7 **Abstract:** Aspect-dependent landslide initiation is an interesting finding, and previous studies have attributed this to
8 the mechanical effects of plant roots. In the present study, an overwhelming landslide probability on a south-facing
9 slope over a north-facing slope was found in a localized area with only granite underneath and high cover of *Larix*
10 *kaempferi*. These observations cannot be attributed to plant roots but may result from factors related to hillslope
11 hydrology. Differential weathering associated with hillslope hydrology behaviors such as rainfall water storage and
12 leakage, pore water pressure, particle component, and hillslope stability fluctuation were used to examine these
13 observations. Remote sensing interpretation using the high-resolution GeoEye-1 image and digitalized topography
14 showed that landslides on south-facing slopes have a higher probability, larger basal area, and shallower depth than
15 those on a north-facing slope. The lower limits of the upslope contributing area and slope gradient condition for
16 south-facing landslides were less than those for north-facing landslides. The higher basal areas of south-facing
17 landslides than those of the north-facing landslides may be attributed to the high peak values and slow dissipation of
18 pore water pressure. The absorbed and drained water flow in a given time interval, together with the calculated water
19 storage and leakage during the measured rainy season measured, demonstrate that the soil mass above the failure
20 zone for south-facing slopes is more prone to pore-water pressure, which results in slope failures. In comparison, the
21 two stability fluctuation results from the finite and infinite models further verified that landslides on south-facing
22 slopes may fail under conditions of prolonged antecedent precipitation and intensive rainfall. Meanwhile, those on
23 north-facing slopes may fail only in response to intensive rainfall. The results of this study will deepen our knowledge
24 of aspect-dependent landslide initiation from both classical mechanics and the state of stress.

25 **Keywords:** Landslide; Pore pressure; suction stress; Hydraulic conductivity; Slope stability

26 1 Introduction

27 In some semi-arid environments of the Northern Hemisphere, aspect-dependent landslide initiation provides
28 valuable insights into the relative importance of different factors in developing accurate landslide susceptibility
29 models (Ebel, 2015; Rengers et al., 2016; Li et al., 2021; Deng et al., 2022). These events provide a thorough
30 understanding of the amount of direct sunlight that translates into differences in vegetation communities, bedrock
31 weathering, and soil development processes (Fu, 1983; Wang, 2008; Bierman and Montgomery, 2014). These earth
32 surface processes indirectly affect hillslope hydrology and landscape dissection at the hillslope scale. Rainfall-
33 induced shallow landslides are geomorphic agents at the hillslope scale and are governed by multiple factors,
34 including hydrology, hillslope materials, bedrock, and vegetation (Birkeland, 1999; Geroy et al., 2011; Lu and Godt,
35 2013). Currently, the aspect-dependent landslide initiation observed has been predominantly attributed to the
36 mechanical effect of plant roots. This is because the differences in vegetation on the south- and north-facing slopes
37 are easier to examine and more pronounced than other factors (Li et al., 2021; Timilsina et al., 2021; Dai et al., 2022;
38 Deng et al., 2022). However, vegetation succession takes place over substantially longer timescales than soil
39 development and bedrock weathering (Watakabe and Matsushi, 2019). In most cases, the plant roots are not deep
40 enough to penetrate into the bedrock (Schwinning, 2010). Hypothesizing for a relatively localized area with the same
41 ecosystem or plant species, aspect-dependent landslide initiation cannot be attributed to plant roots but may result
42 from differences in the properties of hillslope materials due to long-term differential weathering.

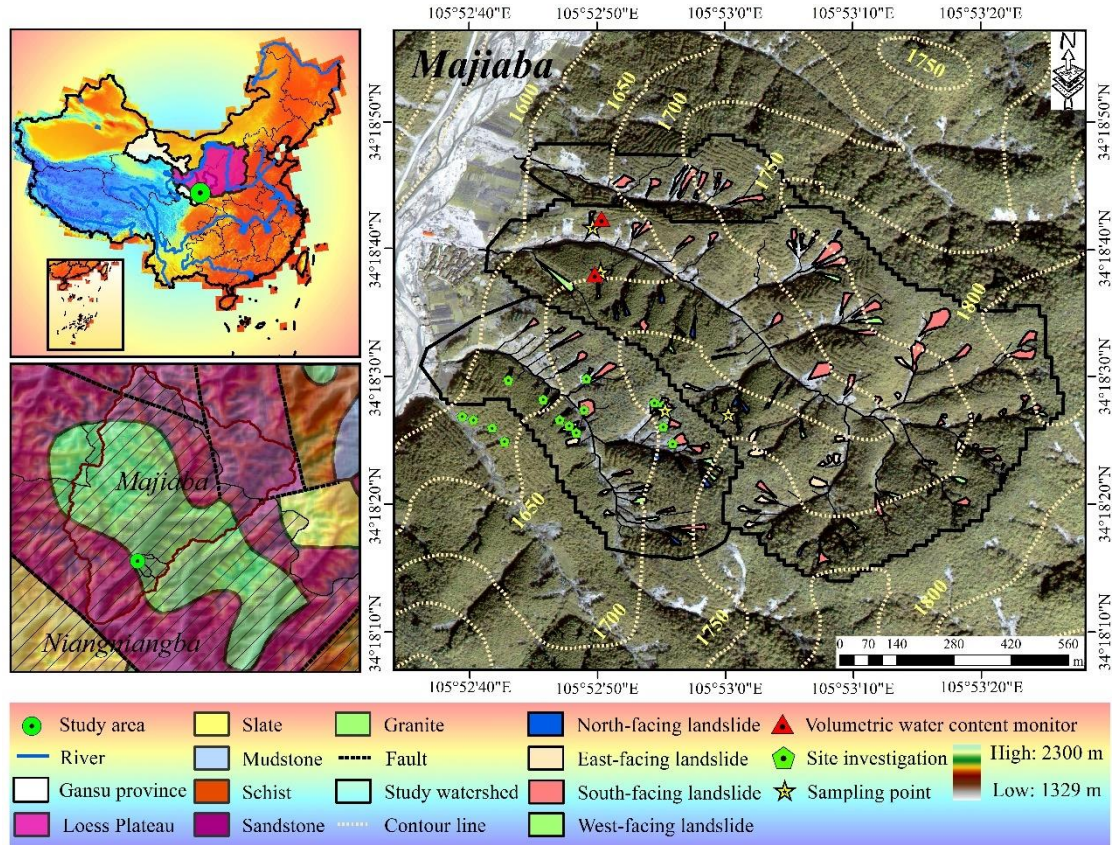

43 Aspect-dependent landslides in Frontal Colorado, USA and the Loess Plateau, China, have attracted interest
44 because vegetation has a considerable influence on landslide distribution. The strong propensity for shallow landslide
45 initiation on south-facing hillslopes in the two regions is closely related to the present-day tree density, regardless of
46 the hillslope aspect (Ebel, 2015; Rengers et al., 2016; Deng et al., 2022). In the Colorado Frontal Range, field
47 observations have shown that south-facing slopes lack thick tree cover and have an abundance of rock outcrops
48 compared to north-facing slopes. In addition, the soil layer is thinner on south-facing slopes (Coe et al., 2014; Ebel
49 et al., 2015). The cohesion supplied by the roots is responsible for the connection observed between landslide
50 distribution and slope aspect (McGuire et al., 2016). On the Loess Plateau, vegetation recovery is one of the main
51 ecological measures for mitigating sediment loss (Fu et al., 2009). Increased soil strength and hydraulic conductivity
52 due to strong root networks may enhance the topographic initiation conditions (Montgomery and Dietrich, 1994;
53 Wang et al., 2020). North- and westward moving storms may potentially produce more intense rainfall on the south-
54 and east-facing slopes. This assumption may be invalid if an aspect-dependent landslide distribution is present in a
55 localized catchment with a specific vegetation community. This study highlights the effect of the mechanical function
56 of plants on landslides. If an aspect-dependent landslide exists in a localized area with vegetation cover comprising
57 the same plant species alongside a high level of vegetation cover, the aspect-dependent landslide initiation observed
58 cannot be attributed to the mechanical effect of plant roots.

59 To determine the relationship observed among vegetation, landslides, and slope aspect, the effects of the
60 physical properties and strength of hillslope materials cannot be excluded. On the northern part of the Loess Plateau,
61 China, as well as in many other semi-arid environments (Fu, 1983; Heimsath et al., 1997; Wang, 2008), different
62 types and densities of vegetation and soils develop on north-facing versus south-facing convergent slopes. This is
63 because systematic differences in the amount of direct sunlight translate into differences in physical and chemical
64 weathering. North-facing convergent slopes have lower evaporation rates, retain snow cover longer in spring, and
65 tend to hold soil moisture longer during the summer growing season. These differences may result in localized
66 ecosystem communities in the presence of trees or shrubs on grass. South-facing slopes experience heavier and more
67 frequent hydration, thermal expansion, or freeze-thaw cycles due to day warming and night cooling and tend to have
68 stronger weathering throughout the year. These differences can result in local differences in the grain component,
69 soil strength, and soil profile. This has indirect effects at the landslide scale through the mechanics of excessive pore
70 water pressure dissipation and sliding surface liquefaction (Terzaghi, 1950; Sassa, 1984), and hillslope hydrology
71 behavior (Godt et al., 2009; Lee and Kim, 2019). Therefore, the physical properties of hillslope materials may be
72 attributed to the aspect-dependent landslide initiation observed.

73 All shallow landslides are examples of debris flow initiation, which often enlarges their scale by multiple
74 mechanics (Hungr et al. 2005; Iverson et al. 2011). When the slope fails, the pore water pressure abruptly increases
75 within the shear zone (Iverson and LaHusen, 1989; Wang and Sassa, 2003). If the excessive pore water pressure
76 persists high over the static pressure for a relatively long duration, the displaced masses enlarge their volume by
77 widespread liquefaction and transform into debris flows (Bogaard and Greco, 2016). The magnitude of the pore
78 water pressure is closely related to the scale of the shallow landslide. Therefore, the scale of shallow landslides can
79 be determined by the role of excessive pore water pressure during the failure process. However, the aspect-dependent
80 landslide distribution in these two areas refers to the differences in landslide probability rather than the landslide
81 scale.

82 In the present study, we used a combination of field soil moisture observation, strength measurement, hydraulic
83 conductivity analysis of hillslope materials, and numerical modeling of slope stability to explain the high potential
84 for landslide initiation on south-facing slopes relative to north-facing slopes with the same vegetation communities.
85 Differences in landslide geometry and initiation conditions, in the form of the contributing area above the scar area
86 and the landslide gradient, were shown using field studies and high-resolution GeoEye-1 images. The differential

87 weathering-related physical properties and strength of the soil mass, including the dry unit weights, porosity, grain
 88 size, effective cohesion, and inner friction angle were examined. We have also highlighted the importance of
 89 excessive pore water pressure, hillslope hydrology, and stability in explaining the aspect-dependent landslide
 90 initiation observed. The results of this work will deepen our understanding of aspect-dependent landslide distribution
 91 in some mountainous areas of the Northern Hemisphere.

92
 93 **Fig. 1.** Location, topography, and simplified lithology of the study area. All maps are created by the authors. The
 94 graph of Majiaba was taken using an Unmanned Aerial Vehicle. The territorial domain of China and
 95 simplified lithology map are from China Geological survey.

96 2 Study area

97 The study area is in the mountainous region of Majiaba village, northeast of Nianguangba town, Tianshui City,
 98 Gansu Province, Central China. It is also close to the dividing crest of the Yellow and Yangtze Rivers and on the
 99 eastern part of the Loess Plateau. Most of the hillslope is underlain by slate, and the stratigraphic units of granite,
 100 sandstone, and mudstone account for a smaller area. This area has four distinctive seasons and a semi-humid climate.
 101 The annual precipitation is approximately 491.6 mm and predominantly falls during June and August. One branch
 102 fault of the Tianshui-Lanzhou fault system runs through the area and has had no rupture records for the last few
 103 decades.

104 The shallow landslides in the study area and nearby surroundings were triggered by the prolonged antecedent
 105 precipitation during July 1–24 and the intensive rainstorm on July 25, 2013 (Yu et al., 2014; Guo et al., 2015). Most
 106 shallow landslides in the entire storm spanned the mountain area with a gradient of 20–25 °, located on south-facing
 107 slopes and in areas with relatively sparse vegetation (Li et al., 2021). The strong root network may promote hydraulic
 108 conductivity of the soil–root composite and the landslide initiation condition of the upslope contributing area–slope
 109 gradient, according to the landslide case studies from the *Larix kaempferi* and *Pinus tabulaeformis* forests (Dai et

110 al., 2022). The three small catchment areas in the Majiaba Watershed are underlain by granite units. The total area is
111 0.88 km² with vegetation cover of over 90% (Fig. 1). The relative relief was approximately 200 m, and the mean
112 hillslope gradient was 37°. The reason why the three catchments in the area were chosen is that the main plant species
113 on the south- and north-facing slope is *Larix kaempferi*, which commonly have highly developed lateral roots with
114 depth < 0.4 m. However, landslides in the three catchments still have a higher propensity for occurrence on south-
115 facing slopes in comparison with the north-facing slopes. This finding differs from the results from Frontal Range,
116 Colorado, USA, and the Central Loess Plateau, where landslides commonly occur in sparsely vegetated areas. Li et
117 al. (2021) only addressed the relationship between landslide probability and vegetation cover at the regional scale,
118 while excluding the importance of the properties of hillslope materials at a more localized scale. Therefore, we
119 hypothesize that such observations in the study area may not be the result of the mechanical effect of plant roots but
120 may be from the distinctive physical properties and strength of hillslope materials due to differential weathering.

121 **3 Materials and methods**

122 **3.1 Landslide information interpretation**

123 The high resolution GeoEye-1 image (0.5 m × 0.5 m) on October 8, 2013 was orthorectified and the landslide
124 boundary was visually interpreted using ENVI 5.1 and e-Cognition 8. An unmanned aerial vehicle (UAV) was used
125 to obtain a digital elevation model (DEM) with a 5 m resolution. The GeoEye-1 orthographic image and DEM were
126 spatially registered in ArcGIS 10.2 as a standard layer of orthoimage. The landslide initiation condition is represented
127 by the competition between the slope gradient and upslope contribution area ($A-S$):

$$128 \quad S = kA^{-b} \quad (1)$$

129 where S is the local slope (m/m); A is the contribution area above the landslide head scar (m²); k is an empirical
130 constant related to lithology, vegetation, and climate; and b is an empirically defined index.

131 Field studies were conducted to measure the depth of the head scar and sidewall area using tape, and the failure
132 depth was taken as their average. The landslide volume could then be calculated using the interpreted scar area and
133 failure depth measured. Detailed landside information including the landslide number and area probability, landslide
134 volume and width, head scar and sidewall depth, and the upslope contributing area–slope gradient condition for the
135 south- and north-facing slopes were compared.

136 **3.2 Field monitoring and soil sampling**

137 To investigate the hillslope hydrology on south- and north-facing slopes, Frequency Domain Reflectometry
138 (FDR) soil moisture sensors were used in this work to record the volumetric water content. To avoid the randomness
139 of data caused by natural factors such as terrain and vegetation, a total of 16 shallow landslides were investigated to
140 excavate soil profiles and take undisturbed soil samples. Sensors were installed at depths of 30 cm, 70 cm, and 110
141 cm on the south- and north-facing slopes to monitor the volumetric water content during June and September 2021.
142 Soil moisture monitoring was implemented at two concave sites on the south- and north-facing slopes. The
143 meteorological station was less than 3 km away from the study area to record the rainfall on a 30 min basis. During
144 the sensor installation, undisturbed soil samples near the sensor location were taken for indoor tests, including the
145 dry unit weight, porosity, grain size, shear strength, and hydraulic conductivity. The grain size was analyzed using a
146 Malvern MS 3000 instrument (Malvern, England). In each layer, at least four samples were collected for the
147 consolidated undrained triaxial compression test (CU). Two samples were collected for unsaturated hydraulic
148 conductivity measurement using transient release and imbibition tests (Lu and Godt, 2013). Saturated hydraulic
149 conductivity was determined using the constant water head method (Table 1).

150 **3.3 Pore water pressure dissipation**

151 CU tests were performed to obtain the effective cohesion, effective internal friction angle, and pore pressure
152 water dissipation curves. Soil samples with a diameter of 50 mm and height of 100 mm were first saturated in a

153 vacuum pump. They were then consolidated in the chamber of the GDS apparatus at 50, 100, 150, and 200 kPa
 154 confining pressures and 10 kPa backpressure. During each test, the shearing rate was set to 0.1 mm/min, and the
 155 device automatically recorded data every 10 s. Owing to the varied particle components and soil texture, the
 156 increasing and dissipation ratios varied. This ratio is closely related to the widespread generation of excessive pore-
 157 water pressure, which increases the landslide scale. A high excessive pore water pressure, rapid increase ratio, and
 158 slow dissipation ratio could cause widespread Coulomb failure within the sliding zone. To demonstrate that the pore
 159 water pressure increases or dissipates, the ratio is

$$160 \quad i = \frac{p_{t+\Delta t} - p_t}{\Delta t} \quad (2)$$

161 where i is the increase or dissipation ratio of the excessive pore water pressure, and p_t and $p_{t+\Delta t}$ are the pore water
 162 pressures measured during the time interval of Δt .

163 3.3 Water storage and drainage

164 The unsaturated permeability of soil mass (diameter 61.8 mm, height 25.4 mm) was measured using the
 165 Transient Release and Imbibition method (TRIM) (Lu and Godt, 2013). In this test, the water outflow mass was
 166 measured on a 10 min basis. In each test, air pressures of 250 kPa and 0 kPa corresponded to the drying and wetting
 167 processes, respectively. The Soil Water Characteristic Curve (SWCC) and Hydraulic Conductivity Function (HCF)
 168 were obtained using Hydrus 1-D (Wayllace and Lu, 2012). Using the models proposed by Mualem (1976) and van
 169 Genuchten (1980), the constitutive relations between the suction head (h), water content (θ), and hydraulic
 170 conductivity (K) under drying and wetting states can be represented by the following equation:

$$171 \quad \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[\frac{1}{1 + (\alpha|h|)^n} \right]^{1 - \frac{1}{n}} \quad (3)$$

172 and

$$173 \quad K = K_s \frac{\left\{ 1 - (\alpha|h|)^{n-1} [1 + (\alpha|h|)^n]^{\frac{1}{n}-1} \right\}^2}{[1 + (\alpha|h|)^n]^{\frac{1}{2} - \frac{1}{2n}}} \quad (4)$$

174 where θ_r is the residual moisture content (%), θ_s is the saturated moisture content (%), α and n are empirical
 175 fitting parameters, α is the inverse of the air-entry pressure head, n is the pore size distribution parameter, and K_s
 176 is the saturated hydraulic conductivity (cm/s).

177 The soil water storage (S_s) and drainage (S_d) during a rainfall event can be evaluated by the soil depth and the
 178 difference between the maximum soil moisture and antecedent soil moisture:

$$179 \quad S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} \quad (5)$$

$$180 \quad S_s = S_e^w \Delta h \quad (6)$$

$$181 \quad S_d = P - S_e^d \Delta h \quad (7)$$

182 where S_e is the degree of saturation, θ is the volumetric moisture content measured (%), Δh is the average soil
 183 thickness (400 mm in this study), S_e^w and S_e^d are the residual soil moisture in the wetting and drying processes
 184 (%), and P is the accumulated rainfall (mm).

185 3.4 Stability fluctuation

186 In this study, we applied a finite and infinite stability model to assess the slope stability fluctuation during the
 187 rainy season as an attempt to examine aspect-dependent landslide initiation from the perspective of classical
 188 mechanics and the state of stress (Schmidt et al., 2001). The finite-slope model evaluates the stability F_s :

$$189 \quad F_s = \frac{S_{sr}}{\tau} = \frac{c_l A_l + c_b A_b + A_b (\rho_s - \rho_w S_e) g z \cos^2 \beta \tan \varphi'}{A_b \rho_s g z \sin \beta \cos \beta} \quad (8)$$

190 where β is the topographic slope angle ($^\circ$), A_l is the lateral area, m^2 , A_b is the basal area, m^2 , z is the sliding
 191 depth (m), c_l is the sum of the effective soil cohesion and the root additional cohesion along the perimeter (kPa),

192 c_b is the basal soil cohesion (kPa), ρ_s is the soil particle density, g/cm³, and ρ_w is the water density, g/cm³.

193 The infinite slope stability model in this study provides insight into the stress variation resulting from changes
194 in the soil suction and water content during infiltration (Lu and Likos, 2006):

$$195 F_s = \frac{\tan \varphi'}{\tan \beta} + \frac{2c'}{\gamma z \sin 2\beta} - \frac{\sigma^s}{\gamma z} (\tan \beta + \cot \beta) \tan \varphi' \quad (9)$$

196 where φ' is the effective friction angle, °; β is the topographic slope angle, °; c' is the effective cohesion, kPa; γ
197 is the unit weight of the soil, KN/m³; and σ^s is the suction stress (kPa), expressed as:

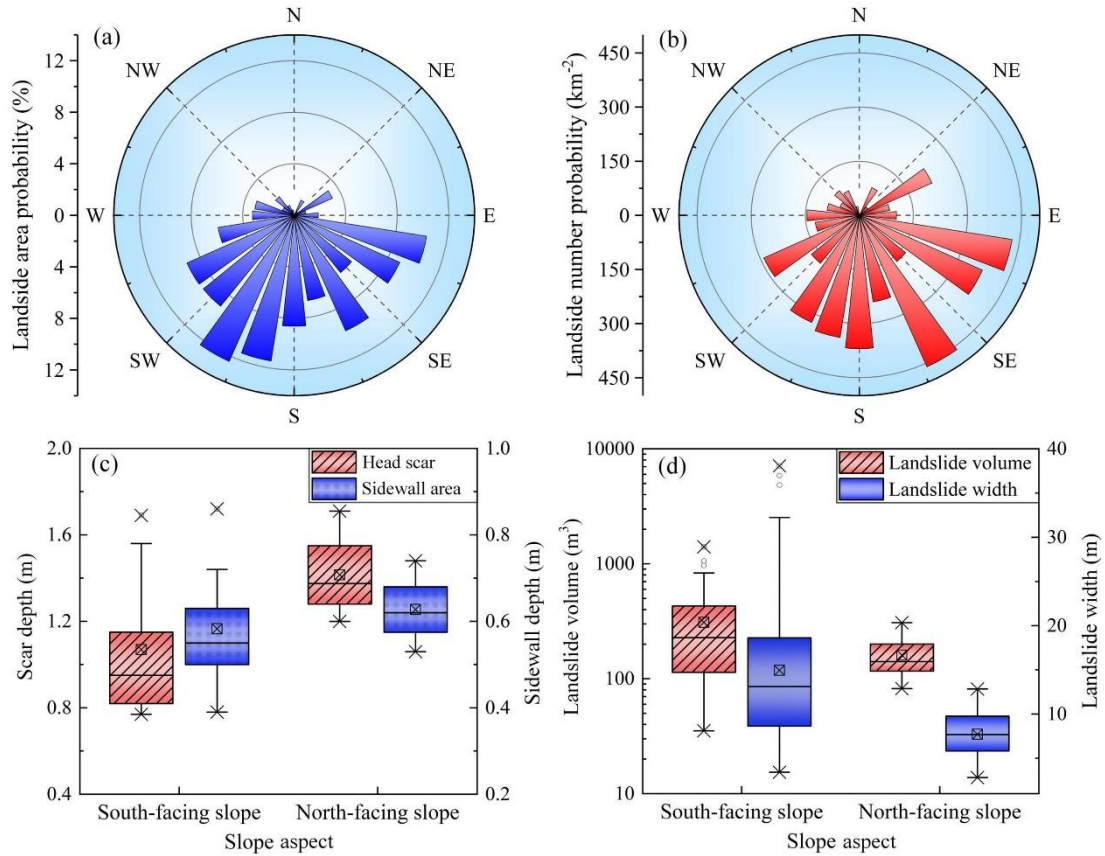

$$198 \sigma^s = -\frac{S_e}{\alpha} \left(S_e^{n/(1-n)} - 1 \right)^{1/n} \quad (10)$$

199 4 Results

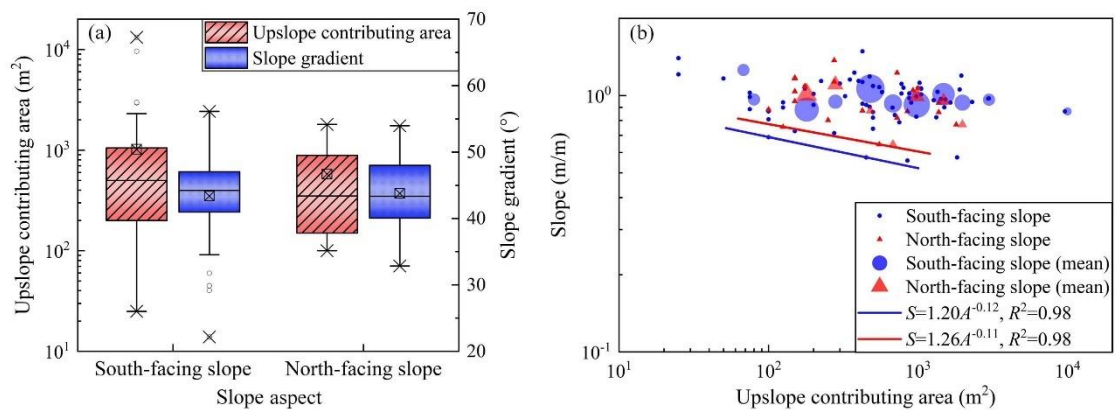

200 4.1 Shallow landslides on south- and north-facing slope

201 In the study area, the south-facing slope was between 157.5 ° and 247.5 ° and the north-facing slope ranged
202 from 0 ° to 67.5 °, and 292.5 ° to 360 ° (0 ° is the due north). There were 71 shallow landslides on the south-facing
203 slope and 20 landslides on the north-facing slope. Figure 2a shows that shallow landslides on south-facing slopes
204 have larger spatial areas than those on north-facing slopes. Most of the shallow landslides occurred on the south-
205 facing slope (Fig. 2b). The volume of landslides on the south-facing slope was greater than that on the north-facing
206 slope. For landslides on the south-facing slope, the basal area was 372.64 m² and the width was 14.9 m on average.
207 For landslides on the north-facing slope, the average basal area was 157.28 m² and the width was 7.7 m (Fig. 2c).
208 Although the landslides on the south-facing slope had a larger volume and greater width, the depth of the head-scar
209 and sidewall area are no greater than those on the north-facing slope. Field studies showed that the averaged depth
210 for landslides on the north-facing slope was 1.02 m, which was deeper than the depth of 0.83 m for landslides on
211 south-facing slope (Fig. 2d). The landslides on the south-facing slope exhibited an overwhelming propensity for
212 occurrence in terms of number and area. Meanwhile, the failure depth was no more than that of the landslides on the
213 north-facing slope.

214 Shallow landslides can be modeled as occurring when sufficient through-flow converges from the upslope
215 contribution area to the hollow area and triggers slope instability (Montgomery and Dietrich, 1994). Their
216 topographic initiation conditions are controlled by the spatial competition between the slope and upslope contribution
217 being area dependent (Stock and Dietrich 2003 and 2006; Horton et al., 2008). For the shallow landslides in the
218 study area, the averaged upslope contributing area and slope gradient did not significantly differ (Fig. 3a). Meanwhile,
219 the lower limit line representing the minimum initiation condition for landslides on south-facing slopes was lower
220 than that on the north-facing slopes (Fig. 3b). This indicates that a higher upslope contribution area was required to
221 provide sufficient through-flow conditions and trigger slope failures on the north-facing slope. Given that the
222 landslides in the study area were triggered by prolonged antecedent precipitation and intensive rainfall (Li et al.,
223 2021), sufficient rainfall infiltration could result in a high soil water content within the displaced mass, leading to a
224 decrease in matric suction and soil strength. The generation of pore pressure in response to intense rainfall also plays
225 an important role in shallow landslides. Therefore, we have proposed two assumptions to elucidate the distribution
226 and scale of aspect-dependent landslides. The first assumption is that the basal area of the landslide may be related
227 to the soil strength and high pore-water pressure. This assumption can be tested by the pore water properties,
228 including the pore water generation potential and dissipation ratio during the failure process. The second assumption
229 is that the south-facing slope may have a higher failure potential than the north-facing slope in a given rainfall process.
230 This can be determined from the stability comparison using equations (8) and (9).

231
 232 **Fig. 2.** Spatial distribution and geometric characteristics of the landslide: (a) Landslide area probability vs slope
 233 aspect; (b) landslide number probability vs slope aspect; (c) landslide volume and width vs slope aspect; (d)
 234 scar depth and sidewall depth vs slope aspect. The edge line of “box” in the box chart shows the 75th quantile,
 235 median and 25th quantile from top to bottom. The length of the box is referred to as the inter-quartile distance.
 236 The crossed square inside the box is the average value. The whiskers extend to the maximum and minimum
 237 values except the outliers. The circles are the outliers, and the cross symbol is the maximum and minimum
 238 values for all the data.

239
 240 **Fig. 3.** Upslope contributing area and slope gradient condition: (a) Upslope contribution area and mean slope vs
 241 slope aspect; and (b) the upslope contributing area vs mean slope gradient above the landslide area. The large
 242 icons are the average value with the radius size proportional to the number of landslides. The small icons
 243 represent all the individual data values.

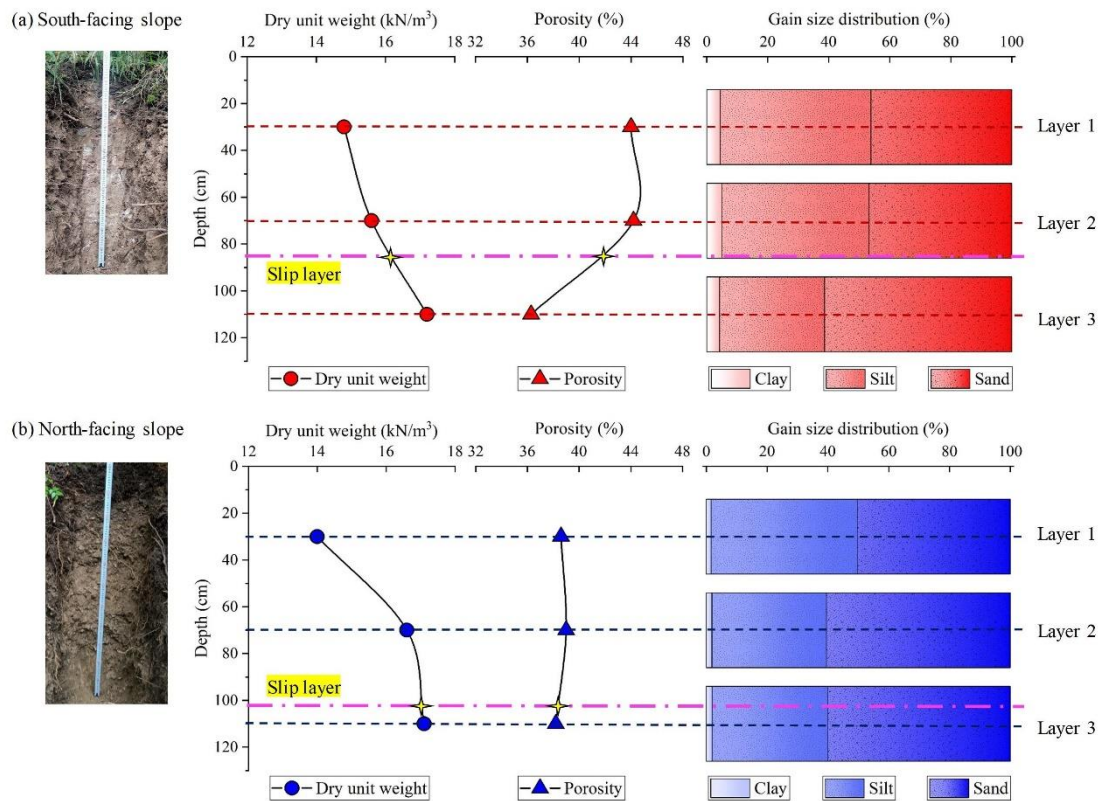

244 4.2 Differences in soil physical properties

245 To show the differences in the physical properties of the hillslope materials, the dry unit weights, porosity, and

246 grain size distribution of the soil mass in the three layers on each slope were compared (Fig. 4). The effective
 247 cohesion and inner friction angle were then examined with respect to the particle component (Table 1 and Fig. 5).
 248
 249

Table 1 Physical properties and strength parameters of the soil mass

Parameters	South-facing slope			North-facing slope		
	Layer 1	Layer 2	Layer 3	Layer 1	Layer 2	Layer 3
Unit weight of soil (kN/m ³)	14.8	15.6	17.2	14	16.6	17.1
Porosity (%)	43.0	43.1	36.2	42.5	37.3	36.4
Effective cohesion (kPa)	6.5	17.5	21.2	5.3	9.1	7.9
Effective inner friction angle (°)	29.8	25	31	27.1	35.2	41
Saturated hydraulic conductivity (cm/s)	6.4×10^{-3}	6.2×10^{-4}	4.4×10^{-4}	8.8×10^{-3}	1.2×10^{-3}	4.3×10^{-3}

250
 251 **Fig. 4.** Differences in the soil properties including dry unit weights, porosity, and grain size in sand, silt, and clay.
 252 (a) Physical properties of soil mass on the south-facing slope; and (b) physical properties of soil mass on the
 253 north-facing slope. The two-soil profile photos were taken by Yanglin Guo during field studies.
 254

255 For the soil mass on the south-facing slope, the dry unit weights increased with soil depth, whereas the porosity
 256 and saturated hydraulic conductivity decreased (Fig. 4a and Table 1). For Soil layers 1 and 2, the soil textures were
 257 similar, because the proportions of sand, silt, and clay did not differ significantly. However, the proportion of silt in
 258 Soil layer No. 3 was no more than that in layers No. 1 and 2, and the sand proportion was higher. The average failure
 259 depth was above Soil Layer No. 3 and below Soil Layer No. 2. For the soil mass on the north-facing slope, the dry
 260 unit weight also increased with soil depth. Unlike the south-facing slope, the porosity of the soil mass for the three
 261 soil layers was approximately 38% and did not differ among them. For the soil texture, the proportion of sand in Soil

262 Layer No. 1 was no more than that in Soil Layers No. 2 and 3 (Fig. 4b). The depth of the failure plane was close to
 263 that of Soil Layer 3.

264 In comparison, one of the main difference was the higher saturated hydraulic conductivity for the soil mass
 265 above the failure plane on the north-facing slope. This may have resulted from the high porosity and sand proportion.
 266 This indicates that the rainfall infiltration on the north-facing slope could penetrate faster than that of the south-
 267 facing slope. The soil mass of the three layers on the south-facing slope had a higher proportion of fine particles than
 268 those on the north-facing slope if gravel was considered (Fig. 5). The saturated hydraulic conductivity for the soil
 269 masses from Soil Layers No. 2 and 3 on the south-facing slope was lower than that on the north-facing slope. This
 270 is expected because the porosity and proportion of fines on the south-facing slope were higher.

271
 272 **Fig. 5.** Soil particle component curves

273 According to the results of the triaxial shear test (Table 1), the soil mass in each layer on the north-facing slope
 274 had a smaller effective cohesion than that on the south-facing slope. The effective cohesion on the failure plane for
 275 landslides on the south-facing slope may be twice that on the north-facing slope. However, the effective inner friction
 276 angles for the soil masses of Soil Layers 2 and 3 on the north-facing slope were far greater than those on the south-
 277 facing slope. These differences in effective cohesion and inner frictional angle may be attributed to the higher clay
 278 and silt and fewer coarse grains within the soil mass on the south-facing slope.

279 **4.3 Pore water pressure properties**

280 The consolidation module of the triaxial shear test was used to measure the generation and dissipation process
 281 of the pore water pressure. The principle is to consolidate and drain soil from the initial saturated state. Under the
 282 same confining pressure, there are pronounced differences in the consolidation rate, consolidation time, and peak
 283 rise in pore water pressure for different soil properties. The results of the pore water pressure during the consolidation
 284 process under 200 kPa effective confining pressure were taken here (Fig. 6). The peak value of pore water pressure
 285 within the soil mass on the south-facing slope was higher than that on the north-facing slope. The peak value of the
 286 pore water pressure within the soil mass on the south-facing slope increased to 150–200 kPa. However, the peak
 287 value of pore water pressure within the soil mass on the north-facing slope was below 150 kPa. Both the rising and
 288 decaying rates of pore water pressure for Soil Mass layers 1 and 2 on the south-facing slope were lower than those

289 on the north-facing slope. The rate and decaying rates for Soil Mass layer No. 2 on the south-facing slope were 1.2
 290 kPa/10 s and -0.031 kPa/10 s, respectively. However, they were 9.6 kPa/10 s and -0.765 kPa/10 s for the soil mass
 291 on the north-facing slope.

292
 293 **Fig. 6.** Variation in pore water pressure under effective confining pressure of 200 kPa by GDS triaxial shear tests.
 294

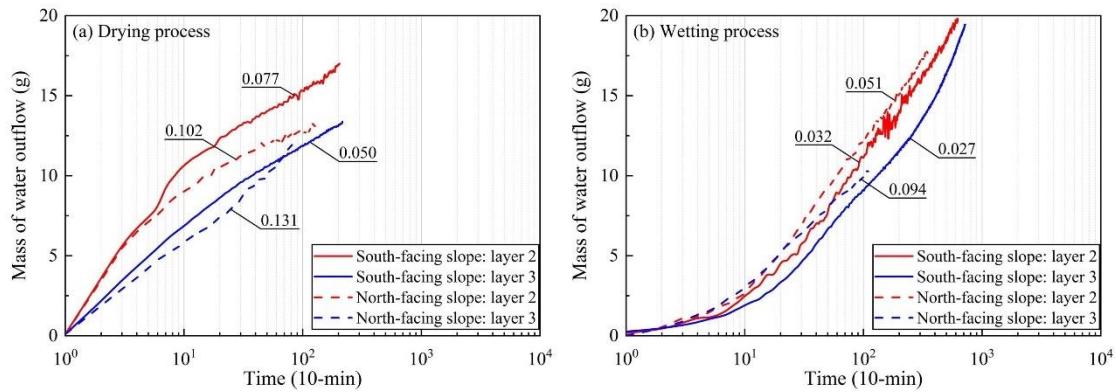

295 The lower peak pore water pressure demonstrates the effect of fine particles on the pore water pressure, which
 296 directly affects landslide mobility and scale. Rainfall-induced landslides result from an increase in positive pore
 297 water pressure within the failure plane, which reduces the effective stress and shear strength of the soil (Terzaghi,
 298 1950). This often occurs in the undrained soil layer, which can easily cause slope liquefaction (Sassa, 1984). The
 299 increase in pore water pressure predominantly depends on the speed of landslide movement, soil deformation, and
 300 soil permeability. If the shear rate is given, the dissipation rate of pore water pressure for high-permeability soil is
 301 faster, and therefore, the increase in pore pressure is smaller (Iverson and LaHusen, 1989; Iverson et al., 1997). As
 302 shown in Table 1, the saturated hydraulic conductivity for Soil Mass Layers No. 2 and 3 on the north-facing slope
 303 was 10 times that of the south-facing slope. Therefore, the peak pore water pressure measured during the test for the
 304 soil mass on the south-facing slope was smaller. The soil mass on the north-facing slope had higher sand and gravel
 305 contents than that on the south-facing slope (Fig. 5). A high clay content on the south-facing slope filled the
 306 macropores within the soil mass and reduced the pore water discharge rate. Wang and Sassa (2003) found that fine
 307 particles play the most important role in the dissipation of pore pressure. The pore water pressure within the saturated
 308 sand increased with shear rate. The soil mass with high coarse particles produced less pore water pressure than the
 309 soil with high fine particles during the shear process. Therefore, the high permeability of the soil mass on the south-
 310 facing slope may result in low peak pore water pressure. The higher fine particles may result in a slow increase and
 311 dissipation of the pore water pressure. This slow pore water pressure dissipation could result in the liquefaction
 312 failure of the sliding mass and a larger landslide area.

313 4.4 Unsaturated hydraulic conductivity

314 4.4.1 Measured water outflow mass

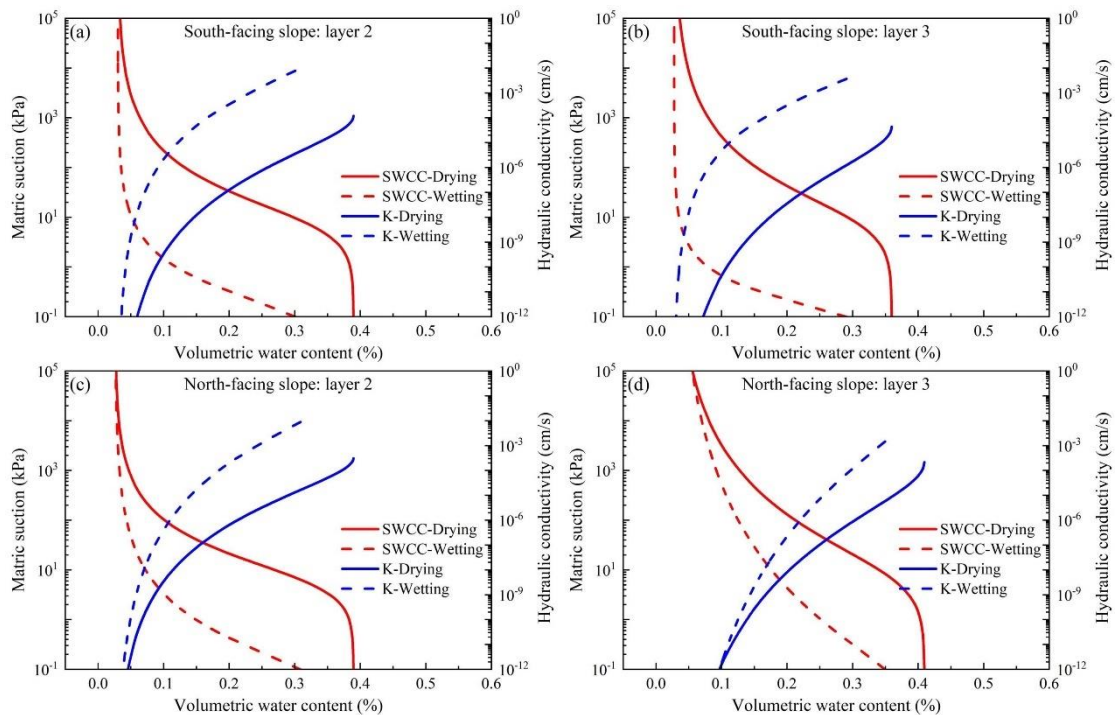

315 Figure 7 shows the water outflow mass measured for a given 10 min period during the drying and wetting
 316 processes. The water outflow masses measured for Soil Layers 2 and 3 on the north-facing slope were generally
 317 higher than those on the south-facing slope. For the drying tests using the soil mass of Soil Layers No. 2 and 3 on

318 the north-facing slope, the given water outflow masses were 0.102 g/10 min and 0.131 g/10 min, respectively.
 319 However, the water outflow masses measured for the soil mass of Soil Layers No. 2 and 3 were 0.077 g/10 min and
 320 0.050 g/10 min, respectively, on the south-facing slope (Fig. 7a). For tests using the same layers of the soil mass in
 321 the wetting process, the water outflow masses measured were 0.051 g/10 min and 0.094 g/10 min on the north-facing
 322 slope, respectively, and 0.032 g/10 min and 0.027 g/10 min, respectively, on the south-facing slope (Fig. 7b). Overall,
 323 the permeability of the soil mass on the north-facing slope was higher than that on the south-facing slope. The same
 324 results were obtained when the saturated hydraulic conductivities of the soil layers were measured using the constant
 325 water head method (Table 1).

326
 327

328

329 **Fig. 8.** Soil water curve obtained using the TRIM test: (a) Layer No. 2 on the south-facing slope, (b) Layer No. 3 on
 330 the south-facing slope, (c) Layer No. 2 on the north-facing slope, and (d) Layer No. 3 on the north-facing slope.

331

332 4.4.2 SWCC and HCF curves

333

Hydraulic properties such as the Soil Water Characteristic Curve (SWCC) and Hydraulic Conductivity Function
 334 (HCF), are critical for the analysis of water flow movement and mechanical behavior of unsaturated soil material.
 335 In this study, the Transient Release and Imbibition Method (TRIM) for unsaturated hydraulic property measurement.

336 The advantage of the TRIM method is that it combines physical and numerical experiments. It employs a relatively
 337 simple and reliable measurement of transient water content using an electronic balance to record the signature of
 338 transient unsaturated flow. It also takes advantage of the robust inverse modeling capability to simulate the physical
 339 process. The apparatus could accommodate both undisturbed and remolded samples. The results of this study were
 340 obtained using the Hydrus-1D code with the reverse modeling option, and the Levenberg–Marquardt non-linear
 341 optimization algorithm. This minimized the error between the results of the test and the simulation (Wayllace and
 342 Lu, 2012). Meanwhile, to ensure the uniqueness of the parameters, the algorithm repeatedly runs with different initial
 343 parameter estimates until it converges to obtain the same or similar results. The prediction results are then compared
 344 with the function curves of water flow and time obtained from the actual experiment so that they can be combined
 345 to meet certain accuracy requirements. In this experiment, the R square of the regression between the optimized
 346 predicted value and the observed value was greater than 0.99. The model constraint effect of the TRIM under two
 347 suction increment steps was better, and the parameters obtained by the inversion calculation were more accurate (Lu
 348 and Godt, 2013). Table 2 shows the soil parameters obtained using the Hydrus 1-D inversion.

349 Using these parameters, the SWCC and HCF curves of the soil mass at Soil Layers 2 and 3 on the north- and
 350 south-facing slopes can be drawn (Fig. 8). Air-entry pressure and residual water content are two important parameters
 351 that describe the hydrological and mechanical characteristics of the hillslope materials. The air-entry pressure
 352 represents the critical value at which air enters the saturated soil and starts to drain. For Soil Layer No. 2, the
 353 difference between the air entry values of the north- and south-facing slopes can reach 14.03 kPa (Figs. 8a and 8c).
 354 The residual water content and air-entry pressure of the south-facing slope were higher than those of the north-facing
 355 slope. For Soil Layer No. 3, the soil mass on the north-facing slope has the smallest air-entry pressure, which is 0.51
 356 times that of the air-entry pressure of the south-facing slope (Figs. 8b and 8d). The saturated hydraulic conductivities
 357 of Soil Layers No. 2 and 3 on the south-facing slope were lower than those on the north-facing slope in both the
 358 drying and wetting processes. The saturated hydraulic conductivity of the soil mass on the north-facing slope in the
 359 wetting test was one order of magnitude higher than that on the south-facing slope. These results suggest that it is
 360 more difficult for the soil mass to absorb and drain water than the soil mass on the north-facing slope.

361 Table 2 Parameters describing the Soil and Water Characteristic Curve (SWCC) and the Hydraulic Conductivity
 362 Function (HCF) from Hydrus 1-D

Parameters	Definition	South-facing slope		North-facing slope	
		Layer 2	Layer 3	Layer 2	Layer 3
θ_r	Residual moisture	0.0302	0.0278	0.0262	0.0268
θ_s^d	Saturated moisture	0.39	0.36	0.39	0.41
θ_s^w		0.36	0.38	0.39	0.42
α^d (kPa ⁻¹)	The inverse of the air-entry pressure head	0.0128	0.0117	0.0156	0.0141
α^w (kPa ⁻¹)		0.78	0.94	1.21	1.86
n^d	The pore size distribution parameter	1.49	1.39	1.57	1.27
n^w		1.63	1.85	1.43	1.18
K_s^d (cm/s)	Saturated hydraulic conductivity	1.52×10^{-4}	0.64×10^{-4}	3.76×10^{-4}	4.56×10^{-4}
K_s^w (cm/s)		9.58×10^{-2}	4.93×10^{-2}	4.10×10^{-1}	4.68×10^{-1}

363 Notes: the superscript *d* and *w* indicate drying and wetting states.

364

365

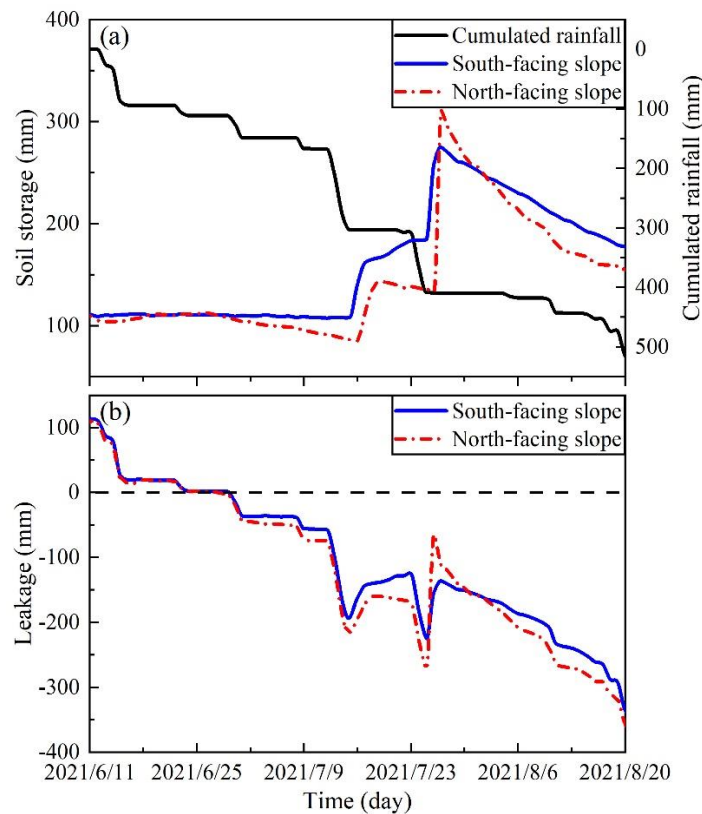

366 4.5 Water storage and drainage

367 To show the water storage during the rainfall process and the water drainage after the rainfall, the timely
 368 recorded soil moisture at various soil layers and the rainfall process during June 11 and August 20 were used (Figs.
 369 9a and 9b). In comparison, this is likely the most important finding, as it shows that the soil becomes nearly saturated
 370 on the south slope, but not on the north slope. This implies that the soil water on the south-facing slope has difficulty
 371 in draining because of the presence of more fine grains and slow pore water pressure dissipation. The stable soil
 372 moisture from Soil Layers No. 2 and 3 for both slopes may be attributed to the long dry seasons in the study area.
 373 The daily rainfall amount > 30 mm on July 9 and 23 resulted in an increase in soil moisture for all the slope layers.

374

375 **Fig. 9.** Field monitored volumetric water content: (a) Soil moisture on the south-facing slope, and (b) soil moisture
 376 on the north-facing slope.

377

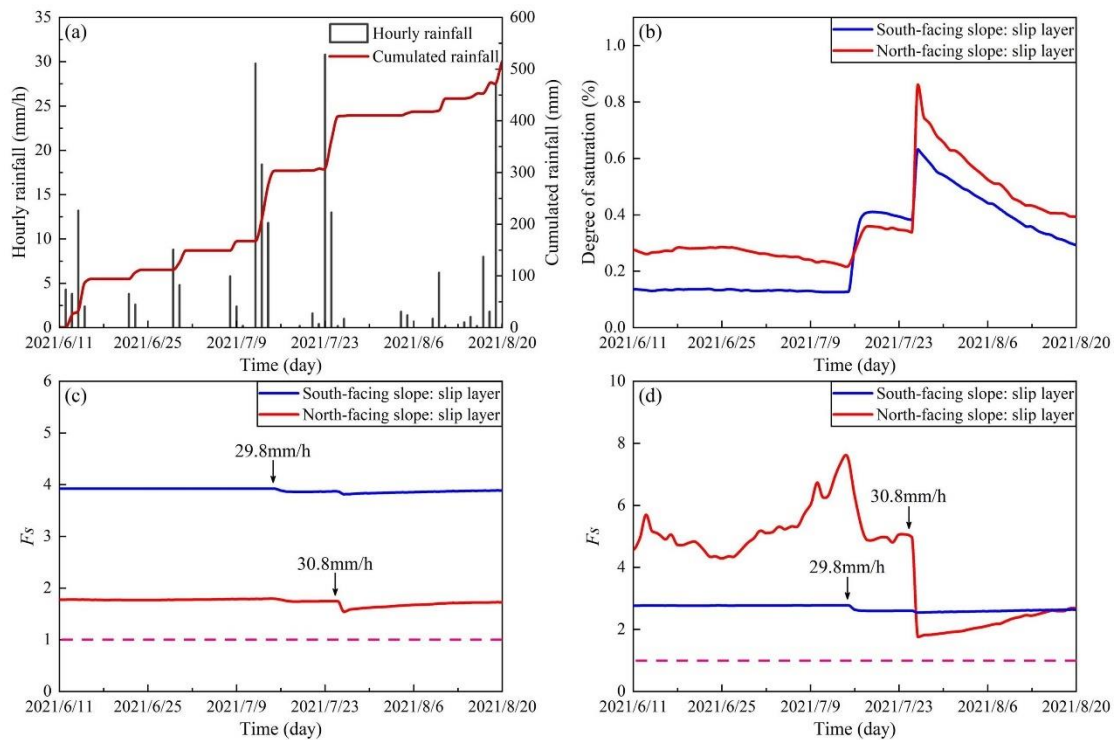

378 **Fig. 10.** Seepage model of slope water storage and drainage. (a) soil water storage, (b) soil water drainage
 379

380 Figure 10a shows that the storied water of the north- and south-facing slopes did not synchronously increase
 381 with accumulated precipitation. When the storied water rapidly increased, the increase in soil water storage of the
 382 north-facing slope was greater than that of the south-facing slope. On July 26, a rainfall of 30.8 mm/h was recorded,

383 and the water storage of the slope reached the peak. The peak of the water storage on the north-facing slope was
 384 higher than that of the south-facing slope. However, when the accumulated rainfall tends to be stable, that is, when
 385 the rainfall stops for a period of time, the decline rate of the soil water storage on the north-facing slope is
 386 substantially higher than that on the south-facing slope. The soil water storage of the south-facing slope was always
 387 higher than that of the north-facing slope during rainfall. During the drainage process, the seepage rate of the north-
 388 facing slope was greater than that of the south-facing slope (Fig. 10b). Therefore, the south-facing slope had a better
 389 water storage performance, and the north-facing slope had a higher drainage performance.

390 4.6 Stability fluctuation

391 In this study, the infinite slope model and the finite slope model were used to characterize the sensitivity of
 392 landslide triggering to determine the main mechanism of high landslide probability on south-facing slopes. The
 393 infinite slope model can be used to examine the transient stress changes caused by water entering the soil,
 394 emphasizing the differences in soil permeability (Lu and Likos, 2006; Lu and Godt, 2013). The finite slope model
 395 focuses on the cohesion of the base surface and lateral periphery of the ground landslide source body, as well as the
 396 influence of the additional lateral cohesion provided by the vegetation root system for the landslide (Schmidt et al.,
 397 2001; Dai et al., 2022).

398
 399 **Fig. 11.** Change in slope stability fluctuation: (a) rainfall records, (b) degree of saturation, (c) stability of finite slope
 400 model, and (d) stability of infinite slope model.

401
 402 Figure 11a shows the rainfall records from June 11 to August 20, 2021. In general, the degree of saturation of
 403 the sliding layer on the south-facing slope was higher than that on the north-facing slope (Fig. 11b). In the finite
 404 model, the stability of the south-facing slope was always higher than that of the north-facing slope (Fig. 11c). In the
 405 infinite model, the stability of the north-facing slope was generally higher than that of the south-facing slope, and
 406 the stability of the north-facing slope fluctuated substantially (Fig. 11d). On July 26, a rainfall event with a maximum
 407 intensity of 30.8 mm/h resulted in a sudden decrease in stability. The estimated stability index of the north-facing
 408 slope decreased to become lower than that of the south-facing slope and then increased afterwards. Although the soil
 409 moisture of the south-facing slope increased substantially during the rainfall event on July 16, the stability fluctuation

410 was relatively small. This may be related to the relatively strong effective cohesion and smaller pore structure.
411 Overall, the results of the finite slope model have shown that the south-facing slope has a relatively high stability.
412 This is predominantly attributed to the effective cohesion of hillslope materials on the south-facing slope being
413 stronger than that of the north-facing slope although the basal area of the landslide is more than double. However,
414 this result is inconsistent with the high landslide density on the south-facing slope. Considering the soil parameters
415 of the soil moisture curve, the results of the infinite slope model have shown that the north-facing slope showed a
416 higher level of stability. In the analysis of finite and infinite models, the stability fluctuation amplitude of the south-
417 facing hillslope was smaller than that of the north-facing hillslope This indicated that the water movement on the
418 south-facing slope was less active than that of the north-facing slope. Therefore, in the study area, the change in soil
419 stress was more sensitive to slope stability than the change in root soil cohesion. The change in soil permeability
420 caused by differential weathering of the bedrock could be responsible for aspect-dependent landslide initiation in the
421 study area.

422 **5 Discussion**

423 The strong propensity for landslides in some arid environments in the Northern Hemisphere is scientifically
424 interesting, and some researchers have highlighted the contribution of plant roots. This finding is to be expected in
425 the future in other mountain regions, where water is a limiting factor for local system sustainability. In the Colorado
426 Frontal range, McGuire et al. (2016) found that the apparent cohesion supplied by roots was responsible for the
427 connection observed between landslide distribution and slope aspect (Ebel, 2015; Rengers et al., 2016). In the study
428 area, Li et al. (2021) also found that plant roots may explain the connection observed between vegetation cover and
429 landslide probability for the entire study area. Dai et al. (2022) found that a strong root network and high saturated
430 hydraulic conductivity may promote the $A-S$ condition of shallow landslides. On the Loess Plateau in China, some
431 researchers have observed that the strong propensity for shallow landslide initiation is closely related to the present-
432 day tree density, and plant roots do not penetrate over the failure plane (Guo et al., 2020; Deng et al., 2022). However,
433 the strong propensity for shallow landslides on north- and south-facing slopes cannot be attributed to plant roots,
434 because the artificial vegetation on both slopes is the same. Conversely, these observations could be the result of the
435 soil hydraulic and mechanical properties from differential weathering.

436 This study has contributed to knowledge of the effect of differential weathering on aspect-dependent landslide
437 initiation from the perspective of soil hydraulic properties, in addition to the mechanical and hydrological effects of
438 plant roots. Except for the strong propensity for a high number of landslides, shallow landslides on south-facing
439 slopes have exhibited larger areas and greater widths than those on the north-facing slopes (Fig. 2). The effective
440 cohesion of the failure zone on the south-facing slope was stronger than that on the north-facing slope. The basal
441 area of shallow landslides in the study area may be attributed to effective cohesion, because some statistical results
442 have shown that incoherent materials favor shallow landslides with no limitation in size. Meanwhile, cohesive
443 materials favor deep landslides and show a limitation for small sizes (Larsen et al., 2010; Frattini and Crosta, 2013;
444 Milledge et al., 2014). However, a stronger effective cohesion tends to promote the $A-S$ conditions of shallow
445 landslides. A larger up-slope contributing area or steeper gradient is required to trigger slope failure. Figure 3 shows
446 that some shallow landslides on south-facing slopes fail at lower upslope contributing areas. Therefore, soil hydraulic
447 property-related factors, such as the rising or dissipation of pore water pressure, water storage, and drainage, may
448 contribute to the phenomena observed.

449 The saturated hydraulic conductivities obtained by the constant water head and TRIM methods coincide, which
450 demonstrates that the hillslope material on the north-facing slope has a larger water infiltration (Tables 1 and 2).
451 However, the results of the stability analysis using the finite and infinite models imply that the failure potential of
452 slides on a north-facing slope is lower than that on a south-facing slope, although the stability index fluctuates more

453 heavily than the north-facing slope. These differences imply that slope failures on a north-facing slope may only
454 occur under intensive rainfall conditions or by a combination of prolonged antecedent precipitation and short
455 duration intensive rainfall. For potential failures on south-facing slopes, the combination of prolonged antecedent
456 precipitation and short duration intensive rainfall should be a potential trigger owing to the low hydraulic
457 conductivity and pore water pressure dissipation. This study highlights the role of hydraulic properties in landslide
458 occurrence. Although the south- and north-facing slopes are underlain by granite, the physical properties of hillslope
459 materials such as excessive pore water pressure, strength of sliding mass, soil water storage, and leakage are
460 significantly different. This finding cannot be random because the study area has been selected on the condition that
461 it is relatively far from the northern and eastern areas where local soils are predominantly loess deposits, and the
462 study areas of Li et al. (2021) and Dai (2022), where the bedrock underneath differs substantially. The main purpose
463 of this work is to elucidate the reason for aspect-dependent landslide initiation from the perspective of soil hydraulic
464 properties. These differences result from differential weathering owing to the amount of direct sunlight. Other
465 mechanics such as numerical or relative dating methods and preferential flow in the macropore distribution could
466 provide new evidence for such observations.

467 **6 Conclusion**

468 Previous research on the strong propensity for shallow landslides on south-facing slopes over north-facing
469 slopes has highlighted the role of plant roots. In a localized area with the same vegetation including plant roots, they
470 do not penetrate the failure layer. These observations cannot be attributed to plant roots and may result from the
471 differential weathering of bedrock under the influence of hydrothermal conditions. In this study, we jointly explained
472 the influence of bedrock weathering on soil hydraulic properties from physical and mechanical properties, pore water
473 pressure, unsaturated hydraulic conductivity, water storage and drainage, and slope stability fluctuation during
474 monitoring, and studied landslide initiation related to slope direction. The following conclusions were drawn:

475 (1) In terms of soil physical and mechanical properties on both slopes, the soil masses on the south-facing slope
476 were rich in clay content, whereas the soil mass on the north-facing slope had relatively high sand content. The
477 effective cohesion of the soil mass on the south-facing slope was higher than that on the north-facing slope, while
478 the effective frictional angle was smaller.

479 (2) The results of the GDS tests showed that the dissipation rate of pore water pressure for soil mass on the
480 south-facing slope was substantially lower than that on the north-facing slope. Higher effective cohesion and slower
481 pore water pressure dissipation may result in a larger basal area for shallow landslides on south-facing slopes.

482 (3) The soil mass on the south-facing slope had a higher residual water content and air entry pressure, and a
483 lower saturated hydraulic conductivity than that of the north-facing slope. For water storage and drainage
484 performance, the storied water from the south-facing slope was higher than that of the north-facing slope, while the
485 north-facing slope had a higher leakage rate. The results of the stability analysis based on the finite and infinite
486 models show that the infinite slope model may be suitable for elucidating aspect-dependent landslide distribution in
487 the study area.
