24 25 **Abstract**

26 The reconstruction of past sea ice distribution in the Southern Ocean is crucial for an improved understanding of
27 ice-ocean-atmosphere feedbacks and the evaluation of Earth system and Antarctic ice sheet models. The Antarctic
28 Peninsula (AP) is experiencing a warming since the start of regular monitoring of the atmospheric temperature in
29 the 1950s. The associated decrease in sea ice cover contrasts the trend of growing sea ice extent in East Antarctica.

30 To reveal the long-term sea ice history at the Northern Antarctic Peninsula (NAP) under changing climate
31 conditions we examined a marine sediment core from the eastern basin of the Bransfield Strait covering the last
32 Deglacial and the Holocene. For sea ice reconstructions, we focused on the specific sea ice biomarker lipid IPSO₂₅,
33 a highly branched isoprenoid (HBI), and sea ice diatoms, whereas a phytoplankton-derived HBI triene (C_{25:3}) and
34 warmer open ocean diatom assemblages reflect predominantly ice-free conditions. We further reconstruct ocean
35 temperatures using glycerol dialkyl glycerol tetraether (GDGTs) and diatom assemblages, and compare our sea
36 ice and temperature records with published marine sediment and ice core data. A maximum ice cover is observed
37 during the Antarctic Cold Reversal (13.8 ka - 13 ka BP), while seasonally ice-free conditions permitting (summer)
38 phytoplankton productivity are reconstructed for the late Deglacial and the early Holocene from 13 ka to 8.3 ka
39 BP. An overall decreasing sea ice trend throughout the Middle Holocene coincides with summer ocean warming
40 and increasing phytoplankton productivity. The Late Holocene is characterized by a highly variable winter sea ice
41 concentrations and a sustained decline in the duration and/or concentration of spring sea ice. Overall diverging
42 trends in GDGT-based TEX_{86L} and RI-OH' SOTs are found to be linked to opposing spring and summer
43 insolation trends, respectively.

44

45 **Key Words:** Bransfield Strait, Holocene, sea ice cover, IPSO₂₅, highly branched isoprenoids, diatoms, GDGTs

46 1 Introduction

47 Sea ice significantly affects the global climate system through its impact on the atmosphere-ocean exchange of
48 heat and gas, the physical and chemical properties of the water masses, ocean circulation, primary production and
49 biogeochemical cycles (Chisholm, 2000; Vancoppenolle et al., 2013). Sea ice cover limits evaporation, affects
50 precipitation and increases the reflection of solar radiation due to a high albedo (Allison et al., 1982; Butterworth
51 and Miller, 2016; Turner et al., 2017). When sea ice forms, cold and dense brines develop, contributing to the
52 formation of intermediate and deep waters (Nicholls et al., 2009). Importantly, the downwelling of these dense
53 water masses can prevent warm currents from reaching the continental shelf and stimulating basal melt of Antarctic
54 ice shelves, with implications for the stability of ice sheets and global sea level (Cook et al., 2016; Escutia et al.,
55 2019; Etourneau et al., 2019; Hellmer et al., 2012; Huss and Farinotti, 2014). During the spring season, sea ice
56 melting boosts marine primary production by seeding algal cells, releasing nutrients and by promoting ocean
57 stratification and a shallow mixed layer depth (Arrigo et al., 1997; Vernet et al., 2008). In addition, nutrient supply
58 can be locally enhanced by wind-driven upwelling activity along the sea ice edge (Alexander and Niebauer, 1981).
59 Enhanced carbon fixation through this sea ice-stimulated biological pump hence leads to an increase of biological

60 material transport and organic carbon export to the ocean floor, thus lowering surface $p\text{CO}_2$ (Han et al., 2019; Kim
61 et al., 2004; Schofield et al., 2018; Wefer et al., 1988).

62 Since satellite-based sea-ice data became available in 1979, fast and profound changes have been observed both
63 in the Arctic as well as West Antarctica and ascribed to anthropogenic global warming (IPCC, 2021). The Western
64 Antarctic Peninsula (WAP), in particular, is experiencing a rapid warming of the atmosphere (Carrasco et al.,
65 2021; Vaughan et al., 2003) and the ocean (Cook et al., 2016). This is accompanied by rapidly retreating glaciers
66 and ice shelves (Cook et al., 2016; Rignot et al., 2019) and by remarkable loss of sea ice cover in the adjacent seas
67 (Parkinson and Cavalieri, 2012).

68 For an assessment of the region's past sensitivity to climate change, the deglacial and Holocene climate history of
69 the Antarctic Peninsula (AP) has been studied extensively. The Deglacial, the transition from the Last Glacial
70 Maximum (LGM, Clark et al., 2012) to the Holocene, is characterized by a rapid warming punctuated by a distinct
71 cold event, the so-called Antarctic Cold Reversal (ACR) from 14.7 ka to 13 ka BP (EPICA Community Members,
72 2004; Mulvaney et al., 2012; Pedro et al., 2016). This drastic cooling of both atmosphere and ocean temperatures
73 in the high Southern latitudes is well reflected in stable isotope records of Antarctic ice cores and within marine
74 sediments (Blunier and Brook, 2001; Domack et al., 2001; Jouzel et al., 1995; Morigi et al., 2003; Stenni et al.,
75 2001). From the Deglacial towards the Middle Holocene, the Antarctic Peninsula Ice Sheet (APIS) retreated
76 rapidly from the outer shelf to its modern configuration with high melt water discharge (Bentley et al., 2014).
77 Several marine and lacustrine Holocene climate records reveal that the timing of both hydrological and
78 environmental changes was highly variable across the AP (Allen et al., 2010; Ingólfsson et al., 2003; Minzoni et
79 al., 2015; Roseby et al., 2022; Sjunneskog and Taylor, 2002; Totten et al., 2022). An overall consensus, however,
80 is that WAP ocean temperatures were, in comparison to the Deglacial or the Late Holocene, warmer during the
81 Early and Middle Holocene, i.e. between 12 ka and 4 ka BP (Shevenell et al., 2011). In contrast, marine sediment
82 records show multiple different climate patterns for the Late Holocene around the AP, including a continuous
83 Neoglacial cooling (Etourneau et al., 2013). Knowledge of past Southern Ocean sea ice variability is crucial to
84 accurately model climate feedbacks (Crosta et al., 2022). For periods beyond the satellite era, information on past
85 sea-ice conditions is based on proxies from marine sediments, ice cores (e.g. Bracegirdle et al., 2015, 2019; Crosta
86 et al., 2022; Escutia et al., 2019; Thomas et al., 2019), and snow petrel stomach oil deposits (McClymont et al.,
87 2022). At present, most climate models not only fail to reproduce observed sea ice trends of the satellite era;
88 simulated sea ice conditions for both glacial and interglacial periods also often disagree with geological proxies
89 (Roche et al., 2012). Ice-core based sea ice reconstructions primarily use the concentrations of sea salt sodium
90 (WAIS Divide Project Members, 2015). However, since sea salt aerosols might be overprinted by the highly

91 variable wind direction and meteorological conditions in Antarctica, sea salt records may not sufficiently reflect
92 regional sea ice conditions (Thomas et al., 2019). Although marine sediment records usually have a lower temporal
93 resolution than ice cores, marine proxy reconstructions can resolve regional and - depending on the spatial
94 distribution of sediment cores - large-scale changes in sea ice conditions, as well as sea surface and subsurface
95 ocean temperature, primary productivity and marine ecology (Hillaire-Marcel and de Vernal, 2007). In addition to
96 commonly used geochemical, lithological and microfossil proxies (*e.g.* ice rafted debris (IRD), diatom
97 assemblages, total organic carbon), new approaches focus on specific organic biomarkers - highly branched
98 isoprenoids (HBIs) - as proxies to distinguish between open marine and seasonally sea ice covered environments.
99 The di-unsaturated HBI IPSO₂₅ (Ice Proxy for the Southern Ocean, C_{25:2}, Belt et al., 2016; Massé et al., 2011) that
100 is produced by sea ice algae and deposited on the ocean floor after the sea ice melt in spring has already been
101 applied in Antarctic sea ice reconstructions (*e.g.* Barbara et al., 2013; Denis et al., 2010; Etourneau et al., 2013).
102 Following the phytoplankton-IP₂₅ **sea-ice index** (PIP₂₅) approach for the Arctic (Müller et al., 2011), IPSO₂₅ has
103 been combined with phytoplankton-derived HBI trienes and/or sterols to determine the phytoplankton-IPSO₂₅ **sea**
104 **ice index** PIPSO₂₅ (Vorrath et al., 2019), which has been successfully evaluated with recent Antarctic spring sea
105 ice concentrations (Lamping et al., 2021). Other studies applied PIPSO₂₅ and examined its potential for sea ice
106 reconstructions over the industrial era (Vorrath et al., 2020) and deglacial and Holocene time intervals in the
107 Amundsen Sea (Lamping et al., 2020). Combining these new molecular proxies with the classical diatom
108 assemblage approach and/or geochemical ice core proxies provides a thorough assessment of past sea ice
109 conditions.

110 Here, we present a marine sediment record covering the past 13.8 ka BP and reconstruct Deglacial and Holocene
111 environmental conditions in the eastern Bransfield Strait at the NAP. Our study is based on a multiproxy approach
112 focusing on the sea ice biomarker IPSO₂₅, an open ocean marine phytoplankton biomarker (HBI triene), and on
113 glycerol dialkyl glycerol tetraether lipids (GDGTs) for subsurface ocean temperatures (SOT). Additional estimates
114 of primary productivity, winter sea ice coverage (WSI) and summer sea surface temperature (SSST) come from
115 bulk sediment organic carbon and biogenic silica contents and diatom assemblages using transfer functions,
116 respectively. In an intercomparison, we evaluate the different approaches to reconstruct sea ice conditions and
117 ocean temperatures. We discuss our proxy results in regard of other marine sediment and ice core records providing
118 further insight into the environmental dynamics at the Antarctic Peninsula across the Deglacial and the Holocene.

119 2 Material and Methods

120 2.1 Study Area

121 The Bransfield Strait is located between the NAP and the South Shetland Islands (SSI; Fig. 1a), comprising a
122 trough (> 2000 m) between a narrow shelf to the north (SSI) and a broad shelf area to the south (AP) (Fig. 1b).

123 The shelf areas were affected by intense ice sheet dynamics during the last glaciation (Canals and Amblas, 2016b;
124 Ingólfsson et al., 2003) leaving ice sheet grounding lines and glacial troughs on the seafloor (Canals et al., 2016;
125 Canals and Amblas, 2016a).

126 The modern Bransfield Basin is influenced by complex oceanic current systems. Cold (< 0 °C) and relatively salty
127 Weddell Sea Water (WSW) enters from the east, flows alongshore the peninsula and fills the Bransfield Strait
128 basins below 150 m water depth. In the western part of the Bransfield Strait, the WSW mixes with warmer
129 Bellingshausen Sea Water (BSW; 0 - 50 m water depth) and Circumpolar Deep Water (CDR; 200 - 550 m water
130 depth; Collares et al., 2018; Sangrà et al., 2011, 2017), which are transported in a branch of the Antarctic
131 Circumpolar Current (ACC) over the Anvers Shelf. BSW and WSW form the Peninsula Front that runs parallel to
132 the Antarctic mainland (Sangrà et al., 2011, 2017). The interplay of currents leads to a pronounced pycnocline
133 within the upper 20 m of the water column in summer, accompanied by a steep temperature gradient in the upper
134 100 m, as observed in hydrographic profiles from the Bransfield Basin that show a dominance of WSW below 200
135 m (see Fig. 1c and Sangrà et al., 2011). Modern sea ice conditions at the core site in the eastern Bransfield Strait
136 are characterized by a mean winter sea ice concentration of ca. 50%, which declines to 18% and less than 2% sea
137 ice concentration during spring and summer, respectively (*cf.* Vorrath et al., 2019). While atmospheric
138 temperatures show a rising trend since the 1950s (Carrasco et al., 2021), ocean temperatures are increasingly
139 influenced by warm water intrusions and higher sea surface temperatures (Martinson and McKee, 2012; Meredith
140 and King, 2005). At the core site, mean annual sea surface temperatures are -0.6 °C with up to 0.8 °C during
141 summer (WOA 18; Boyer et al., 2018; Locarnini et al., 2018).

142 Primary production in the Bransfield Strait is mainly driven by mixing of water masses at the fronts (Gonçalves-
143 Araujo et al., 2015), mixed layer depth and upwelling (Sangrà et al., 2011), sea ice dynamics (Vernet et al., 2008)
144 and iron availability (Klunder et al., 2014). High concentrations of chlorophyll *a* and diatoms are distributed north
145 of the PF and at the SSI, while lower production and communities of plankton nanoflagellates are found between
146 the Peninsula Front and the WAP (Gonçalves-Araujo et al., 2015). Further, changes in coastal primary production
147 are driven by upwelling, elevated iron availability, as well as the nutrient release and surface water stratification
148 generated by melting sea ice in the austral spring (Vernet et al., 2008). A robust link between marine primary
149 production in surface waters and the sediment composition at the underlying ocean floor is reflected in high

150 concentrations of total organic carbon (TOC), pigments, sterols and diatoms (Cárdenas et al., 2019), and supported
151 by studies confirming high fluxes of sinking particles (Kim et al., 2004; Wefer et al., 1988). In the study area,
152 particle flux is highly variable with seasonal peaks occurring in late spring, which accounts for 85% of the total
153 flux (Ducklow et al., 2008). Lithologically, the sediments consist mainly of terrigenous silt and clay with varying
154 amounts of diatom mud and ooze, and sand (Cádiz Hernández, 2019; Lamy, 2016; Wu et al., 2019).

155

156 **2.2 Sediment samples and age model**

157 Piston core PS97/072-1 (62° 0.39' S, 56° 3.86' W, 1993 m water depth, 1583 cm in length) was recovered in the
158 eastern Bransfield Strait Basin during R/V *Polarstern* cruise PS97 (Lamy, 2016) (Fig. 1). The sediment is
159 dominated by silt with thin layers of sand, clay, and traces of volcanic ash. Single pebbles are present below 630
160 cm. The core is disturbed below 1015 cm depth and we only considered samples from above this level for our
161 analyses. Sampling for different analytical approaches was done at the Alfred Wegener Institute (AWI) where the
162 samples were stored frozen in glass vials (for biomarker analysis) and at 4 °C in plastic bags (for
163 micropaleontology).

164 The age model of core PS97/072-1 is based on radiocarbon dating of eight benthic foraminiferal and mollusk
165 fragments samples with the mini carbon dating system (MICADAS) available at AWI (Mollenhauer et al., 2021).
166 From the conventional ¹⁴C age we subtracted a reservoir age based on modelling by Butzin et al. (2017) and also
167 subtracted an estimated ventilation age of 1200 years to account for the considerable water depth of our site (see
168 table supplement section 1), before we calibrated the ages with the calibration curve IntCal20 (Reimer et al., 2020)
169 to calendar years before present (cal BP) with Calib 7.1 (Stuiver et al., 2018). To estimate the age of the core top,
170 TOC and biogenic opal data of the piston core were matched with data from a multicore from the same sampling
171 site that has been previously dated via ²¹⁰Pb (Vorrath et al., 2020; supplement section 2). Ages of sediments below
172 the oldest radiocarbon date (868.5 cm; 12.04 ka BP) were extrapolated assuming a constant sedimentation rate.
173 We applied the Bayesian age modelling tool *hummingage*, a freely available tool developed at AWI that has been
174 successfully applied in previous studies (e.g. Ronge et al., 2021). As the lack of age constraints between 12 ka and
175 6 ka BP may introduce chronological uncertainties, we only focus on overall trends reflected in our data and refrain
176 from detailed allocations of known climatic events in this older time period.

177 **2.3 Organic geochemical analyses of piston core PS97/072-1**

178 For the analyses of the bulk organic geochemical composition and biomarkers, 334 sediment samples were freeze-
179 dried and homogenized in an agate mortar. Prior to sediment homogenization, coarse grains were separated using
180 a sieve (5 µm mesh size). Total carbon (C) and nitrogen (N) were measured with a CNS analyzer (Elementar Vario

181 EL III, error of standards and duplicates < 5%). TOC was measured on 0.1 g of acidified samples (500 µl HCl)
182 and determined in a carbon-sulphur determinator (CS-800, ELTRA, standard error < 0.6%). To identify the source
183 of TOC, measurements of stable carbon isotopes of bulk organic matter were done at Universität Hamburg (UHH),
184 Germany, and at Washington State University (WSU), USA. At UHH, the samples were acidified three times with
185 100 µl 1 N HCl and dried on a hotplate. High-temperature combustion was done in an Elementar CHNOS Vario
186 isotope elemental analyser at 950 °C and the analysis was conducted with an Elementar IsoPrime 100 isotope ratio
187 mass spectrometer. We calibrated the pure tank CO₂ with the International Atomic Energy Agency reference
188 standards IAEA-CH6 and IAEA-CH7. These and two other standards (IVA Sediment and Sucrose) acted as
189 internal standards in the measurement. The error of continuous standard duplicates was < 0.2‰ and <0.06‰ for
190 sample duplicates. At WSU, 100 mg of freeze-dried sediment samples were used. An elemental analyzer coupled
191 with an Isoprime isotope ratio mass spectrometer (IRMS) was used, with a precision of 0.1‰. The running
192 standard was a protein hydrolysate calibrated against NIST standards. Isotope ratios are expressed in units per mil
193 (‰). δ¹³C values are expressed in ‰ against Vienna Pee Dee Belemnite (VPDB).

194 Biogenic opal was estimated on 327 samples following the alkaline extraction procedure described by Mortlock
195 and Froelich (1989), but using 0.5M NaOH as a digestion solution (Müller and Schneider, 1993). Extraction and
196 analysis by molybdate-blue spectrophotometry were conducted at the University of Concepción, Chile. Values are
197 expressed as biogenic opal by multiplying the Si (%) by 2.4 (Mortlock and Froelich, 1989). Opal values could be
198 overestimated by 2 - 2.5% since we did not correct for the release of extractable Si from coexisting clay minerals
199 (Schlüter and Rickert, 1998). Instrumental precision was ±0.5%; error of duplicates ≤ 3%). Details on the
200 methodology used can be found in Cárdenas et al. (2019).

201 The extraction, purification and identification of 137 samples to identify HBIs followed the analytical protocol
202 published e.g. in Belt et al. (2014) and Vorrath et al. (2019). Prior to extraction, 40 µl 7-hexylnonadecane (7-HND;
203 0.0019 µg/µl) and 100 µl C₄₆ (0.0098 µg/µl) were added as internal standards. Lipids were extracted using ultra
204 sonication and a mixture of CH₂Cl₂:MeOH (v/v 2:1; 6 ml). HBIs and GDGTs were separated by means of open
205 column chromatography using SiO₂ as the stationary phase and hexane, and CH₂Cl₂:MeOH (v/v 1:1) as eluents.
206 HBIs were analyzed by means of an Agilent 7890B gas chromatograph (30 m DB 1MS column, 0.25 mm diameter,
207 0.250 µm film thickness) coupled to an Agilent 5977B mass spectrometer (MSD, 70 eV constant ionization
208 potential, ion source temperature 230 °C). The initial oven temperature of 60 °C was held for 3 min, ramped to
209 325 °C within 23 min, and was held at 325 °C for 16 min. HBIs were identified *via* comparison of their retention
210 times (IPSO25 and HBI triene with RI 2084DB-1MS and 2046DB-1MS, respectively) and mass spectra with
211 published mass spectra (Belt, 2018) and quantified using the ratio of peak areas of individual HBIs (*m/z* 346; *m/z*

212 348) and the 7-HND (m/z 266) standard and consideration of instrumental response factors. The error of duplicates
213 was <1.4% for IPSO₂₅, <2.6% for HBI trienes. The phytoplankton-IPSO₂₅ index (PIPSO₂₅) was calculated after
214 Vorrath et al. (2019) as:

$$215 \text{PIPSO}_{25} = \frac{\text{IPSO}_{25}}{\text{IPSO}_{25} + (c \times \text{phytoplankton marker})} \quad (1)$$

216 The concentrations of the phytoplankton-derived HBI z-triene are at the same level as IPSO₂₅ and the c-factor was
217 hence set to 1 (Vorrath et al., 2019). To confirm the sea-ice origin of IPSO₂₅, the stable carbon isotope composition
218 of IPSO₂₅ was examined in 8 samples (with minimum 50 ng carbon) via GC-irm-MS at the GFZ Potsdam,
219 Germany. The GC (7890N Agilent) equipped with an Ultra1 column (50 m x 0.2 mm diameter, 0.33 μm film
220 thickness) was connected to a DeltaVPlus isotope ratio mass spectrometer through a modified GC-Isolink
221 interface. Each sample was separated chromatographically using a temperature program that started with an oven
222 temperature of 80 °C, which was held for 3 min, ramped to 250 °C with 3 °C per min and then ramped to 320 °C
223 with 5 °C per min and finally reached temperature of 325 °C with a ramp of 1 °C per min and held for 15 min.
224 The organic substances of the GC effluent stream were oxidized to CO₂ in the combustion furnace held at 940 °C
225 on a CuO/Ni/Pt catalyst. Samples were measured in duplicate and the standard deviation was ≤0.5 ‰. The quality
226 of the isotope measurements was checked regularly (for each analysis) by measuring different *n*-alkane standards
227 with known isotopic composition of n-C15, n-C20, n-C25 (in equal concentration) and n-C16 to n-C30 (in various
228 concentrations) provided by Campro Scientific, Germany and Arndt Schimmelmann, Indiana University, USA.
229 GDGTs were re-dissolved in 120 μl hexane:isopropanol (v/v 99:1) and filtered through polytetrafluoroethylene
230 filters (0.45 μm in diameter) and analyzed using high performance liquid chromatography (HPLC, Agilent 1200
231 series HPLC system) coupled to a single quadrupole mass spectrometer (MS, Agilent 6120 MSD) via an
232 atmospheric pressure chemical ionization (APCI) interface. The individual GDGTs were separated at 30 °C on a
233 Prevail Cyano column (150 mm x 2.1 mm, 3μm). After injection of the sample (20 μl) it passed a 5 min isocratic
234 elution with mobile phase A (hexane/2-propanol/chloroform; 98:1:1, flow rate 0.2 ml/min). The mobile phase B
235 (hexane/2-propanol/chloroform; 89:10:1) was increased to 100% in two steps: a linear increase to 10% over 20
236 min followed by an increase to 100% within 10 min. During the measurement, the column was cleaned after 7 min
237 via backflush (5 min, flow 0.6 ml/min) and re-equilibrated with solvent A (10 min, flow 0.2 ml/min). The
238 conditions of the APCI were a nebulizer pressure of 50 psi, vaporizer temperature and N₂ drying gas temperature
239 350 °C, flow 5 l/min, capillary voltage 4 kV, and corona current 5 μA. Following Liu et al. (2020), iGDGTs and
240 brGDGTs were detected by selective ion monitoring (SIM) of (M+H⁺) ions (dwell time 76 ms) using their
241 molecular ions (GDGTs-1 (m/z 1300), GDGTs-2 (m/z 1298), GDGTs-3 (m/z 1296), crenarchaeol (m/z 1292) and
242 GDGTs-Ia (m/z 1022), GDGTs-IIa (m/z 1036), GDGTs-IIIa (m/z 1050)) and quantified in relation to the internal

243 standard C₄₆ (*m/z* 744). The hydroxylated GDGTs OH-GDGT-0 (*m/z* 1318), OH-GDGT-1 (*m/z* 1316), and OH-
 244 GDGT-2 (*m/z* 1314) were quantified in the scans of their related GDGTs (Fietz et al., 2013). The standard deviation
 245 was 0.01 units of TEX^L₈₆.

246 Kalanetra et al. (2009) showed that GDGT-producing Thaumarchaeota are abundant in subsurface marine waters
 247 in both Arctic and Antarctic regions. As Thaumarchaeota were found between 50 m and 200 m water depth in
 248 Antarctica (Kim et al., 2012), temperatures based on GDGTs are suggested to reflect sub-surface waters
 249 (Etourneau et al., 2013, 2019). Similarly, also RI-OH' based temperatures in Prydz Bay have been interpreted to
 250 reflect subsurface water temperatures (Liu et al., 2020). We therefore consider our results to reflect subsurface
 251 ocean temperatures (SOTs). We calculated TEX^L₈₆ after Kim et al. (2012) with the *m/z* 1296 (GDGT-3), *m/z* 1298
 252 (GDGT-2), *m/z* 1300 (GDGT-1):

$$253 \quad \text{TEX}_{86}^L = \log \log \left(\frac{[\text{GDGT-2}]}{[\text{GDGT-1}] + [\text{GDGT-2}] + [\text{GDGT-3}]} \right)$$

254 (2)

255 and calibrated with SOT = 50.8 * TEX^L₈₆ + 36.1 (Kim et al., 2012). (3)

256 For the calculation of temperatures based on hydroxylated GDGTs we followed the approach of Lü et al. (2015)

$$257 \quad \text{RI} - \text{OH}' = \frac{[\text{OH-GDGT-1}] + 2 \times [\text{OH-GDGT-2}]}{[\text{OH-GDGT-0}] + [\text{OH-GDGT-1}] + [\text{OH-GDGT-2}]}$$

258 and calibrated it with SOT = (RI-OH' - 0.1) / 0.0382. (5)

259 For the branched and isoprenoid tetraether (BIT) index for indicating terrestrial organic matter (Hopmans et al.,
 260 2004) we used crenarchaeol (*m/z* 1292) and the branched GDGTs and calculated it as:

$$261 \quad \text{BIT} = \frac{[\text{GDGT-Ia}] + [\text{GDGT-IIa}] + [\text{GDGT-IIIa}]}{[\text{Crenarchaeol}] + [\text{GDGT-Ia}] + [\text{GDGT-IIa}] + [\text{GDGT-IIIa}]}$$

262

263 2.4 Diatom analyses

264 We selected a set of 76 samples for the analysis of diatom assemblages. At first, sampling resolution was every
 265 40-50 cm; thereafter, and based on the biogenic opal results, resolution was increased (every 8 cm) at intervals
 266 with high variability. Freeze-dried samples (20-120 mg) were treated with hydrogen peroxide and sodium
 267 pyrophosphate to remove organic matter and clays, respectively, washed several times with DI water until reaching
 268 neutral pH. The treated samples were then settled for six hours in B-Ker2 settling chambers to promote an even
 269 distribution of settled particles (Scherer, 1994; Schrader and Gersonde, 1978; Warnock and Scherer, 2015). Once
 270 the samples were dry, the quantitative slides were mounted with Norland mounting medium (refraction
 271 index=1.56). Diatom valves per slide were counted across traverses (at least 400 valves per slide) using an
 272 Axioscop 2 Plus and Olympus BX60 at a magnification of ×1000. The counting procedure and definition of

273 counting units followed those of Schrader and Gersonde (1978). We performed two sets of counts, with and
274 without *Chaetoceros* resting spores. Diatoms were identified to species or species group level and, if applicable,
275 to variety or form level following the taxonomy described by e.g., Gersonde and Zielinski (2000), Armand and
276 Zielinski (2001), Esper et al. (2010), Esper and Gersonde (2014a, 2014b). Diatom analyses were done by the same
277 investigator at the University of Concepción, Chile, and at Colgate University, USA.

278 Because diatom distribution in the Southern Ocean is directly associated with the temperature zonation and the
279 frontal systems of the ACC (Cárdenas et al., 2019; Esper et al., 2010; Esper and Gersonde, 2014a, 2014b; Zielinski
280 and Gersonde, 1997), diatom species were grouped into ecological assemblages reflecting i) seasonal sea ice –
281 associated with temperatures -1.8 to 0°C; ii) cold open ocean – associated with the maximum sea-ice extent in
282 winter and temperatures between 1 and 4°C; iii) warmer open ocean – with temperatures between 4 and 14°C, and
283 iv) benthic-epiphytic habitats (Buffen et al., 2007; Cárdenas et al., 2019). Additionally, a group of reworked
284 diatoms was identified (specific group composition is described in detail in supplement section 3). A Spearman
285 principal component analysis (PCA) was applied to the diatom assemblages to differentiate their temporal
286 distribution.

287 For estimation of winter sea ice (WSI) concentrations, we applied the transfer function MAT-D274/28/4an to the
288 total diatom counts (including *Chaetoceros* resting spores). The transfer function comprises 274 reference samples
289 with 28 diatom taxa/taxa groups and considers an average of 4 analogues (Esper and Gersonde, 2014a). The
290 analogues refer to surface sediments from the Atlantic, Pacific and western Indian sector of the Southern Ocean.

291 **There are 10 analogues from the immediate vicinity of the Antarctic Peninsula.** The WSI renders sea ice
292 concentrations in a 1° by 1° grid for the September average of the period 1981 to 2010 (Reynolds et al., 2002,
293 2007). The threshold between the open ocean and the sea ice covered area is set at 15% of sea ice concentration
294 (Zwally et al., 2002) and the average sea ice edge is defined at 40% (Gersonde et al., 2005; Gloersen et al., 1993).
295 The estimation of summer sea surface temperature (SSST) came from the transfer function IKM-D336/29/3q
296 comprising 336 reference samples (Pacific, Atlantic and Indian Southern Ocean) with 29 diatom taxa and three
297 factors (Esper and Gersonde, 2014b). The calculations for WSI were done with the software R (R Core Team,
298 2012) using the packages Vegan (Oksanen et al., 2012) and Analogue (Simpson and Oksanen, 2012).

299 **3 Results**

300 Based on our age model, sediment core PS97/072-1 covers the last 13.8 ka BP with a mean sedimentation rate of
301 67 cm/ka and a temporal resolution ranging between 50 and 150 years per sample interval. We note a higher

302 sedimentation rate of 95 cm/ka between 5.5 ka and 3 ka BP and few short intervals of lower (19 cm/ka) and higher
303 (190 cm/ka) sedimentation (Fig. 2).

304 Organic geochemical bulk parameters (TOC, biogenic opal), concentrations of HBIs (IPSO₂₅, C_{25:3} HBI triene) and
305 diatom species of warmer open ocean conditions and sea ice assemblages of piston core PS97/072-1 are
306 summarized in Figure 3 (additional data can be found in the supplement section 4). TOC increases from very low
307 values of 0.1 wt% at 13.7 ka BP to an average concentration of ~0.8 wt% between 9.9 ka BP and the top of the
308 core with recurring short-lived minima down to 0.03 wt% during the Middle and Late Holocene (Fig. 3f). Some
309 of these TOC minima occur within thin sandy layers of volcanic ash. Biogenic opal shows a similar pattern with
310 minimum values in the lower part of the record (3.2 wt% at 13.0 ka BP) and increases throughout the Deglacial to
311 Holocene with average values of 30 wt% and a maximum of 54.4 wt% at 5.3 ka BP (Fig. 3e).

312 Between 13.8 ka and 13.4 ka BP, both IPSO₂₅ and HBI triene concentrations are close to or below the detection
313 limit (0.1 µg g⁻¹ OC). Throughout the record, the IPSO₂₅ concentration ranges between 0.1 to 31.5 µg g⁻¹ TOC,
314 while the concentration of the HBI triene ranges between 0.1 and 6.6 µg g⁻¹ TOC (Fig. 3). IPSO₂₅ is absent before
315 13.5 ka BP and rises rapidly to maximum values of 31.5 µg g⁻¹ TOC at 12.8 ka BP. Subsequently, concentrations
316 decrease steadily until 8.5 ka BP and then remain at an average level of ~4 µg g⁻¹ TOC with a slightly decreasing
317 trend to 1 µg g⁻¹ TOC towards the present and smaller peaks of 10 µg g⁻¹ TOC at 6.0 and 3.0 ka BP. Only traces
318 of the HBI triene occur until 13.0 ka BP, while its concentration increases up to 6.6 µg g⁻¹ TOC after 8.5 ka BP
319 with large fluctuations of more than 5 µg g⁻¹ TOC in the Middle Holocene and from 3.4 ka BP to the present.

320 The diatom composition has two contrasting groups indicating open ocean conditions, a cold water assemblage
321 and a warm water assemblage, and a seasonal sea ice assemblage (Fig. 3; see supplement section 3). Although the
322 group reflecting seasonal sea ice is present throughout the core (mostly >20%), the highest contributions are seen
323 before 13 ka BP and between 10.8 and 9.9 ka BP. The contribution of the warmer open ocean assemblage is very
324 low in the Deglacial and Early Holocene, rises to highest values in the Middle Holocene and remains around 10%
325 in the Late Holocene. A biplot of a principal component analysis (PCA) shows the relationship of the ecological
326 groups for three time intervals with clear dominance of seasonal sea ice before 13 ka BP and warmer open ocean
327 conditions after 8.5 ka BP (supplement section 5 and 6).

328 Sea ice concentration estimates based on diatom assemblages (WSI) and the PIPSO₂₅ index as well as the content
329 of IRD in PS97/072-1 are summarized in figure 4 (a-c). Reconstructed winter sea ice concentrations (% WSI)
330 derived from the MAT transfer function range from 80% to 90% during the ACR and the Deglacial (13.8 ka – 11
331 ka BP) and exhibit an overall decreasing trend over the Middle Holocene with fluctuations reaching minimum sea
332 ice concentrations of ca. 65% during the Middle and Late Holocene (Fig. 4a). PIPSO₂₅ values show a similar trend

333 indicating higher sea ice cover during the ACR, the Deglacial and the Early Holocene (PIPSO₂₅ > 0.8) and a
334 successive decline to 0.5 on average throughout the Middle and Late Holocene with a distinct minimum at 0.5 ka
335 BP (Fig. 4b). IRD (lithic particles and pebbles > 5 µm) occurs frequently between 13.8 ka and 9 ka BP and is
336 virtually absent in the younger part of the sediment core (Fig. 4c).

337 Figure 5 provides ocean temperature anomalies based on diatom assemblages (SSST) and GDGT-derived RI-OH'
338 and TEX₈₆^L SOTs in core PS97/072-1 (Fig. 5 b-d). Diatom-derived SSST estimates generally depict lower
339 temperatures during the Deglacial and Early Holocene, accompanied by a shift to ca. 1 °C warmer temperatures
340 in the Middle and Late Holocene (Fig. 5b). A short cold event with a SSST decrease of ca. 1.5 °C occurred around
341 3.1 ka BP. Similar to SSSTs, RI-OH'-derived SOTs likewise reflect generally lower temperatures during the
342 Deglacial and Early Holocene, and 0.4 °C warmer temperatures in the Middle and Late Holocene (Fig. 5c).
343 TEX₈₆^L-derived SOTs display an opposite trend to both SSST and RI-OH' SOT with peak temperatures during
344 the Deglacial and an overall Holocene cooling towards present (Fig. 5e).

345

346 4 Discussion

347 4.1 The late Deglacial (13.8 ka to 11.7 ka BP)

348 In the oldest part of our sediment record, covering the later part of the last Deglacial from 13.8 ka until 11.7 ka
349 BP, we observe a remarkable environmental change indicated by large shifts in the TOC, biomarker and diatom
350 records (Fig. 3). The very low concentrations of HBIs (Fig. 3b and d), TOC (Fig. 3f), and biogenic opal (Fig. 3e)
351 between 13.8 ka and 13.5 ka BP suggest that primary production of phytoplankton and also sea ice algae
352 synthesizing IPSO₂₅ was diminished, while sea ice related diatom species show the highest contribution of 73%
353 (Fig. 3c), albeit with very low concentrations (see online resource). Highest WSI concentrations and PIPSO₂₅
354 values (Fig. 4a, b) are pointing towards a maximum sea ice cover and are well in line with peak ssNa
355 concentrations in the EDML and WAIS ice core records, referring to an extended sea ice cover until 13 ka BP
356 (Fig. 4; EPICA Community Members, 2006; Fischer et al., 2007; WAIS Divide Project Members, 2015). We note
357 that for the interpretation of PIPSO₂₅ values, changes in both IPSO₂₅ and HBI triene concentrations need to be
358 evaluated carefully to reliably deduce information on sea ice conditions. High PIPSO₂₅ values may refer to an
359 extended sea ice cover that lasts until summer (thus hampering phytoplankton productivity/HBI triene synthesis),
360 whereas low PIPSO₂₅ values point to a reduced sea ice cover in terms of duration (in spring) and/or sea ice
361 concentration. The near absence of IPSO₂₅, the HBI triene and warm open ocean diatom species between 13.8 ka
362 and 13.5 ka BP evidences a permanent, potentially perennial ice cover or at least sea ice that was too thick to allow

363 photosynthesis of sea ice algae inhabiting the sea ice. Similarly, Lamping et al. (2020) related the absence of
364 IPSO₂₅ and phytoplankton-derived dinosterol in sediments in the western Amundsen Sea to the re-advance of a
365 floating ice shelf canopy during the ACR. At the PS97/072-1 core site in the eastern Bransfield Strait, both the
366 presence of perennial sea ice, or an ice shelf tongue extending from the APIS, could explain the lack of indicators
367 of phytoplankton productivity and IPSO₂₅-synthesizing ice algae. We hence assume that the very low absolute
368 concentrations of sea ice-associated diatoms result from lateral transport underneath the ice or reworking of
369 sediments older than 13.5 ka BP. The abrupt increase in IPSO₂₅ concentrations at 13.5 ka BP may indicate the
370 retreat or thinning of such an ice-canopy, permitting sea ice algae growth during spring and a subsequent increase
371 in primary production reflected in rapidly rising HBI triene concentrations since 13 ka BP (Fig. 3b, d). Such a
372 transition from a perennial floating ice canopy to conditions characterized by (seasonal) sea ice cover is also
373 reported by Milliken et al. (2009) for the nearby Maxwell Bay (King George Island; SSI) between 14 ka and 10 ka
374 BP. Interestingly, a prominent decrease in sea ice associated diatoms between 13 ka and 12 ka BP (Fig. 3c) is not
375 mirrored by the still high WSI concentrations. This discrepancy could relate to a weaker preservation potential of
376 certain diatoms reflecting seasonal sea ice (e.g. *Synedropsis* sp., *Nitzschia stellata*) that are not considered within
377 the transfer function to estimate WSI, which highlights the need to examine silica dissolution effects for the
378 interpretation of diatom records.

379 With regard to the ocean temperatures recorded at core site PS97/072-1, we note that the overall cool deglacial
380 temperatures derived from diatom data (SSST) and hydroxylated GDGTs (RI-OH') seem to be linked to the
381 lowered summer insolation (Fig. 5a), whereas higher TEX₈₆^L temperatures seem to be associated with a higher
382 spring insolation (Fig. 5d). While the impact of seasonality on GDGT-based ocean temperature estimates is still
383 under debate and would require further improvements in regional calibration, the observation of maximum
384 abundances of thaumarchaeota species (producing isoGDGTs applied to determine TEX₈₆^L) in Antarctic coastal
385 waters during spring (Kalanetra et al., 2009; Murray et al., 1998) seems to support our interpretation and also helps
386 to explain the divergent trends in TEX₈₆^L and RI-OH' derived SOT estimates, as the latter proxy might be also
387 sourced by other archaea species that probably grow mostly during the summer season.

388 While the ACR lasts from 14.7 ka to 13 ka BP (Pedro et al., 2016) as indicated by e.g. the WAIS Divide ice core
389 records (Fig. 5i, WAIS Divide Project Members, 2013), our sediment record shows that cold conditions with an
390 extended sea ice cover, limiting summer phytoplankton productivity (Fig. 4a, b) in the eastern Bransfield Strait,
391 lasted until ca. 11 ka BP. Further, the Deglacial and Early Holocene IRD content (Fig. 4.c; including the presence
392 of single large pebbles) in core PS97/072-1 points to the frequent occurrence of icebergs, evidencing the overall
393 ice sheet disintegration along the WAP that occurred around 14 ka BP at the SSI and promoted seasonally open-

394 marine conditions at Anvers-Hugo Trough at 13.6 ka BP (middle WAP shelf) and at 12.9 ka BP in Palmer Deep
395 (inner WAP shelf), respectively (Domack et al., 2001; Domack, 2002; Jones et al., 2022; Milliken et al., 2009;
396 Roseby et al., 2022). At our core site, rising RI-OH' SOTs and a slight decrease in PIPSO₂₅ values characterize
397 the late Deglacial between 13 ka and 11.7 ka BP (Fig. 4b, 5c). A prominent decline in large-scale sea ice cover is
398 also reflected in the decreasing ssNA concentrations in the EDML and WAIS ice cores between 13 ka and 11.7 ka
399 BP (Fig. 4e, f) likely related to a distinct atmospheric warming, as reflected in ice core stable water isotopes (Fig.
400 5h).

401 The ACR cooling and the subsequent Late Deglacial warming may relate to inter-hemispheric teleconnections
402 through a global reorganization of atmospheric and ocean circulation that is associated with the bipolar seesaw
403 pattern of opposite climate trends between the northern and southern hemisphere (Anderson et al., 2009; Broecker,
404 1998; EPICA Community Members, 2006; Pedro et al., 2016). While a northward shift of the southern westerlies
405 during the ACR (Fletcher et al., 2021) promoted Antarctic sea ice expansion and glacier readvance (potentially
406 causing an ice cover over the PS97/072-1 core site), a cooling of the northern hemisphere with a southward shift
407 of the Intertropical Convergence Zone and the southern hemisphere westerlies (Lamy et al., 2007) resulted in
408 intensified wind stress in the Drake Passage (Timmermann et al., 2007). This pattern would have increased
409 upwelling that may have driven the continued ocean warming and sea ice retreat in Antarctica towards the
410 Holocene (Anderson et al., 2009).

411

412 **4.2 Early Holocene warming from 11.7 ka to 8.2 ka BP**

413 The Early Holocene from 11.7 ka to 8.2 ka BP is characterized by a progressively decreasing spring sea ice cover
414 inferred from declining PIPSO₂₅ values (Fig. 4b), as well as highly variable winter sea ice cover with prominent
415 shifts in sea ice concentration (from 90% to 65%; Fig. 4a). These WSI fluctuations are not reflected in the sea ice
416 diatom assemblage, which, similar to the biogenic opal content, follows an increasing trend until 10.5 ka BP (Fig.
417 3c, e). Increased accumulation of biogenic opal and a better preservation of (thin-walled) sea ice-related diatoms
418 that are not used for the transfer function may explain the mismatch between the WSI record and sea ice diatom
419 assemblage. The increase in biogenic opal is further accompanied by rising TOC content, while concentrations of
420 the HBI triene and warm open ocean diatoms remain low, only an increase after 9 ka BP, signalling higher
421 phytoplankton productivity (Fig. 3a, b). Diatom-derived SSSTs exhibit marked fluctuations but remain relatively
422 low until 8.2 ka BP (Fig. 5b). RI-OH' and TEX₈₆^L SOTs display diverging trends following the summer and spring
423 insolation, respectively (Fig. 5). While PIPSO₂₅ values display a gradual decrease in sea ice coverage, the WSI
424 record suggests a highly variable sea ice cover, with several distinct sea ice minima between 11 ka and 10 ka BP

425 and around 9 ka BP (Fig. 4a and b). These sea ice minima may have resulted from punctuated warming events,
426 *e.g.* around 10 ka BP, when SSST shows a short temperature peak, which might have led to a delayed sea ice
427 formation in autumn and winter (Fig. 5b). Another WSI minimum at 9 ka BP coincides with a major, final peak
428 in IRD deposition at the core site (Fig. 4), evidencing iceberg discharge during episodes of peak AP ice-sheet
429 retreat and enhanced calving (Jones et al., 2022). As sea ice melting may have been an important driver of ocean
430 stratification, we suggest warmer, stratified surface waters with moderate production in summer, supported by
431 increasing summer insolation (Fig. 5a). Ameliorating climate conditions, ice-shelf retreat along the NAP and the
432 establishment of modern-like ocean conditions after 9 ka BP have also been proposed for the western Bransfield
433 Strait by Heroy et al. (2008) and are well in line with the rising concentrations of warm open ocean diatoms and
434 the phytoplankton-derived HBI triene at our core site after 9 ka BP (Fig. 3). The general decrease in spring sea ice
435 cover (reflected in declining PIPSO₂₅ values) may have been fostered by a maximum spring and rising summer
436 insolation (Fig. 5a, d), shortening the duration of sea ice cover. Rising RI-OH' temperatures are consistent with
437 the overall slight warming trend recorded in the WAIS Divide ice core (Fig. 5h), which has been shown to be
438 mainly driven by increasing summer temperatures (Jones et al., 2022). The decreasing TEX₈₆^L SOT trend at core
439 site PS97/072-1 corresponds to the declining TEX₈₆ temperatures reported for ODP site 1098 in Palmer Deep (Fig.
440 5g; Shevenell et al., 2011) though the latter displays a more pronounced temperature drop (of ca. 6 °C) between
441 11.7 ka and 8.2 ka BP. These regional differences may relate to changing ocean circulation patterns, associated
442 shifts in water mass distribution along the WAP and the local post-glacial environmental development during the
443 Early Holocene. Deposition of laminated diatom oozes in the Anvers-Hugo Trough at the WAP middle shelf
444 during the early Holocene, *e.g.*, documents episodes of extremely high productivity in response to a southward
445 shift of the southern hemisphere westerlies and the advection of warm and nutrient-rich CDW (Roseby et al.,
446 2022). We propose that the eastern Bransfield Strait remained mainly “inaccessible” for CDW and BSW until
447 further ice recession between 10 ka and 5 ka BP (Ó Cofaigh et al., 2014 and references therein) permitted advection
448 of these water masses into the Bransfield Strait.

449

450 **4.3 Middle Holocene from 8.2 ka until 4.2 ka BP**

451 The Middle Holocene from 8.2 ka to 4.2 ka BP was a period of sea ice retreat and minimum iceberg activity at the
452 core site indicated by decreasing WSI and PIPSO₂₅ values and virtually absent IRD (Fig. 4). Diatoms associated
453 with warmer open ocean conditions, peak HBI triene concentrations and maximum TOC as well as biogenic opal
454 contents (Fig. 3) indicate a high export production during the Middle Holocene. This higher primary productivity
455 can be linked to a decrease in both winter and spring sea ice indicated by WSI and PIPSO₂₅ minima, respectively

456 (Fig. 4a, b), elevated SSSTs and (summer) SOTs (Fig. 5b, c) promoting ice-free summer ocean conditions
457 favorable for phytoplankton productivity. These Middle Holocene sea-ice conditions compare well with modern
458 situation at the core site characterized by a seasonal decrease in sea ice concentration from 50% during winter to
459 mainly ice-free summers (NSIDC; Cavalieri et al., 1996).

460 The continued retreat of the previously grounded APIS adjacent to the Bransfield Strait between 10 ka and 5 ka
461 BP finally opened the passage for ACC waters to enter the Bransfield Strait from the west (Bentley et al., 2014; Ó
462 Cofaigh et al., 2014). As a result, we suggest that sea ice conditions at our core site were influenced by incursions
463 of warmer ocean waters carried with the ACC (i.e. BSW and CDW), while cold water inflow and sea ice advection
464 from the Weddell Sea was diminished due to the still grounded ice sheet at the tip of the AP (Ó Cofaigh et al.,
465 2014), leading to a shorter sea ice season in the eastern Bransfield Strait. This shift towards a warmer, less ice-
466 covered ocean setting in the eastern Bransfield Strait is reflected in the transition from proximal to distal
467 glacialmarine conditions in Maxwell Bay (Milliken et al., 2009) and may be associated with the Mid-Holocene
468 climatic optimum. This timing contrasts the notion of Heroy et al. (2008), who, confined the Mid-Holocene
469 climatic optimum to a shorter time interval between 6.8 ka and 5.9 ka BP based on diatom assemblage analyses of
470 a sediment core in the western Bransfield Strait. We propose that this temporal offset may relate to regionally
471 different responses, glacial retreat patterns impacting oceanic pathways and the position of frontal systems
472 controlling primary productivity within Bransfield Strait. The generally decreasing WSI and variable PIPSO₂₅
473 values further depict different trends than PIPSO₂₅ values determined for the JPC10 in Palmer Deep (Fig. 4d;
474 Etourneau et al., 2013), which suggest an overall increase in spring sea ice along the WAP until 4.2 ka BP. Though
475 minima in spring sea ice at 7.5 ka, 6.5 ka and 5.4 ka BP at core site PS97/072-1 may be related to PIPSO₂₅ minima
476 observed for JPC10, the lack of Middle Holocene age tie points in our core from the Bransfield Strait prevents us
477 from concluding on a common driver for these sea ice reductions.

478 Regarding ocean temperatures, we observe a sustained warming in RI-OH' SOT, punctuated by a cooling at 5.5
479 ka BP (Fig. 5c), while TEX₈₆^L temperatures depict a subtle cooling of ca. 0.5 °C between 8.2 ka and 7 ka BP,
480 followed by a warm reversal until 6 ka BP, and a further cooling until 4.2 ka BP (Fig. 5e). This Middle Holocene
481 slight cooling trend is also observed in the TEX₈₆^L records from the core sites in Palmer Deep at the WAP (Fig.
482 5f, g; Etourneau et al., 2013; Shevenell et al., 2011). The similarity between these records encourages us to assume
483 that these TEX₈₆-derived temperatures from along the WAP and NAP are driven by spring insolation rather than
484 being a reflection of annual mean ocean temperature conditions.

485 **4.4 Late Holocene and Neoglacial from 4.2 ka BP until today**

486 The Late Holocene covering the past 4.2 ka BP is characterized by a highly variable winter sea ice and decreasing
487 spring sea ice cover at core site PS97/072-1, as indicated in the MAT-derived WSI and a decline in PIPSO₂₅ values
488 over the past 2 ka (Fig. 4a, b). Rather constant biogenic opal and TOC contents (Fig. 3e, f), however, suggest that
489 primary productivity remained relatively unaffected by this reduction in spring sea ice cover. While decreasing
490 IPSO₂₅ concentrations between 2.5 ka BP and the core top (Fig. 3d) suggest a reduced productivity of the sea ice
491 diatom species synthesizing this molecule, no significant changes are observed in the sea ice diatom assemblage
492 (Fig. 3c), which supports the assumption that only a restricted group of diatoms - at least *Berkeleya adeliensis* -
493 produce IPSO₂₅ (Belt et al., 2016). The warm open ocean diatom assemblage follows an overall declining trend
494 throughout the Late Holocene, which is not reflected in the highly variable and slightly increasing HBI triene
495 concentrations (Fig. 3a, b), and a prominent decrease in HBI triene concentrations occurs only at 1 ka BP. While
496 the observation of cooler sea surface temperatures, and a diminished spring sea ice cover indicated by the joint
497 decrease in the warm open ocean diatom assemblage and PIPSO₂₅ values since 2 ka BP may seem counterintuitive,
498 Milliken et al. (2009) report a similar development in Maxwell Bay since 2.6 ka BP. Interestingly, records of
499 diatom and radiolarian assemblages of a sediment core (Gebra-2) collected in close vicinity to PS97/072-1
500 document an overall increase in sea-ice taxa over the past 3 ka BP with distinct Neoglacial events characterized
501 by higher (denser and longer) sea ice cover (Bárcena et al., 1998). The lower sampling resolution and missing age
502 control for the past 3 ka BP in PS97/072-1, however, hamper a more detailed comparison of diatom species in our
503 core with those investigated for Gebra-2. The Neoglacial increase in spring sea ice cover is also indicated by a
504 prominent rise of PIPSO₂₅ values determined for JPC10 in Palmer Deep (Fig. 4d; Etourneau et al., 2013). Similarly,
505 deposition of ssNa in the EDML ice core (Fischer et al., 2007) increases since 2 ka BP.

506 Minimum PS97/072-1 PIPSO₂₅ values at 0.5 ka BP result from notably reduced IPSO₂₅ and HBI triene
507 concentrations (Fig. 3b, d). While this pattern of minimum HBI triene and IPSO₂₅ concentrations is similar to the
508 period between 13.8 ka and 13.5 ka BP, which was characterized by cold conditions and a pronounced - potentially
509 perennial - ice cover, the elevated TOC and biogenic opal values, as well as the presence of diatoms associated
510 with warm open ocean conditions at 0.5 ka BP, point to favorable ocean conditions. We hence relate this drop in
511 HBI concentrations to a shift in the diatom community rather than to an abrupt readvance of an ice cover.

512 Late Holocene ocean temperature reconstructions for core PS97/072-1 display different patterns. Generally
513 increasing diatom-derived SSTs are only punctuated by a cooling event at 3.1 ka BP, while RI-OH' SOT remains
514 relatively constant with a very subtle cooling of ca. 0.2 °C between 1.5 ka and the present, which could be linked
515 to the slight decrease in summer insolation (Fig. 5a, b, c). The decrease in TEX₈₆^L SOT by about 1 °C between 4

516 **ka and 3.3 ka BP in eastern Bransfield Strait** is also depicted in the $\text{TEX}_{86}^{\text{L}}$ data from the Palmer Deep core JPC10
517 (Fig. 5e, f; Etourneau et al., 2013). The following warming reflected in PS97/072-1 $\text{TEX}_{86}^{\text{L}}$ SOT until ca. 2 ka BP
518 may relate to the establishment of open marine conditions fostering primary productivity at the Perseverance Drift
519 north of Joinville Island (northern tip of the AP) as a result of warm water intrusions (Kyrmanidou et al., 2018).
520 This warming is reversed by another cooling at about 2 ka BP - coincident with an abrupt temperature increase of
521 ca. 4 °C depicted in the ODP1089 TEX_{86} SOT record in Palmer Deep (Fig. 5g; Shevenell et al., 2011). The latter
522 warming is not displayed in the $\text{TEX}_{86}^{\text{L}}$ data of the nearby JPC10 and we relate this contrast to the different
523 approaches used to determine SOT (*i.e.*, TEX_{86} vs. $\text{TEX}_{86}^{\text{L}}$ omitting the crenarchaeol regio-isomer, which seems
524 to be less important for membrane adaptation in polar waters; Kim et al., 2010).
525 Evidently, temperature trends at the AP in the Late Holocene are highly variable between different areas (Allen et
526 al., 2010; Barbara et al., 2016; Bárcena et al., 1998; Bentley et al., 2009; Etourneau et al., 2013; Mulvaney et al.,
527 2012; Shevenell et al., 2011) and this is likely associated with the complex oceanographic and atmospheric
528 settings. This heterogeneous pattern, however, contrasts with the currently observed large-scale ocean warming
529 along the AP driven by intrusions of ACC-derived warm CDW onto the continental shelf of the WAP (Couto et
530 al., 2017) and the NAP (Ruiz Barlett et al., 2018), as well as the overall loss of sea ice (Parkinson and Cavalieri,
531 2012), which supports the assumption that **the changes** impacting the AP already exceed natural variability.

533 **5 Conclusions**

534 We reconstructed the sea ice and climate development at the NAP since the last Deglacial using the sediment core
535 PS97/072-1 from the eastern Bransfield Strait. Pursuing a multi-proxy approach that focuses on organic
536 geochemical bulk and biomarker analyses, diatom assemblage studies and transfer functions as well as IRD data,
537 we identified different Deglacial and Holocene environmental conditions impacted by sea ice and ocean
538 temperature changes. Our results reveal the retreat of a perennial ice cover after the ACR and an overall sea ice
539 reduction and warming summer ocean temperatures during the Holocene. The late Deglacial from 13.8 ka to 11.7
540 ka BP was a highly dynamic period: until 13.4 ka BP primary productivity was **diminished** due to a permanent ice
541 cover during the ACR. The ACR terminated with a shift to slightly warming conditions at 13 ka BP along with a
542 reduction in the length of the sea ice season, which permitted phytoplankton productivity at least during summer.
543 The Early Holocene from 11.7 ka to 8.2 ka BP was characterized by increasing summer ocean temperatures, further
544 decreasing sea ice cover in terms of duration and/or sea ice concentration and highly variable winter sea ice cover.
545 In the Middle Holocene from 8.2 ka to 4.2 ka BP, increased advection of BSW and CDW led to a shortened sea

546 ice season confined to winter and spring and rising summer ocean temperatures fostering primary production,
547 indicating the Middle Holocene Climatic Optimum. During the Late Holocene, the core site experienced distinct
548 fluctuations in WSI with concentrations shifting between 90% and 60%, while PIPSO₂₅ values declined
549 continuously suggesting a less intensive or shorter spring sea ice cover. We note that GDGT-based TEX₈₆^L and
550 RI-OH' SOTs correspond to spring and summer insolation, respectively, which may explain the divergent trends
551 displayed by both SOT proxies. Clearly, while this observation may help with the interpretation of other Southern
552 Ocean GDGT-based temperature estimates and the reconstruction of seasonal SOT variability, more investigations
553 into the mechanisms driving GDGT synthesis in polar waters are needed.
554

555 **Data Availability**

556 All data mentioned in this paper will be available at the open access repository www.pangaea.de
557 (<https://doi.pangaea.de/10.1594/PANGAEA.952279>).

558 **Author contributions**

559 The study was conceived by MV and JM. Data collections and experimental investigations were done by MV
560 together with CBL (core description, sampling, diatoms, biogenic opal, age model), PC (diatoms), AL (age model,
561 diatoms), OE (diatom transfer function), GM (GDGTs, ¹⁴C dating), AVH ($\delta^{13}\text{C}$ IPSO²⁵), NL ($\delta^{13}\text{C}$ TOC), LLJ
562 (foraminifera, age model), SMS (age model, humming age), JE, DE and CE provided temperature and salinity
563 profiles near the study site. MV drafted the manuscript. All authors contributed to the interpretation and discussion
564 of the data and the finalization of this manuscript.

565

566 **Competing interests**

567 None of the authors have a conflict of interest.

568

569 **Acknowledgement**

570 We thank the captain, crew and chief scientist Frank Lamy of RV Polarstern cruise PS97. Denise Diekstall, Jens
571 Hefter, Alejandro Avila and Victor Acuña are thanked for their laboratory support. We thank Helge Arz for his
572 help with the age model. Simon Belt is acknowledged for providing the 7-HND internal standard for HBI
573 quantification. Financial support was provided through the Helmholtz Research grant VH-NG-1101. Partial
574 support from the Centers IDEAL (grant FONDAP 15150003) and COPAS (grants AFB170006 and FB210021),
575 Chile, and the Spanish Ministry of Economy, Industry and Competitiveness grants CTM2017-89711-C2-1/2-P, co-
576 funded by the European Union through FEDER funds, is acknowledged. We appreciate support by the Open
577 Access Publication Funds of Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung.

995

996

998

999

1000 Figure 1: a) Overview map with modern oceanography in the study area (Hofmann et al., 1996; Sangrà et al., 2011). ACC =
 1001 Antarctic Circumpolar Current, BSW = Bellingshausen Sea Water, CDW = Circumpolar Deep Water, WSW = Weddell Sea
 1002 Water, and PF = Peninsula Front. b) Bathymetric features in the Bransfield Strait with the location of sediment core PS97/072-
 1003 1 (red star) and other sediment records discussed in the text (green), and the CTD station (purple cross) where c) the vertical
 1004 profile of ocean temperature and salinity (cruise POWELL2020, CTD 007 (62°09.075'S, 56°37.09'W) from 27.01.2020) shows
 1005 a clear stratification of the upper 100 m of the water column. It indicates that surface waters are dominated by the BSW, while
 1006 the basin is filled with WSW water. Maps were done with QGIS 3.0 (QGIS, 2018) and the bathymetry was taken from
 1007 GEBCO_14 from 2015.

1008
1009

1010 Figure 2: Age-depth model for sediment core PS97/072-1 based on eight ^{14}C dated calcite samples (black) with
 1011 error bars and mean sedimentation rates (cm/ka, dashed blue line). The core top age (red) was estimated as 0.05
 1012 ka BP from matching with the ^{210}Pb -dated multicore PS97/072-2 (Vorrath et al., 2020; see supplement section 2).

1013

1014

1015

1016 Figure 3: Overview of organic geochemical parameters and main diatom assemblages determined in sediment core
 1017 PS97/072-1 used to characterize the environmental setting over the past 14 ka BP. a) warm open ocean diatom
 1018 assemblage, b) C_{25:3} HBI triene, c) sea ice diatom assemblage, d) IPSO₂₅, e) biogenic opal and f) TOC contents.
 1019 Asterisks in f) mark layers of volcanic ash, where ** can be linked to a tephra layer in a sediment core from the
 1020 Bransfield Strait at 5.5 ka BP (Heroy et al., 2008). Black lines display running averages. Grey shaded interval
 1021 refers to the Antarctic Cold Reversal.

1022

1023

1024

1025 Figure 4: Sea ice related proxies in sediment core PS97/072-1 with a) the diatom based WSI, b) the sea ice index
 1026 PIPSO₂₅, and c) ice rafted debris (IRD). For comparison: PIPSO₂₅ values of sediment core d) JPC10 from the
 1027 Palmer Deep station (Etourneau et al., 2013) and ssNa records of e) the EDML ice core (Fischer et al., 2007) and
 1028 f) the WAIS ice core (WAIS Divide Project Members, 2015). Black lines display running averages. Grey shaded
 1029 interval refers to the Antarctic Cold Reversal.

1030

1031

1032

1033 Figure 5: A comparison of a) December insolation (Laskar et al., 2004), b) diatom-based SSST, c) RI-OH'-derived
 1034 SOT, d) September insolation (Laskar et al., 2004), e) TEX_{86}^L -SOT of sediment core PS97/072-1, and temperature
 1035 reconstructions f) TEX_{86}^L from JPC10, Palmer Deep (Etourneau et al., 2013), g) TEX_{86} from ODP1098, Palmer
 1036 Deep (Shevenell et al., 2011), and h) ice core stable isotope record of WAIS Divide (WAIS Divide Project
 1037 Members, 2013). Ocean temperatures are displayed as anomalies with respect to the mean of the individual SOT
 1038 and SSST values of the entire record. Black lines display running averages. Grey shaded area refers to the Antarctic
 1039 Cold Reversal.
