and bare soil on the side wall of the landslide, the effective cohesion of the root  
 204 soil complex and the effective cohesion of the bare soil are added in corresponding proportion. The mechanical  
 205 parameters of the root soil complex are the mechanical parameters of the soil Layer 1 in Table 1.  $c_b$  is the basal  
 206 soil cohesion (kPa), and adopts the cohesion of layer 3,  $\rho_s$  is the soil particle density,  $\text{g}/\text{cm}^3$ , and  $\rho_w$  is the water  
 207 density,  $\text{g}/\text{cm}^3$ .

208 The infinite slope stability model in this study provides insight into the stress variation resulting from changes  
 209 in the soil suction and water content during infiltration (Lu and Likos, 2006):

$$210 \frac{F_s' F_s''}{\tau} = \frac{\tan \varphi'}{\tan \beta} + \frac{2c'}{\gamma z \sin 2\beta} - \frac{\sigma^s}{\gamma z} (\tan \beta + \cot \beta) \tan \varphi' \quad (9)$$

211 where  $\varphi'$  is the effective friction angle,  $^\circ$ ;  $\beta$  is the topographic slope angle,  $^\circ$ ;  $c'$  is the effective cohesion, kPa;  $\gamma$   
 212 is the unit weight of the soil,  $\text{KN}/\text{m}^3$ ; and  $\sigma^s$  is the suction stress (kPa), expressed as:-

$$213 \sigma^s = -\frac{S_e}{\alpha} (S_e^{n/(1-n)} - 1)^{1/n} \quad (10)$$

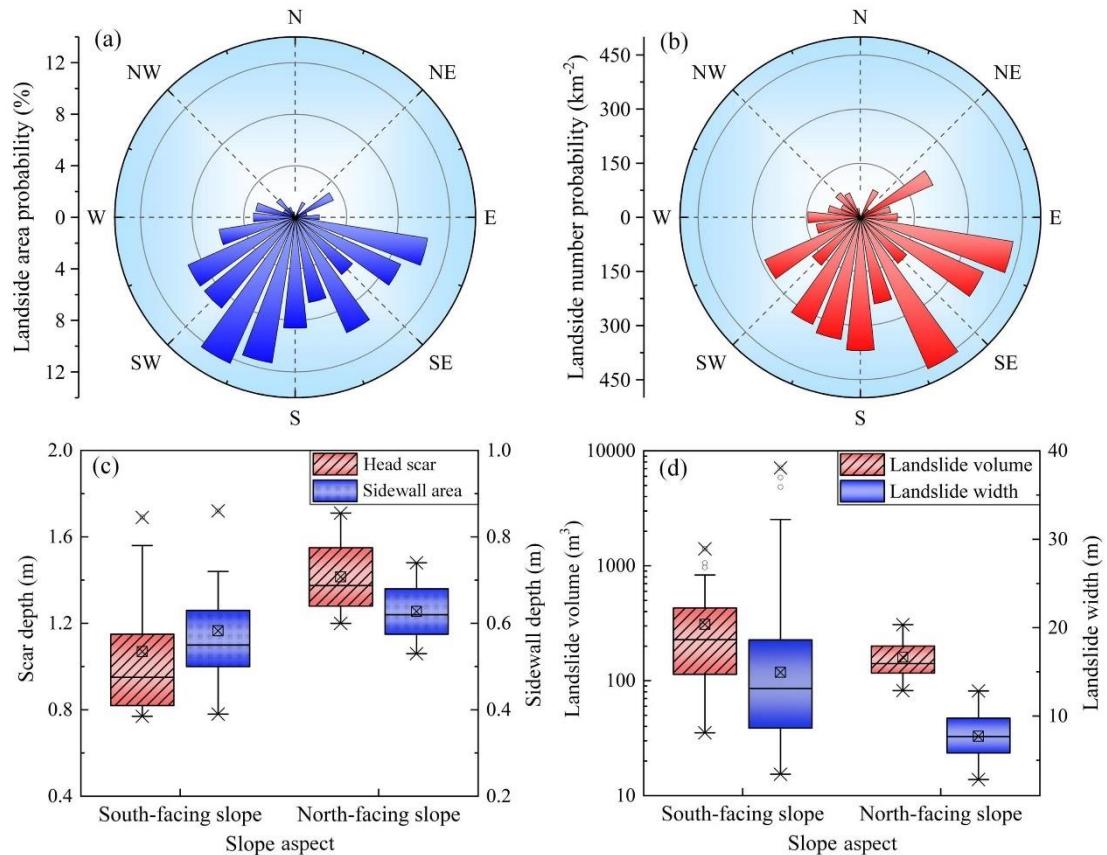

## 214 4 Results

### 215 4.1 Shallow landslides on south- and north-facing slope

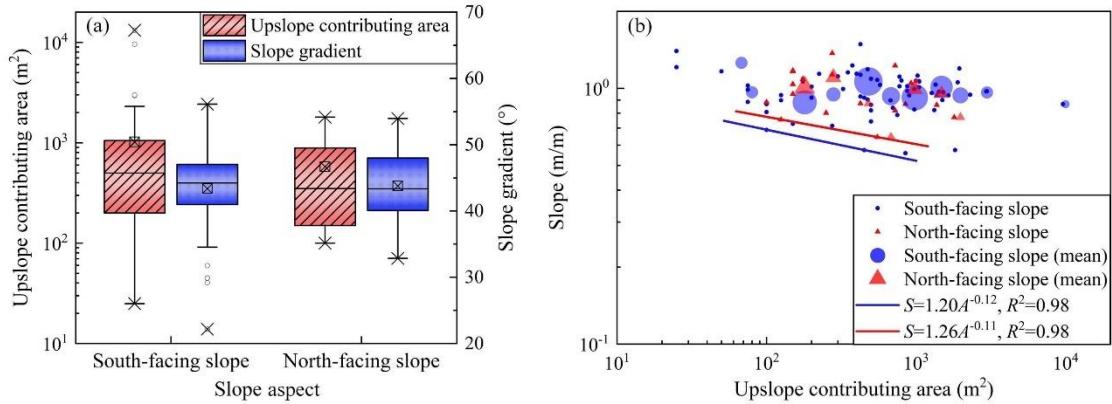

216 In the study area, the direct sunlight does not coincide with the aspect orientation because it is in the north the  
 217 Tropic of Cancer. China belongs to the Northern HemisphereIn the study area, The south-facing slope is defined  
 218 wasbetween 157.5  $^\circ$  and 247.5  $^\circ$  and the north-facing slope ranged fromis between 0  $^\circ$  to 67.5  $^\circ$ , and 292.5  $^\circ$  to 360  $^\circ$   
 219 (0  $^\circ$  is the due north). There were 71 shallow landslides on the south-facing slope and 20 landslides on the north-  
 220 facing slope in the study area. Figure 2a shows that shallow landslides on south-facing slopes have larger spatial  
 221 areas than those on north-facing slopes. Most of the shallow landslides occurred on the south-facing slope (Fig. 2b).  
 222 The volume of landslides on the south-facing slope was greater than that on the north-facing slope. For landslides  
 223 on the south-facing slope, the basal area was 372.64  $\text{m}^2$  and the width was 14.9 m on average. For landslides on the  
 224 north-facing slope, the average basal area was 157.28  $\text{m}^2$  and the width was 7.7 m (Fig. 2c). Although the landslides  
 225 on the south-facing slope had a larger volume and greater width, the depth of the head-scar and sidewall area are no  
 226 greater than those on the north-facing slope. Field studies showed that the averaged depth for landslides on the north-  
 227 facing slope was 1.02 m, which was deeper than the depth of 0.83 m for landslides on south-facing slope (Fig. 2d).  
 228 The landslides on the south-facing slope exhibited an overwhelming propensity for occurrence in terms of number  
 229 and area. Meanwhile, the failure depth was no more than that of the landslides on the north-facing slope.

230 Shallow landslides can be modeled as occurring when sufficient through-flow converges from the upslope  
 231 contribution area to the hollow area and triggers slope instability (Montgomery and Dietrich, 1994). Their  
 232 topographic initiation conditions are controlled by the spatial competition between the slope and upslope contribution

233 being area dependent (Stock and Dietrich 2003 and 2006; Horton et al., 2008). For the shallow landslides in the  
 234 study area, the averaged upslope contributing area and slope gradient did not significantly differ (Fig. 3a). Meanwhile,  
 235 the lower limit line representing the minimum initiation condition for landslides on south-facing slopes was lower  
 236 than that on the north-facing slopes (Fig. 3b). This indicates that a higher upslope contribution area was required to  
 237 provide sufficient through-flow conditions and trigger slope failures on the north-facing slope. Given that the  
 238 landslides in the study area were triggered by prolonged antecedent precipitation and intensive rainfall (Li et al.,  
 239 2021), sufficient rainfall infiltration could result in a high soil water content within the displaced mass, leading to a  
 240 decrease in matric suction and soil strength. The generation of pore-pore-water pressure in response to intense rainfall  
 241 also plays an important role in shallow landslides. Therefore, we have proposed two assumptions to elucidate the  
 242 distribution and scale of aspect-dependent landslides. The first assumption is that the basal area of the landslide may  
 243 be related to the soil strength and high pore-water pressure. This assumption can be tested by the pore-pore-water  
 244 properties, including the pore-pore-water generation potential and dissipation ratio during the failure process. The  
 245 second assumption is that the south-facing slope may have a higher failure potential than the north-facing slope in  
 246 given rainfall process. This can be determined from the stability comparison using equations (8) and (9).

247  
 248 **Fig. 2.** Spatial distribution and geometric characteristics of the landslide: (a) Landslide area probability vs slope  
 249 aspect; (b) landslide number probability vs slope aspect; (c) landslide volume and width vs slope aspect; (d)  
 250 scar depth and sidewall depth vs slope aspect. The edge line of “box” in the box chart shows the 75<sup>th</sup> quantile  
 251 (Q3), median and 25<sup>th</sup> quantile (Q1) from top to bottom. The length of the box is referred to as the inter-quartile  
 252 range (IQR) distance. The crossed square inside the box is the average value. The whiskers extend to the  
 253 maximum and minimum values except the mild outliers. The upper limit and lower limit of whiskers are  
 254  $Q3+1.5IQR$  and  $Q1-1.5IQR$  respectively. The circles are the outliers, and the cross symbol is the maximum  
 255 and minimum values for all the data.

256  
257 **Fig. 3.** Upslope contributing area and slope gradient condition: (a) Upslope contribution area and mean slope vs  
258 slope aspect; and (b) the upslope contributing area vs mean slope gradient above the landslide area. The  
259 definitions of the whiskers are shown in caption of fig. 2. The circles are averaged slopes with the radius size  
260 proportional to the number of landslides. The small cross represent all individual data values. The The large  
261 icons are the average value with the radius size proportional to the number of landslides. The small icons  
262 represent all the individual data values. Power-law linear regression is fitted with the dataset closet to the axis  
263 origin.

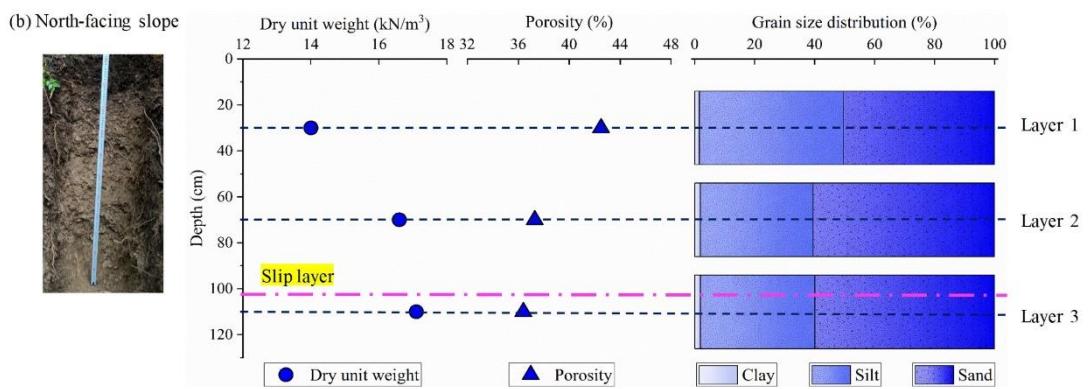

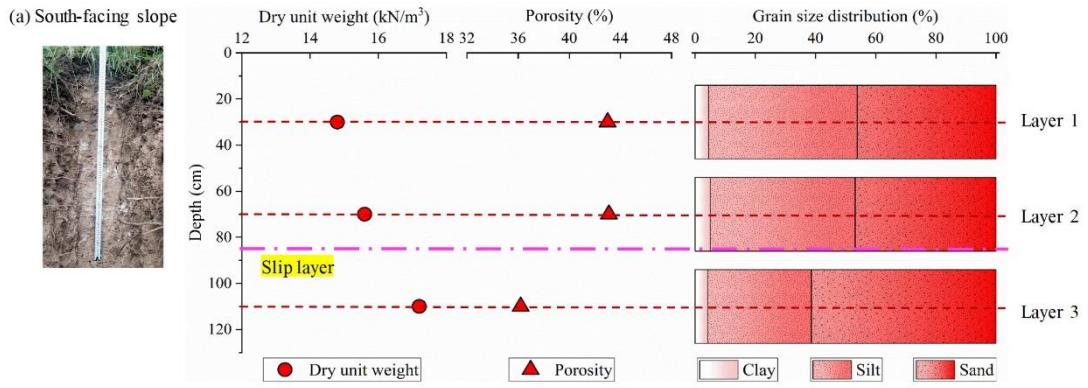

264 used to fit and analyze the lower limit of upslope contributing area and slope gradient condition.

#### 265 4.2 Differences in soil physical properties

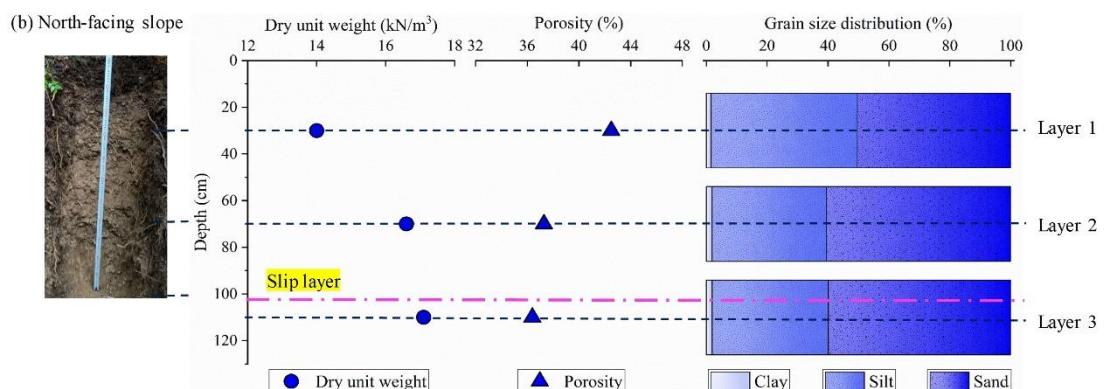

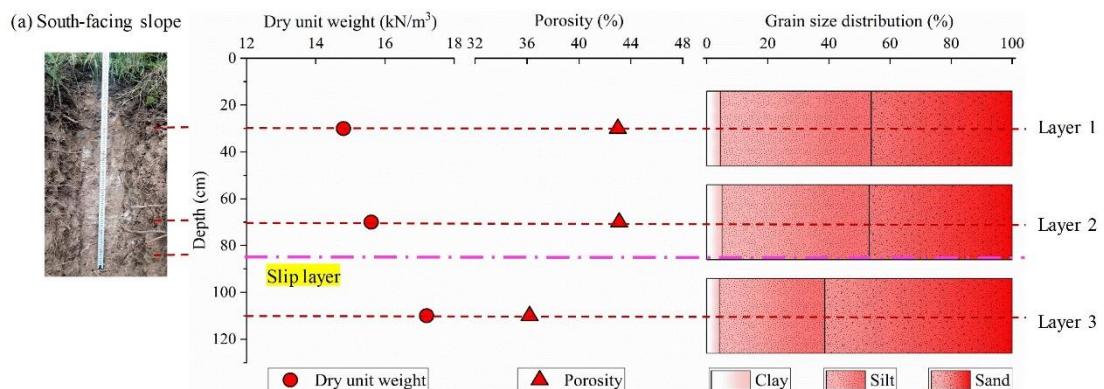

266 To show the differences in the physical properties of the hillslope materials, the dry unit weights, porosity, and  
267 grain size distribution of the soil mass in the three layers on each slope were compared (Fig. 4). The effective  
268 cohesion and inner friction angle were then examined with respect to the particle component (Table 1 and Fig. 5).  
269

270 Table 1 Physical properties and strength parameters of the soil mass

Parameters	South-facing slope			North-facing slope		
	Layer 1	Layer 2	Layer 3	Layer 1	Layer 2	Layer 3
Unit weight of soil ( $kN/m^3$ )	14.8	15.6	17.2	14	16.6	17.1
Porosity (%)	43.0	43.1	36.2	42.5	37.3	36.4
Effective cohesion (kPa)	6.5	17.5	21.2	5.3	9.1	7.9
Effective inner friction angle ( $^\circ$ )	29.8	25	31	27.1	35.2	41
Saturated hydraulic conductivity ( $cm/s$ )	$6.4 \times 10^{-3}$	$6.2 \times 10^{-4}$	$4.4 \times 10^{-4}$	$8.8 \times 10^{-3}$	$1.2 \times 10^{-3}$	$4.3 \times 10^{-3}$

271

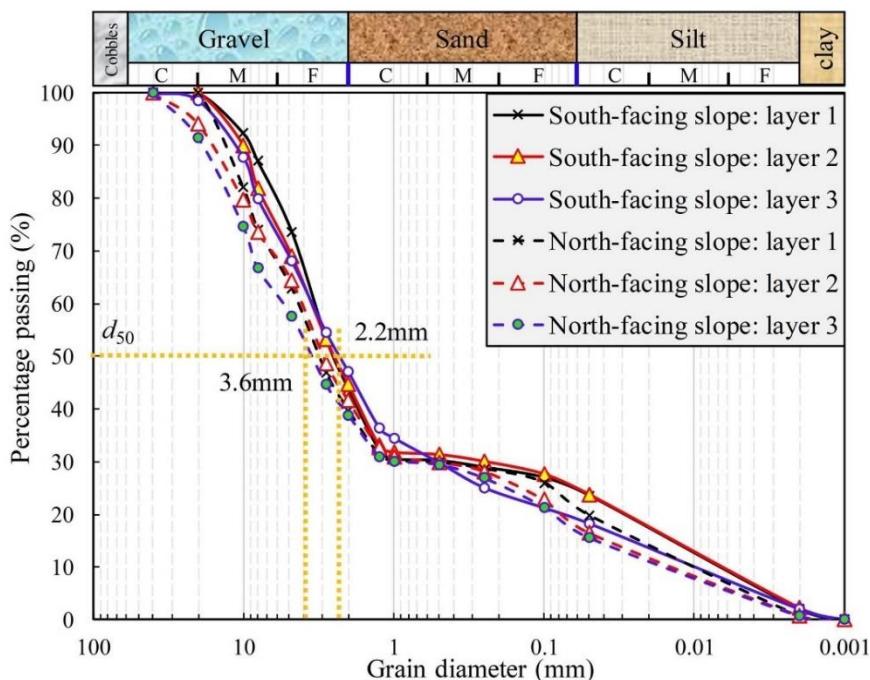

272

273 **Fig. 4.** Differences in the soil properties including dry unit weights, porosity, and grain size in sand, silt, and clay.  
274 (a) Physical properties of soil mass on the south-facing slope; and (b) physical properties of soil mass on the  
275 north-facing slope. The two-soil profile photos were taken by Yanglin Guo during field studies.  
276

277 For the soil mass on the south-facing slope, the dry unit weights increased with soil depth, whereas the porosity  
 278 and saturated hydraulic conductivity decreased (Fig. 4a and Table 1). For Soil layers 1 and 2, the soil textures were  
 279 similar, because the proportions of sand, silt, and clay did not differ significantly. However, the proportion of silt in  
 280 Soil layer No. 3 was no more than that in layers No. 1 and 2, and the sand proportion was higher. The average failure  
 281 depth was above Soil Layer No. 3 and below Soil Layer No. 2. For the soil mass on the north-facing slope, the dry  
 282 unit weight also increased with soil depth. Unlike the south-facing slope, the porosity of the soil mass for the three  
 283 soil layers was approximately 38% and did not differ among them. For the soil texture, the proportion of sand in Soil  
 284 Layer No. 1 was no more than that in Soil Layers No. 2 and 3 (Fig. 4b). The depth of the failure plane was close to  
 285 that of Soil Layer 3.

286 In comparison, one of the main difference was the higher saturated hydraulic conductivity for the soil mass  
 287 above the failure plane on the north-facing slope. This may have resulted from the high porosity and sand proportion.  
 288 This indicates that the rainfall infiltration on the north-facing slope could penetrate faster than that of the south-  
 289 facing slope. The soil mass of the three layers on the south-facing slope had a higher proportion of fine particles than  
 290 those on the north-facing slope if gravel was considered (Fig. 5). The saturated hydraulic conductivity for the soil  
 291 masses from Soil Layers No. 2 and 3 on the south-facing slope was lower than that on the north-facing slope. This  
 292 is expected because the porosity and proportion of fines on the south-facing slope were higher.

293  
 294 Fig. 5. Soil particle component curves

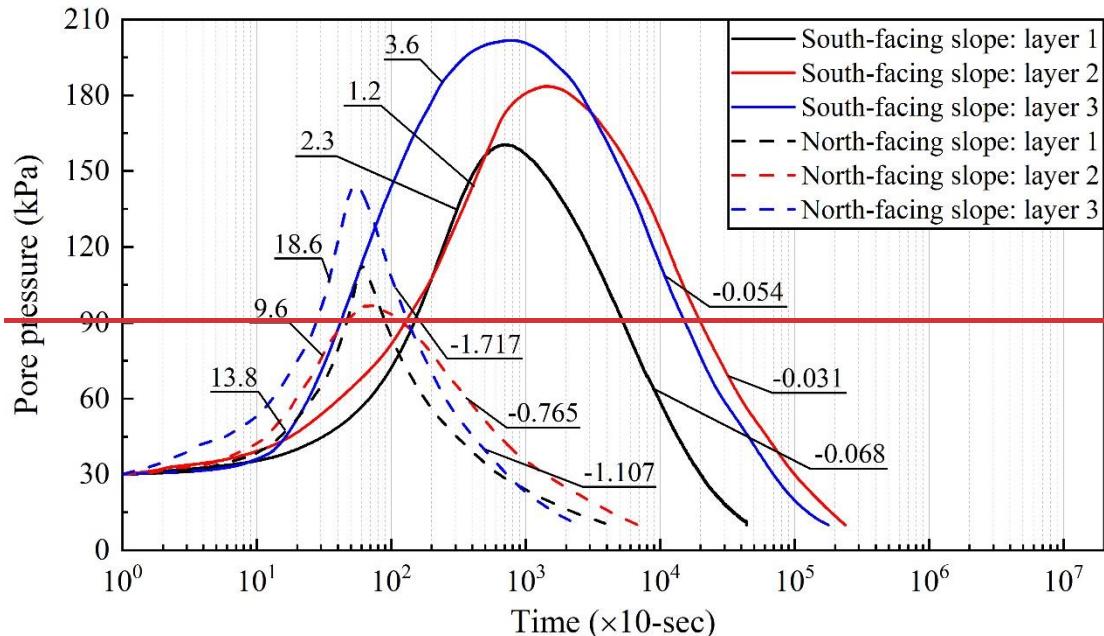

295 According to the results of the triaxial shear test (Table 1), the soil mass in each layer on the north-facing slope  
 296 had a smaller effective cohesion than that on the south-facing slope. The effective cohesion on the failure plane for  
 297 landslides on the south-facing slope may be twice that on the north-facing slope. However, the effective inner friction  
 298 angles for the soil masses of Soil Layers 2 and 3 on the north-facing slope were far greater than those on the south-  
 299 facing slope. These differences in effective cohesion and inner frictional angle may be attributed to the higher clay  
 300 and silt and fewer coarse grains within the soil mass on the south-facing slope.

#### 301 4.3 Pore-pore-water pressure properties

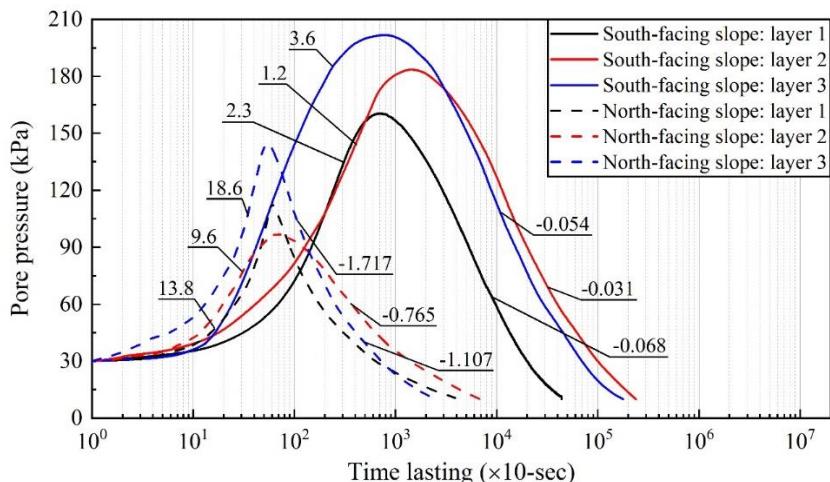

302 The consolidation module of the triaxial shear test was used to measure the generation and dissipation process  
 303 of the pore-pore-water pressure. The principle is to consolidate and drain soil from the initial saturated state. Under  
 304 the same confining pressure, there are pronounced differences in the consolidation rate, consolidation time, and peak

305 rise in pore-pore-water pressure for different soil properties. The results of the pore-pore-water pressure during the  
 306 consolidation process under 200 kPa effective confining pressure were taken compared here (Fig. 6). The peak  
 307 value of pore-pore-water pressure within the soil mass on the south-facing slope was higher than that on the north-  
 308 facing slope. The peak value of the pore-pore-water pressure within the soil mass on the south-facing slope increased  
 309 to 150–200 kPa. However, the peak value of pore-pore-water pressure within the soil mass on the north-facing slope  
 310 was below 150 kPa. Both the rising and decaying rates of pore-pore-water pressure for Soil Mass layers 1 and 2 on  
 311 the south-facing slope were lower than those on the north-facing slope. The rate and decaying rates for Soil Mass  
 312 layer No. 2 on the south-facing slope were 1.2 kPa/10 s and -0.031 kPa/10 s, respectively. However, they were 9.6  
 313 kPa/10 s and -0.765 kPa/10 s for the soil mass on the north-facing slope.

314

315

316

**Fig. 6.** Variation in pore-pore-water pressure under effective confining pressure of 200 kPa by GDS triaxial shear tests. The values in the figure 6 are the average rates of rise and dissipation of pore-water pressure during consolidation calculated by Equation 2. The unit of x-axis marks the time record interval of 10 seconds. The software automatically reads a measured pore pressure data every 10 s, so the graph start from  $10^0 = 10$  s of the X-axis.

317

318

319

320

321

322

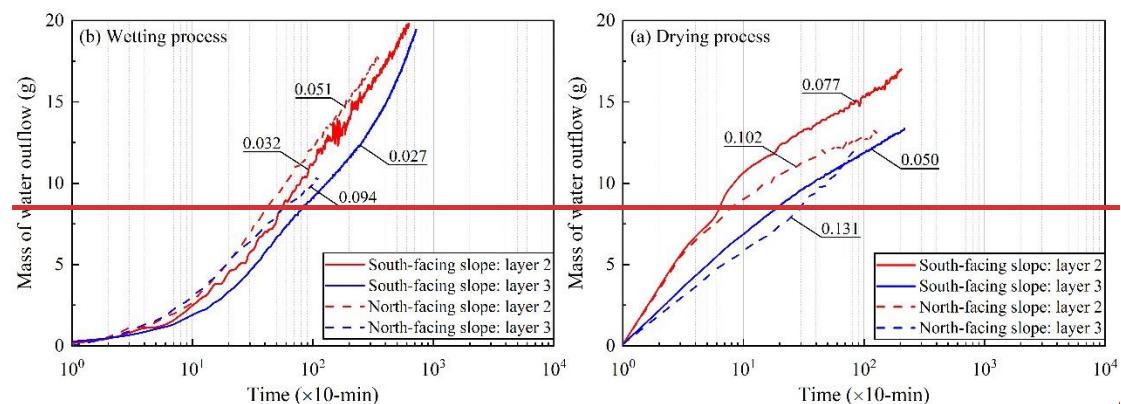

The lower peak pore-pore-water pressure demonstrates the effect of fine particles on the pore-pore-water

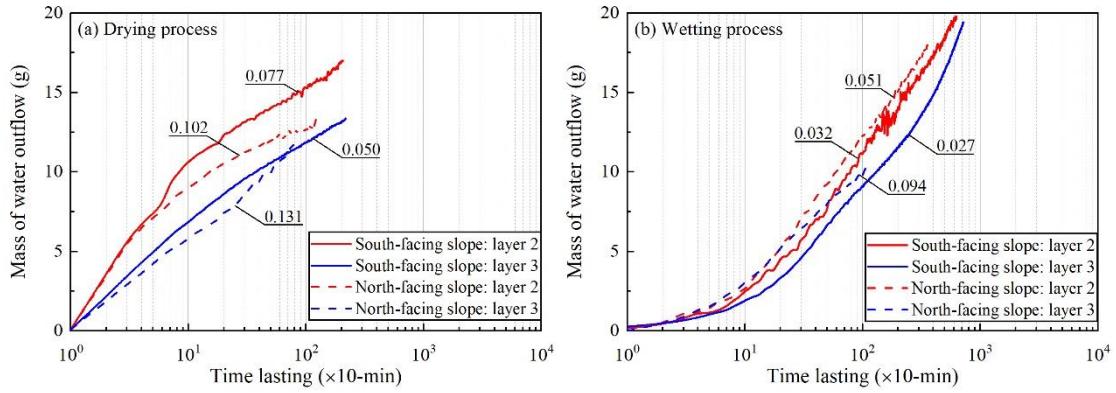

323 pressure, which directly affects landslide mobility and scale. Rainfall-induced landslides result from an increase in  
 324 positive pore-pore-water pressure within the failure plane, which reduces the effective stress and shear strength of  
 325 the soil (Terzaghi, 1950). This often occurs in the undrained soil layer, which can easily cause slope liquefaction  
 326 (Sassa, 1984). The increase in pore-pore-water pressure predominantly depends on the speed of landslide movement,  
 327 soil deformation, and soil permeability. If the shear rate is given, the dissipation rate of pore-pore-water pressure for  
 328 high-permeability soil is faster, and therefore, the increase in pore pressure is smaller (Iverson and LaHusen, 1989;  
 329 Iverson et al., 1997). As shown in Table 1, the saturated hydraulic conductivity for Soil-soil Mmass of Layers No. 2  
 330 and 3 on the north-facing slope was 10 times that of the south-facing slope. Therefore, the peak pore-pore-water  
 331 pressure measured during the test for the soil mass on the south-facing slope was smallerhigher. The soil mass on  
 332 the north-facing slope had higher sand and gravel contents than that on the south-facing slope (Fig. 5). A high clay  
 333 content on the south-facing slope filled the macropores within the soil mass and reduced the pore-pore-water  
 334 discharge rate. Wang and Sassa (2003) found that fine particles play the most important role in the dissipation of  
 335 pore pressure. The pore-pore-water pressure within the saturated sand increased with shear rate. The soil mass with  
 336 high coarse particles produced less pore water pressure than the soil with high fine particles during the shear process.  
 337 Therefore, the high permeability of the soil mass on the norseth-facing slope may result in low\_low peak-peak-pore  
 338 water pressure. The higher fine particles may result in a slow increase and dissipation of the pore-pore-water pressure.  
 339 This slow pore-pore-water pressure dissipation could result in the liquefaction failure of the sliding mass and a larger  
 340 landslide area. –

#### 341 4.4 Unsaturated hydraulic conductivity

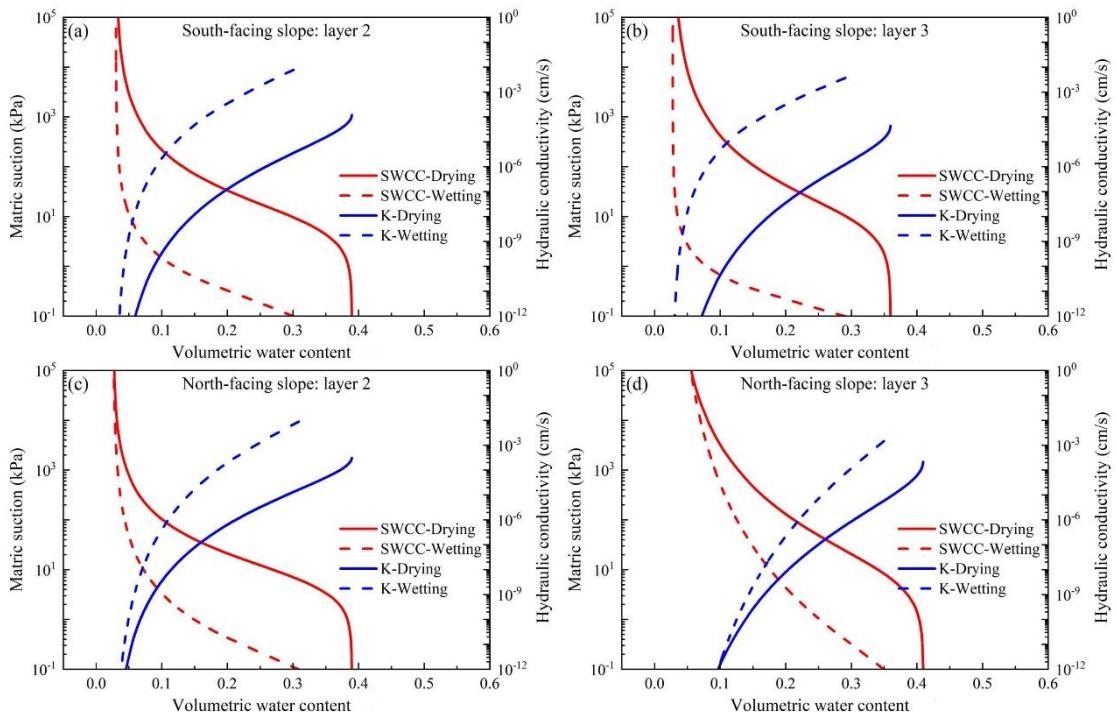

##### 342 4.4.1 Measured water outflow mass

343 Figure 7 shows the water outflow mass measured for a given 10 min period during the drying and wetting  
 344 processes. The water outflow masses measured for Soil Layers 2 and 3 on the north-facing slope were generally  
 345 higher than those on the south-facing slope. For the drying tests using the soil mass of Soil Layers No. 2 and 3 on  
 346 the north-facing slope, the given water outflow masses were 0.102 g/10 min and 0.131 g/10 min, respectively.  
 347 However, the water outflow masses measured for the soil mass of Soil Layers No. 2 and 3 were 0.077 g/10 min and  
 348 0.050 g/10 min, respectively, on the south-facing slope (Fig. 7a). For tests using the same layers of the soil mass in  
 349 the wetting process, the water outflow masses measured were 0.051 g/10 min and 0.094 g/10 min on the north-facing  
 350 slope, respectively, and 0.032 g/10 min and 0.027 g/10 min, respectively, on the south-facing slope (Fig. 7b). Overall,  
 351 the permeability of the soil mass on the north-facing slope was higher than that on the south-facing slope. The same  
 352 results were obtained when the saturated hydraulic conductivities of the soil layers were measured using the constant  
 353 water head method (Table 1).

355  
356 **Fig. 7.** Mass of water outflow during the drying and wetting process: (a) drying tests, (b) wetting tests. [The software](#)  
357 [automatically records reads a measured the mass of water outflow every 10 min each, so the graphx-axis](#)  
358 [starts from 10<sup>0</sup> = 10 min of the X-axis.](#)

359  
360 **Fig. 8.** Soil water curve obtained using the TRIM test: (a) Layer No. 2 on the south-facing slope, (b) Layer No. 3 on  
361 the south-facing slope, (c) Layer No. 2 on the north-facing slope, and (d) Layer No. 3 on the north-facing slope.

#### 363 4.4.2 SWCC and HCF curves

364 [The hydraulic properties such as the Soil Water Characteristic Curve \(SWCC\) and Hydraulic Conductivity](#)  
365 [Function \(HCF\),](#) are critical for the analysis of water flow movement and mechanical behavior of unsaturated soil  
366 material. In this study, the Transient Release and Imbibition Method (TRIM) for unsaturated hydraulic property  
367 measurement [\(Lu and Godt, 2013\)](#). The advantage of the TRIM method is that it combines physical [and numerical](#)  
368 [experiments and calibration.](#) It employs a relatively simple and reliable measurement of transient water content using  
369 an electronic balance to record the signature of transient unsaturated flow. It also takes advantage of the robust  
370 inverse modeling capability to simulate the physical process. The apparatus could accommodate both undisturbed  
371 and remolded samples. The results of this study were obtained using the Hydrus-1D code with the reverse modeling  
372 option, and the Levenberg–Marquardt non-linear optimization algorithm. This minimized the error between the

373 results of the test and the simulation (Wayllace and Lu, 2012). Meanwhile, to ensure the uniqueness of the parameters,  
 374 the algorithm repeatedly runs with different initial parameter estimates until it converges to obtain the same or similar  
 375 results. The prediction results are then compared with the function curves of water flow and time obtained from the  
 376 actual experiment so that they can be combined to meet certain accuracy requirements. In this experiment, the R  
 377 square of the regression between the optimized predicted value and the observed value was greater than 0.99. The  
 378 model constraint effect of the TRIM under two suction increment steps was better, and the parameters obtained by  
 379 the inversion calculation were more accurate (Lu and Godt, 2013). Table 2 shows the soil parameters obtained using  
 380 the Hydrus 1-D inversion.

381 Table 2 Parameters describing the Soil and Water Characteristic Curve (SWCC) and the Hydraulic Conductivity  
 382 Function (HCF) from Hydrus 1-D

Parameters	Definition	South-facing slope		North-facing slope	
		Layer 2	Layer 3	Layer 2	Layer 3
$\theta_r$	Residual moisture	0.0302	0.0278	0.0262	0.0268
$\theta_s^d$	Saturated moisture	0.39	0.36	0.39	0.41
$\theta_s^w$		0.36	0.38	0.39	0.42
$\alpha^d$ (kPa <sup>-1</sup> )	The inverse of the air-entry pressure head	0.0128	0.0117	0.0156	0.0141
$\alpha^w$ (kPa <sup>-1</sup> )		0.78	0.94	1.21	1.86
$n^d$	The pore size distribution parameter	1.49	1.39	1.57	1.27
$n^w$		1.63	1.85	1.43	1.18
$K_s^d$ (cm/s)	Saturated hydraulic conductivity	$1.52 \times 10^{-4}$	$0.64 \times 10^{-4}$	$3.76 \times 10^{-4}$	$4.56 \times 10^{-4}$
$K_s^w$ (cm/s)		$9.58 \times 10^{-2}$	$4.93 \times 10^{-2}$	$4.10 \times 10^{-1}$	$4.68 \times 10^{-1}$

383 Notes: the superscript *d* and *w* indicate drying and wetting states.

384

385 Using these parameters, the SWCC and HCF curves of the soil mass at Soil Layers 2 and 3 on the north- and  
 386 south-facing slopes can be drawn (Fig. 8). Air-entry pressure and residual water content are two important parameters  
 387 that describe the hydrological and mechanical characteristics of the hillslope materials. The air-entry pressure  
 388 represents the critical value at which air enters the saturated soil and starts to drain. For Soil Layer No. 2, the  
 389 difference between the air entry values of the north- and south-facing slopes can reach 14.03 kPa (Figs. 8a and 8c).  
 390 The residual water content and air-entry pressure of the south-facing slope were higher than those of the north-facing  
 391 slope. For Soil Layer No. 3, the soil mass on the north-facing slope has the smallest air-entry pressure, which is 0.51  
 392 times that of the air-entry pressure of the south-facing slope (Figs. 8b and 8d). **The saturated hydraulic conductivities**  
 393 **of Soil Layers No. 2 and 3 on the south-facing slope were lower than those on the north-facing slope in both the**  
 394 **drying and wetting processes. The saturated hydraulic conductivity of the soil mass on the north-facing slope in the**  
 395 **wetting test was one order of magnitude higher than that on the south-facing slope. In Table 1, the saturated**  
 396 **permeability coefficient measured by the constant head test method also shows that the soil mass on north-facing**  
 397 **slope has higher permeability.** These results suggest that it is more difficult for the soil mass **on south-facing slope**  
 398 to absorb and drain water than the soil mass on the north-facing slope.

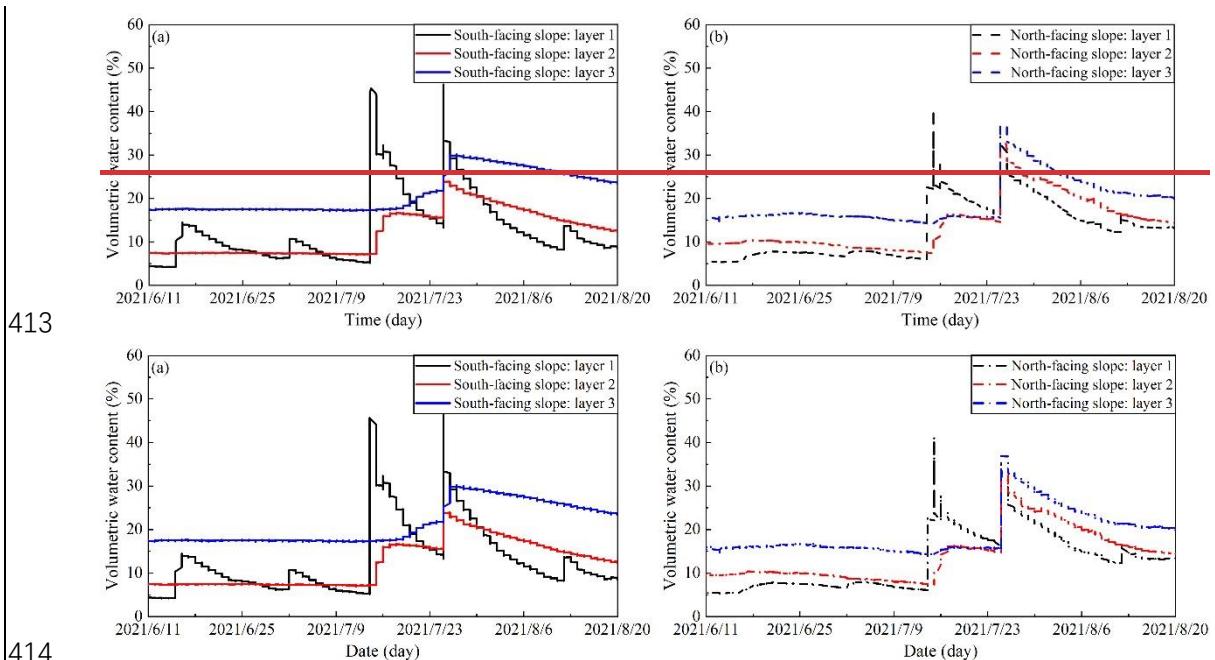

399 Table 2 Parameters describing the Soil and Water Characteristic Curve (SWCC) and the Hydraulic Conductivity  
 400 Function (HCF) from Hydrus 1-D

401 Notes: the superscript *d* and *w* indicate drying and wetting states.

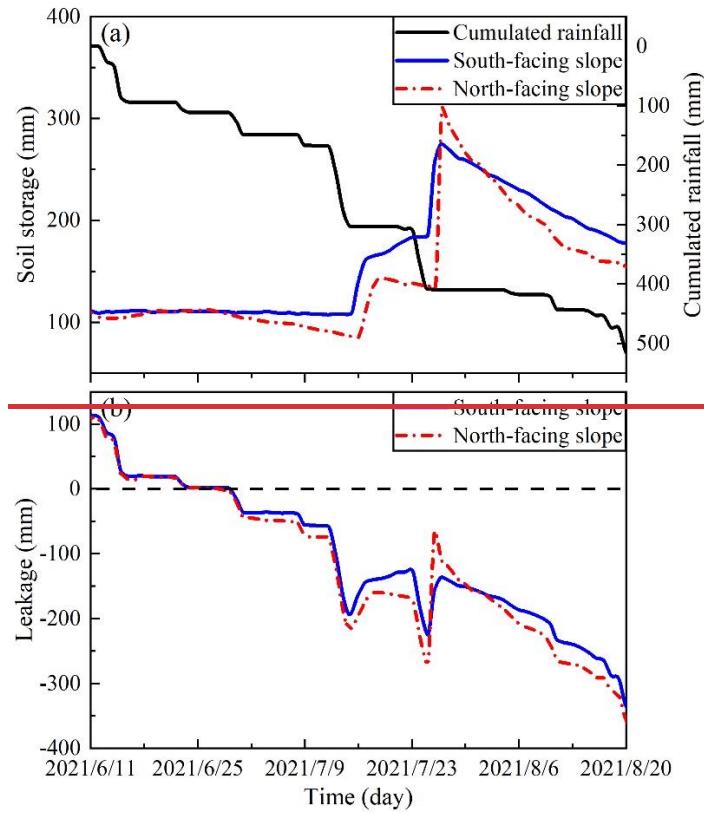

402  
403

404 **4.5 Water storage and drainage**

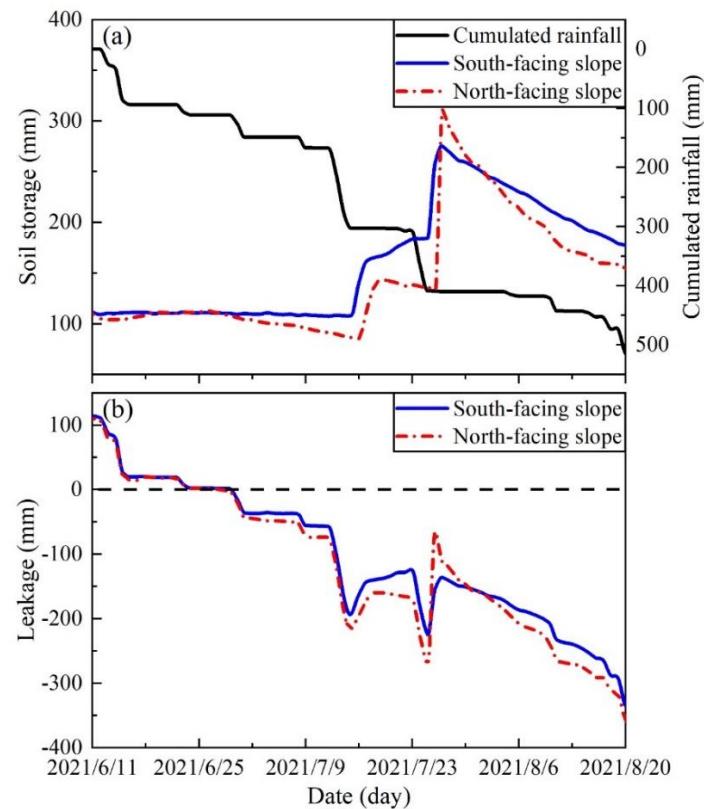

405 To show the water storage during the rainfall process and the water drainage after the rainfall, the timely  
406 recorded soil moisture at various soil layers and the rainfall process during June 11 and August 20 were used (Figs.  
407 9a and 9b). In comparison, this is likely the most important finding, as it shows that the soil becomes nearly saturated  
408 on the south slope, but not on the north slope. This implies that the soil water on the south-facing slope has difficulty  
409 in draining water because of the presence of more fine grains and slow pore-pore-water pressure dissipation. The  
410 stable soil moisture from Soil Layers No. 2 and 3 for both slopes may be attributed to the long dry seasons in the  
411 study area. The daily rainfall amount  $> 30$  mm on July 9 and 23 resulted in an increase in soil moisture for all the  
412 slope layers.

415 **Fig. 9.** Field monitored volumetric water content: (a) Soil moisture on the south-facing slope, and (b) soil moisture  
416 on the north-facing slope.

417

418

419 **Fig. 10.** Seepage model of slope water storage and drainage. (a) soil water storage, (b) soil water drainage

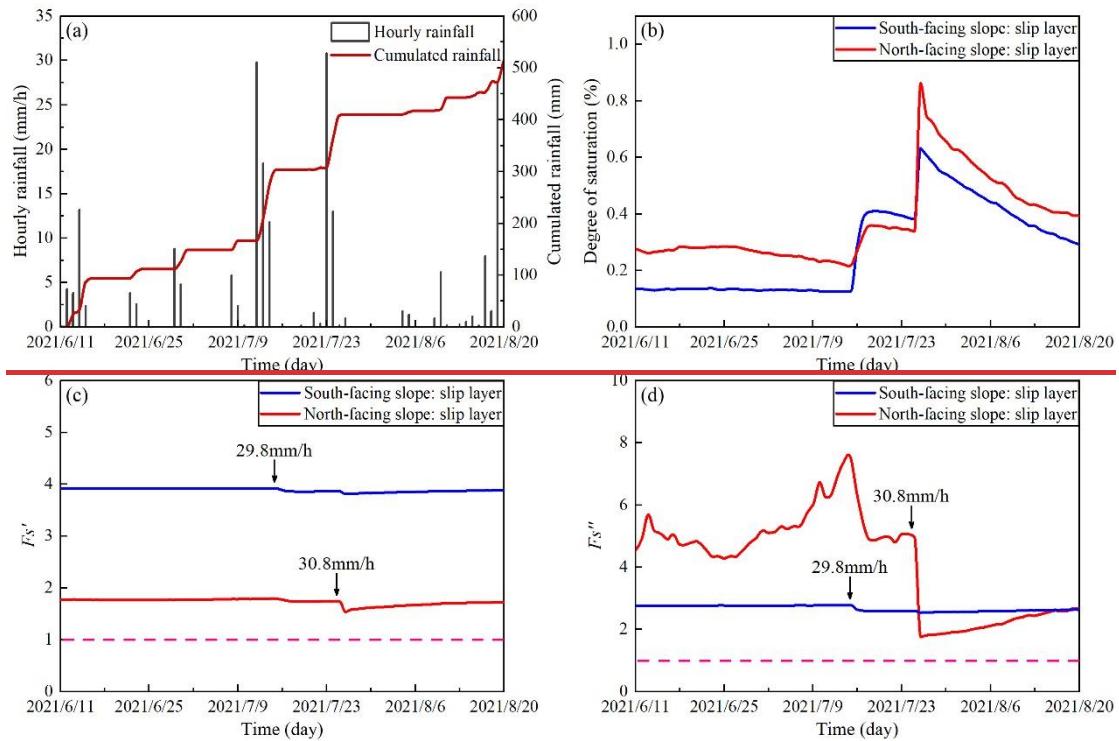

420

421 Figure10a shows that the storied water of the north- and south-facing slopes did not synchronously increase  
422 with accumulated precipitation. When the storied water rapidly increased, the increase in soil water storage of the

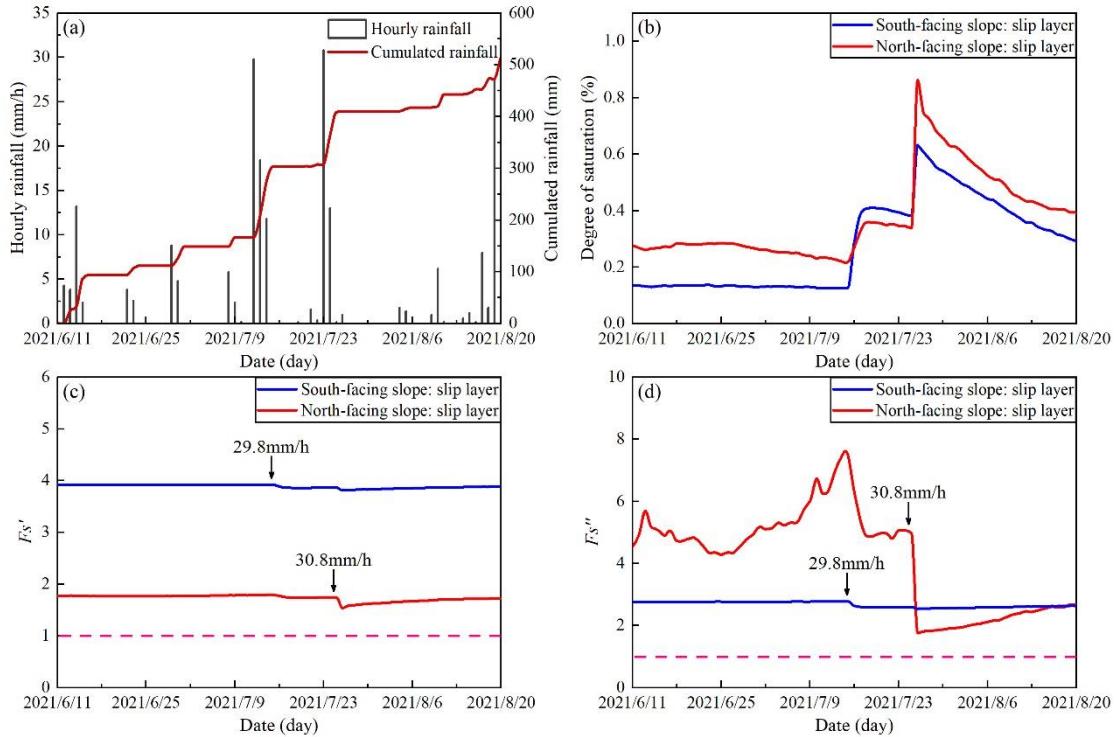

423 north-facing slope was greater than that of the south-facing slope. On July 26, a rainfall of 30.8 mm/h was recorded,  
 424 and the water storage of the slope reached the peak. The peak of the water storage on the north-facing slope was  
 425 higher than that of the south-facing slope. However, when the accumulated rainfall tends to be stable, that is, when  
 426 the rainfall stops for a period of time, the decline rate of the soil water storage on the north-facing slope is  
 427 substantially higher than that on the south-facing slope. The soil water storage of the south-facing slope was always  
 428 higher than that of the north-facing slope during rainfall. During the drainage process, the seepage rate of the north-  
 429 facing slope was greater than that of the south-facing slope (Fig. 10b). Therefore, the south-facing slope had a better  
 430 water storage performance, and the north-facing slope had a higher drainage performance.

#### 431 4.6 Stability fluctuation

432 In this study, the infinite slope model and the finite slope model were used to characterize the sensitivity of  
 433 landslide triggering to determine the main mechanism of high landslide probability on south-facing slopes. The  
 434 infinite slope model can be used to examine the transient stress changes caused by water entering the soil,  
 435 emphasizing the differences in soil permeability (Lu and Likos, 2006; Lu and Godt, 2013). The finite slope model  
 436 focuses on the cohesion of the base surface and lateral periphery of the ground landslide source body, as well as the  
 437 influence of the additional lateral cohesion provided by the vegetation root system for the landslide (Schmidt et al.,  
 438 2001; Dai et al., 2022).

439

440  
441 **Fig. 11.** Change in slope stability fluctuation: (a) rainfall records, (b) degree of saturation,  
442 (c) stability of finite slope model, and (d) stability of infinite slope model. The pink dotted lines indicate the stability index equals to 1.0.  
443

444 Figure 11a shows the rainfall records from June 11 to August 20, 2021. In general, the degree of saturation of  
445 the sliding layer on the south-facing slope was higher than that on the north-facing slope (Fig. 11b). In the finite  
446 model, the stability of the south-facing slope was always higher than that of the north-facing slope (Fig. 11c). In the  
447 infinite model, the stability of the north-facing slope was generally higher than that of the south-facing slope, and  
448 the stability of the north-facing slope fluctuated substantially (Fig. 11d). On July 26, a rainfall event with a maximum  
449 intensity of 30.8 mm/h resulted in a sudden decrease in stability. The estimated stability index of the north-facing  
450 slope decreased to become lower than that of the south-facing slope and then increased afterwards. Although the soil  
451 moisture of the south-facing slope increased substantially during the rainfall event on July 16, the stability fluctuation  
452 was relatively small. This may be related to the relatively strong effective cohesion and smaller pore structure. In  
453 finite slope model, the results have shown that the south-facing slope has a relatively high stability. Overall, the  
454 results of the finite slope model have shown that the south-facing slope has a relatively high stability. This is  
455 predominantly attributed to the effective cohesion of hillslope materials on the south-facing slope being stronger  
456 than that of the north-facing slope although the basal area of the landslide is more than double. However, this result  
457 contradicts is inconsistent with the high landslide density on the south-facing slope in the study area. In fact, the  
458 finite slope model does not consider suction stress, and the effective cohesion of hillslope materials mainly affects  
459 the stability result. In contrast, the results of the infinite slope model asserts that the state of the stress of the soil or  
460 regolith is modified by infiltration and changes in soil matrix suction. Furthermore, the fluctuation in fig. 11d also  
461 proves that the role of infiltration of water into shallow soils and the subsequent pore-water pressure response at  
462 depth is critical to the understanding the transient conditions that lead to shallow slope failure, because the stability  
463 fluctuation amplitude of the south-facing hillslope was smaller than that of the north-facing hillslope. Considering  
464 the soil parameters of the soil moisture curve, the results of the infinite slope model have shown that the north-facing  
465 slope showed a higher level of stability. In the analysis of finite and infinite models, the stability fluctuation  
466 amplitude of the south-facing hillslope was smaller than that of the north-facing hillslope. This indicated that

467 the water movement on the south-facing slope was less active than that of the north-facing slope. Therefore, in the  
468 study area, the change in soil suction stress was more sensitive to slope stability than the change in root soil cohesion.  
469 The change in soil permeability caused by differential weathering of the bedrock could be responsible for aspect-  
470 dependent landslide initiation in the study area.

471 **5 Discussion**

472 The strong propensity for landslides in some arid environments in the Northern Hemisphere is scientifically  
473 interesting, and some researchers have highlighted the contribution of plant roots. This finding is to be expected in  
474 the future in other mountain regions, where water is a limiting factor for local system sustainability. In the Colorado  
475 Frontal range, McGuire et al. (2016) found that the apparent cohesion supplied by roots was responsible for the  
476 connection observed between landslide distribution and slope aspect (Ebel, 2015; Rengers et al., 2016). In the study  
477 area, Li et al. (2021) also found that plant roots may explain the connection observed between vegetation cover and  
478 landslide probability for the entire study area. Dai et al. (2022) found that a strong root network and high saturated  
479 hydraulic conductivity may promote the *A–S* condition of shallow landslides. On the Loess Plateau in China, some  
480 researchers have observed that the strong propensity for shallow landslide initiation is closely related to the present-  
481 day tree density, and plant roots do not penetrate over the failure plane (Guo et al., 2020; Deng et al., 2022). However,  
482 the strong propensity for shallow landslides on north- and south-facing slopes cannot be attributed to plant roots,  
483 because the artificial vegetation on both slopes is the same. Conversely, these observations could be the result of the  
484 soil hydraulic and mechanical properties from differential weathering.

485 This study has contributed to knowledge of the effect of differential weathering on aspect-dependent landslide  
486 initiation from the perspective of soil hydraulic properties, in addition to the mechanical and hydrological effects of  
487 plant roots. Except for the strong propensity for a high number of landslides, shallow landslides on south-facing  
488 slopes have exhibited larger areas ~~and and~~ – greater widths – than those on the north-facing slopes (Fig. 2). This may  
489 be attributed to the fact that the slow dissipation of excessive pore-water pressure because widespread liquefaction  
490 may cause extend the landslide scale. For the thinner slip layer of landslides on south-facing slope, it may result  
491 from differential weathering, because the theoretical maximum or maximum slip layer for strong-cohesive slope  
492 should be larger than weak-cohesive slope at given slope (Iida, 1999; D'Odorico and Fagherazzi, 2003). One of the  
493 reasons may be that cohesive soil mass often hold tight together to displace downslope owing to the strength loss.  
494 The relatively weak-cohesive soil mass often loosens to displace downslope, with the slip layer close to the boundary  
495 between soil mass and bedrock underneath. The effective cohesion of the failure zone on the south-facing slope was  
496 stronger than that on the north-facing slope. The basal area of shallow landslides in the study area may be attributed  
497 to effective cohesion, because some statistical results have shown that incoherent materials favor shallow landslides  
498 with no limitation in size. Meanwhile, cohesive materials favor deep landslides and show a limitation for small sizes.  
499 This may be attributed to the fact that the effective cohesion of the failure zone on the south-facing slope is stronger  
500 than that on the north-facing slope. The size of effective cohesion may affect the base area of landslide. Some  
501 statistical results have shown that for cohesive materials, in order to overcome the constant strength contribution of  
502 cohesion available at any stress level, the landslide needs to be large enough or deep enough to ensure sufficient  
503 shear stress, so that the higher the cohesion, the larger the minimum size of the landslide. At the same time, the soil  
504 thickness sets the upper limit of the depth of the shallow landslide. Most of the shallow landslides are usually  
505 damaged at the bottom of the colluvial soil with reduced permeability and increased strength. At the same time, the  
506 increase of the friction provided by the lateral soil mass of the landslide will also reduce the minimum critical area,  
507 mainly reflected in the width of the sliding slope (Larsen et al., 2010; Frattini and Crosta, 2013; Milledge et al.,  
508 2014). Therefore, due to the high cohesion of the soil layer, the low thickness of the soil layer and the shallow depth  
509 of the colluvial soil on the south-facing slope, once a landslide occurs, it needs to have a large enough scale to

510 ~~overcome the shear stress, while the soil on the north-facing slope has a high friction force, which plays a certain~~  
511 ~~role in the lateral restraint of the landslide (Larsen et al., 2010; Frattini and Crosta, 2013; Milledge et al., 2014).~~

512 However, a stronger effective cohesion tends to promote the A-S conditions of shallow landslides. A larger up-slope  
513 contributing area or steeper gradient is required to trigger slope failure. Figure 3 shows that some shallow landslides  
514 on south-facing slopes fail at lower upslope contributing areas. Therefore, soil hydraulic property-related factors,  
515 such as the rising or dissipation of ~~pore-pore~~-water pressure, water storage, and drainage, may contribute to the  
516 phenomena observed.

517 The saturated hydraulic conductivities obtained by the constant water head and TRIM methods coincide, which  
518 demonstrates that the hillslope material on the north-facing slope has a larger water infiltration (Tables 1 and 2).

519 ~~However, the difference between  $K_s^d$  and  $K_s^w$  is strikingly high and the  $K_s^d$  is smaller. Although the Trim test in this~~  
520 ~~work measures the permeability of soil matrix, the influence of other factors, such as the soil development and~~  
521 ~~weathering, preferential flow pathway and macro pore, cannot be ignored (Lohse and Dietrich, 2005; Maier et al.,~~  
522 ~~2020), and the contribution of such influence on the permeability rate cannot be evaluated at present. However, the~~

523 results of the stability analysis using the finite and infinite models imply that ~~the failure potential of slides on a north-~~  
524 ~~facing slope is lower than that on a south-facing slope, because the stability index of south-facing slope is always~~  
525 ~~close to 1.0 although the stability index fluctuates more heavily than the sounorth-facing slope.~~ These differences  
526 imply that slope failures on a north-facing slope may only occur under intensive rainfall conditions or by a  
527 combination of prolonged antecedent precipitation and short duration intensive rainfall. For potential failures on  
528 south-facing slopes, the combination of prolonged antecedent precipitation and short duration intensive rainfall  
529 should be a potential trigger owing to the low hydraulic conductivity and ~~pore-pore~~-water pressure dissipation. This

530 study highlights the role of hydraulic properties in landslide occurrence. Although the south- and north-facing slopes  
531 are underlain by granite, the physical properties of hillslope materials such as excessive ~~pore-pore~~-water pressure,  
532 strength of sliding mass, soil water storage, and leakage are significantly different. ~~One of the possible limitations~~

533 ~~of this work lies in that the representativeness of the moisture observation and the uncertainty. Considering the~~  
534 ~~multiple factors influencing landslides, the study area is selected with same bedrock underneath and similar plant~~  
535 ~~species. Then, the moisture observation sites were selected on condition that similar soil profile, landscape with~~  
536 ~~majority of landslides and the common topographical conditions. Therefore, this finding cannot be random because~~  
537 ~~the study area has been selected on the condition that it is relatively far from the northern and eastern areas where~~  
538 ~~local soils are predominantly loess deposits, and the study areas of Li et al. (2021) and Dai (2022), where the bedrock~~  
539 ~~underneath differs substantially. This finding cannot be random because the study area has been selected on the~~  
540 ~~condition that it is relatively far from the northern and eastern areas where local soils are predominantly loess~~  
541 ~~deposits, and the study areas of Li et al. (2021) and Dai (2022), where the bedrock underneath differs substantially.~~

542 The main purpose of this work is to elucidate the reason for aspect-dependent landslide initiation from the perspective  
543 of soil hydraulic properties. These differences result from differential weathering owing to the amount of direct  
544 sunlight. Other ~~methodsmechanies~~ such as numerical or relative dating methods and preferential flow in the  
545 macropore distribution could provide new evidence for such observations.

## 546 6 Conclusion

547 Previous research on the strong propensity for shallow landslides on south-facing slopes over north-facing  
548 slopes has highlighted the role of plant roots. In a localized area with the same vegetation including plant roots, they  
549 do not penetrate the failure layer. ~~Such overwhelming landslide phenomenon. These observations cannot be~~  
550 ~~attributed to plant roots~~ and may result from the differential weathering of bedrock under the influence of  
551 hydrothermal conditions. In this study, we jointly explained the ~~influence of bedrock weathering on~~ soil hydraulic  
552 properties from physical and mechanical properties, ~~pore-pore~~-water pressure, unsaturated hydraulic conductivity,

553 water storage and drainage, and slope stability fluctuation during monitoring, and studied landslide initiation related  
554 to slope direction. The following conclusions were drawn:

555 (1) In terms of soil physical and mechanical properties on both slopes, the soil masses on the south-facing slope  
556 ~~have higher silt content than those on were rich in clay and silt contents, whereas the soil mass on~~ the north-facing  
557 slope ~~had relatively high sand content~~. The effective cohesion of the soil mass on the south-facing slope was higher  
558 than that on the north-facing slope, while the effective frictional angle was smaller.—

559 (2) The results of the GDS tests showed that the dissipation rate of ~~pore-pore~~-water pressure for soil mass on  
560 the south-facing slope was substantially lower than that on the north-facing slope. Higher effective cohesion and  
561 slower ~~pore-pore~~-water pressure dissipation may result in a larger basal area for shallow landslides on south-facing  
562 slopes.

563 (3) The soil mass on the south-facing slope had a higher residual water content and air entry pressure, and a  
564 lower saturated hydraulic conductivity than that of the north-facing slope. For water storage and drainage  
565 performance, the storied water from the south-facing slope was higher than that of the north-facing slope, while the  
566 north-facing slope had a higher leakage rate. The results of the stability analysis based on the finite and infinite  
567 models show that the infinite slope model may be suitable for elucidating aspect-dependent landslide distribution in  
568 the study area.

## 569 **Acknowledgements**

574 [Nature Science Foundation of China \(42177309\)](#). The authors sincerely thank the contributions of other colleges,  
575 including Muyang Li, Zhisheng Dai, Lv Miao, Lijuan Wang, and Jiayong Deng, for their previous work near the  
576 study area.

## 577 **Code/Data availability**

578 The raw/processed data in this work cannot be shared at this time, because the data also form part of an ongoing  
579 study.

## 580 **Author contributions**

581 Professor Ma Chao found a strong propensity for shallow landslide initiation on south-facing hillslopes in the study  
582 area and launched a research proposal. Miss Yanglin Guo completed the sampling collection and indoor tests.

## 583 **Competing interests**

584 All authors have declared that there were no conflicts of interests and competing interests.—
