**Abstract.** The Earth's albedo is observed to be symmetric between the hemispheres on the annual mean timescale, despite the clear-sky albedo being asymmetrically higher in the northern hemisphere due to more land area and aerosol sources; this is because the mean cloud distribution currently compensates for the clear-sky asymmetry almost exactly. We investigate the evolution of the hemispheric difference in albedo in CMIP6 coupled model simulations following an abrupt quadrupling of CO<sub>2</sub> concentrations, to which all models respond with an initial decrease of albedo in the northern hemisphere (NH) due to loss of Arctic sea ice. After this initial NH darkening, the evolution of the hemispheric albedo difference diverges among models, with some models remaining at their new hemispheric albedo difference, and others returning towards their pre-industrial difference through either a reduction in SH clouds or an increase in NH clouds, or a combination of the two. These responses have different implications on the reduction in global albedo, and thereby the strength of the shortwave cloud feedback: if a cross-hemispheric communicating mechanism is primarily responsible for maintaining hemispheric albedo symmetry, the total shortwave radiative feedback must be more strongly positive. We also show that in these models, there is a link between the extent of reductions in SH extratropical cloud cover and Antarctic albedo decline due to increased poleward heat transport in the SH.

## 1 Introduction

The Earth's albedo is hemispherically symmetric to a high degree; the northern hemisphere (NH) minus southern hemisphere (SH) difference in annual mean hemispheric albedo (henceforth referred to as asymmetry) has been on the order of -0.1% for the past two decades (Datseris and Stevens, 2021; Jönsson and Bender, 2022). This was first noted, although with greater uncertainty, during the first generation of satellite observations of Earth's radiative energy balance (Haar and Suomi, 1971), and persists without detectable trends in modern satellite observations (Voigt et al., 2013; Stephens et al., 2015; Datseris and Stevens, 2021; Jönsson and Bender, 2022). This is possible because in the all-sky albedo, the annual mean cloud distribution compensates for the clear-sky albedo asymmetry that exists due to differences in surface properties and aerosol loading between the NH and SH (Stephens et al., 2015; Jönsson and Bender, 2022; Diamond et al., 2022). Climate models have a large spread of albedo asymmetry (Stephens et al., 2015; Jönsson and Bender, 2022), but the variability of asymmetry in model

simulations is low, with most models exhibiting relatively small changes between pre-industrial (PI) and present-day (PD) historical asymmetries (Jönsson and Bender, 2022).

Higher cloud amount in the SH subtropics as well as higher cloud amount and cloud albedo in the SH midlatitudes than in their NH counterparts compensate for both the clear-sky albedo asymmetry and higher cloud amount in the NH tropics than in the SH tropics (Bender et al., 2017). Thus, extratropical cloud cover has been highlighted as important for maintaining the hemispheric albedo symmetry in the annual mean and beyond (Datseris and Stevens, 2021; Jönsson and Bender, 2022; Rugenstein and Hakuba, 2021), while variability in tropical cloud cover has been found to contribute to variability in the albedo asymmetry time series (Jönsson and Bender, 2022). The clear-sky hemispheric albedo asymmetry is determined mostly by contributions from the clear-sky atmosphere (Stephens et al., 2015; Jönsson and Bender, 2022), pointing to a strong influence from aerosols in the NH in leading to a presently higher NH than SH clear-sky albedo (Diamond et al., 2022). In higher latitudes, the surface contributes a greater share of the albedo (Stephens et al., 2015). Because of aerosol emission drawdown and changes in the cryosphere due to global warming, the clear-sky hemispheric albedo asymmetry is likely to change in the near future (Diamond et al., 2022).

The Earth's albedo is to a large degree determined by contributions from clouds, accounting for over half of the upwelling shortwave (SW) radiative fluxes at the top of the atmosphere (TOA) in the global mean. This means that the planetary albedo is relatively sensitive to changes in cloud properties and coverage with a changing climate. The sum effect of clouds on changes in planetary albedo and thus reflected SW radiation on Earth's radiative balance at the TOA in response to change in temperature is referred to as the total SW cloud radiative feedback, and its spatial distribution as well as its global mean magnitude is the greatest source of uncertainty in estimating the climate's sensitivity to CO<sub>2</sub> forcing (Forster et al., 2021). The spread of SW cloud radiative feedbacks estimated by coupled models has increased in the latest phase of Coupled Model Intercomparison Project (CMIP6) compared to the previous (CMIP5), and its average value has increased from slightly negative in CMIP5 to slightly positive in CMIP6 (Zelinka et al., 2020). Observational constraints also support this positive SW cloud radiative feedback estimate (Ceppi and Nowack, 2021; Forster et al., 2021). The hemispheric albedo symmetry is thereby relevant in addressing a significant source of uncertainty in constraining estimates of climate sensitivity: understanding any mechanisms that might maintain this symmetry can aid in estimating the magnitude and distribution of the total SW cloud radiative feedback.

While there is no known physical mechanism or explanation for the observed hemispheric albedo symmetry, it is important to pose the question: what would a mechanism for maintaining a hemispheric albedo symmetry entail for climate? Given that there is no observed trend in the hemispheric difference in albedo despite changes in the global radiative energy balance and despite global changes in albedo (Stephens et al., 2022), the hemispheric symmetry is at least over this period robust. In this study, we investigate the implications for Earth's climate if its albedo is forced out of its current hemispheric symmetry due to warming processes, to guide an exploration of possibilities for changes in the global cloud distribution in a changing climate.

We examine possible pathways for the Earth's albedo symmetry response to warming using climate models, and discuss how these pathways for hemispheric albedo differences in a perturbed climate manifest in terms of changes to the cloud distribution, heat transport, energy balance, and warming. To this end, we use simulations from an ensemble of coupled atmosphere-ocean and earth system models from the Coupled Model Intercomparison Project phase 6 (CMIP6) (Eyring et al., 2016)

in which CO<sub>2</sub> concentrations are abruptly quadrupled from PI levels. These idealized single-forcing experiments allow for  
 60 study of the evolution of albedo asymmetry in models in response only to greenhouse gas (GHG)-forced warming, without  
 consideration of aerosol forcing that is presently significant but can be expected to be much smaller than the CO<sub>2</sub> forcing in  
 the future if ongoing aerosol emission drawdown continues (Myhre et al., 2015; Szopa et al., 2021). We show how modeled  
 albedo asymmetries evolve as the climate warms, and categorize model behavior by symmetry-maintaining responses (Section  
 3.1). We then characterize potential albedo symmetry-maintaining mechanisms and how strongly they act among the models  
 65 (Sections 3.2 and 3.3). Finally, we describe the implications that symmetry-maintaining mechanisms have for the strength  
 of SW cloud radiative feedbacks (Section 3.4), and discuss the realism of these mechanisms as well as the possibility to  
 observationally constrain them (Section 4).

## 2 Methods

### 2.1 Model output

70 In this analysis, we use CMIP6 abrupt, strong forcing (abrupt-4xCO<sub>2</sub>) experiments as well as simulations of PI conditions  
 (piControl) and those using historical forcings (Eyring et al., 2016). Abrupt forcing simulations can be used to estimate each  
 model's equilibrium climate sensitivity (ECS) by regressing the global mean temperature response against the magnitude of  
 radiative forcing in the model; this slope yields the effective climate sensitivity (EffCS), a first-order estimate of ECS (Gregory  
 et al., 2004). This method requires a reasonable amount of simulation time (the minimum for CMIP6 participation being  
 75 150 years) compared to the millennia that are needed for a model's climate to equilibrate and yield a calculation of the ECS  
 (Rugenstein et al., 2020), and thus includes a high number of models. The abrupt forcing simulations allow sequences of  
 events in the adjustment of the climate system to be studied as they occur on separate timescales. In this study, we consider  
 one realization (r1i1p1f1) each from 34 models (listed in Table 1) and discuss their evolution over 150 years of simulation time  
 following the onset of forcing. We use one realization (r1i1p1f1) of historical simulations for each model to estimate values  
 80 of PD conditions over the years 2000-2014, to compare to Clouds and the Earth's Radiant Energy System, Energy Balanced  
 and Filled (CERES EBAF) (Loeb et al., 2018) values obtained from observations over March 2000-February 2015. We also  
 make use of estimates of radiative feedback strengths published by Zelinka et al. (2022). We choose only models where all  
 radiative flux variables were available, but some models are excluded when other variables are presented where output was not  
 available; these are specified in Appendix A.

### 85 2.2 Calculations

We focus our analysis on modeled reflected SW radiative fluxes at the TOA ( $F_{TOA}^{\uparrow}$ ) and albedo  $\alpha$  in all- and clear-sky condi-  
 tions, as well as the SW cloud radiative effect (CRE), defined as the difference between clear- and all-sky  $F_{TOA}^{\uparrow}$ :

$$\text{SW CRE} = F_{TOA, \text{clear}}^{\uparrow} - F_{TOA, \text{all}}^{\uparrow}, \quad (1)$$

so that a negative CRE implies TOA cooling. NH minus SH hemispheric differences in  $F_{TOA}^{\uparrow}$  are referred to as *asymmetry*,  
 90 and hemispheric differences in other values are denoted with  $\delta_{HD}$ . Differences in time are denoted with  $\Delta$ . Area averages are  
 calculated using meridional weights given by the cosine of latitude, i.e. assuming a spherical Earth model. In calculating time  
 averages, we weight CERES EBAF time averages by the length of months in days, but we do not weight values of monthly  
 averages in models by the length of the month due to differences in model calendars; we motivate this with the assumption  
 that differences in time averages among the 34 models presented here should arise primarily from differences in the models  
 95 themselves and secondarily by the 5-day ( $\sim 1\%$ ) spread in model calendar years.

To estimate meridional heat transport (MHT) and its components, we use monthly mean TOA and surface energy fluxes  
 following the methods outlined in (Donohoe et al., 2020). We show only the tendency of meridional redistributions of energy  
 absorbed by the climate system, as the modeled climate systems in these simulations are not in equilibrium. The implied  
 total (ocean plus atmosphere) MHT is assumed to be driven by the meridional distribution of TOA energy imbalance, and  
 100 the implied atmospheric heat transport (AHT) is assumed to be driven by the energy input into the atmosphere, or difference  
 between the TOA energy input and the total surface energy input.

### 3 Results

#### 3.1 Modeled albedo asymmetry responses to CO<sub>2</sub> forcing

Figure 1 depicts the time evolution of modeled asymmetries relative to their PI mean hemispheric albedo difference; Figure 2  
 105 includes profiles of zonal mean changes in all- and clear-sky reflected radiation as well as SW CRE throughout the simulations.  
 In all models, asymmetry immediately becomes more negative following a reduction of NH albedo, which occurs primarily in  
 the first 50 years after the forcing is applied; from here on, we will refer to the period between 30-50 years into the experiment  
 as ‘Mid’, and use its mean conditions as representative of the model state after the initial NH darkening response (Figure 1a,  
 b). This NH darkening is primarily due to the reduction in high-latitude albedo, which can be seen in Figure 2a, and can be  
 110 ascribed to loss of NH sea ice. The spread in the magnitude of the initial asymmetry response is due partly to a spread in  
 clear-sky albedo reductions (Figure 2b) and partly to spread in SW CRE at high latitudes in the NH (Figure 2c). The initial  
 polar albedo reductions in the SH are smaller than those in the NH (Fig 2a, b), but also show some spread among models,  
 contributing to the overall response of the hemispheric albedo symmetry. The model spread in clear-sky asymmetry evolution  
 can be seen in Figure 1b, and Figure 1c illustrates that much of the all-sky asymmetry response throughout the 150 years is  
 115 determined by the clear-sky asymmetry response.

All models generally see a weakening in negative subtropical SW CRE in both hemispheres throughout the 150 years  
 (Figure 2c, 2f and 2i). Figure 1d shows that the hemispheric mean difference in net TOA energy input follows the change in  
 asymmetry by roughly 1:1  $\text{W m}^{-2}$  among models. A negative (positive) disturbance in the NH-SH hemispheric mean difference  
 in net TOA heating means that an anomalous northward (southward) cross-equatorial energy transport relative to PI — or if  
 120 cross-equatorial transport is not changed, hemispherically asymmetric warming — would be induced.

After the ‘Mid’ period, the evolution of the asymmetry time series diverges among the models, with some models’ asymmetry remaining relatively static and others recovering towards their PI mean asymmetry. In two models, EC-Earth3-Veg and EC-Earth3-AerChem, asymmetry continues to strengthen in the negative direction due to continued NH darkening. By 150 years, several models have recovered their PI mean asymmetry, with some overcompensating towards a more positive asymmetry than in PI conditions. Models that recover towards their PI mean asymmetry by the end of the simulation (we will refer to the years 130-150 as the ‘End’ period) do so primarily by weakening negative SH extratropical and midlatitude SW CRE beyond ‘Mid’ (Figure 2i).

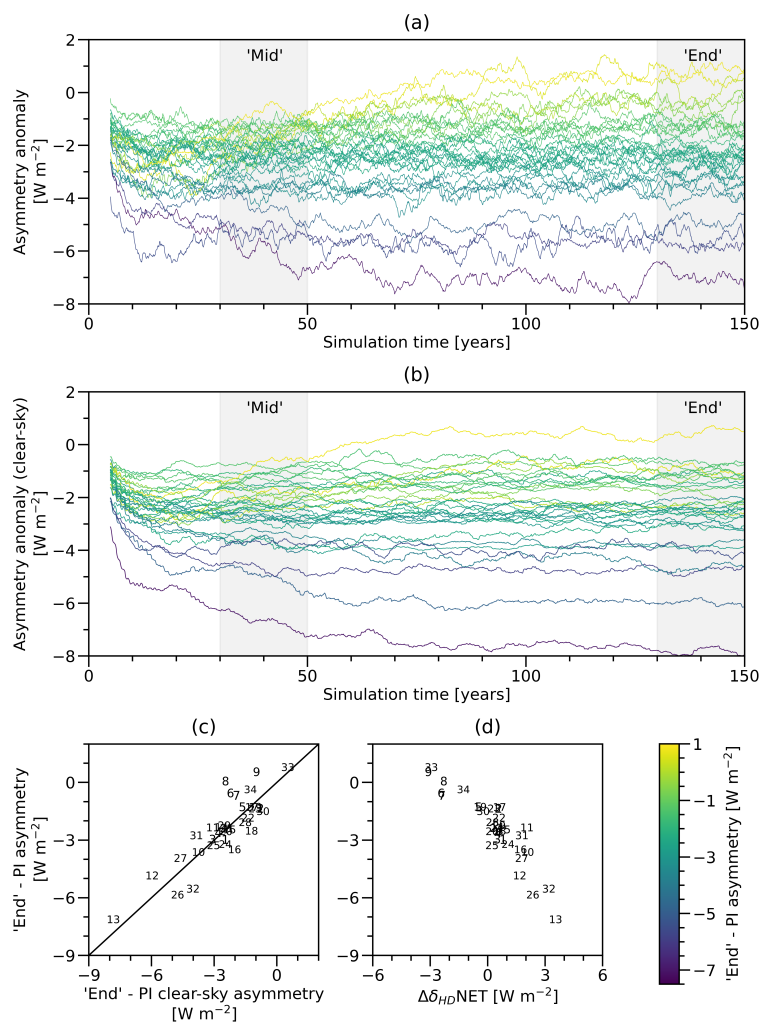

While models agree on clear-sky albedo reductions in the NH in response to warming, the spread in magnitude of total albedo reductions points to differences among the models in whether clouds serve to either amplify or reduce the total albedo reduction in the hemispheric mean. Disturbances in the hemispheric albedo symmetry with warming may be reduced by clouds when they dampen albedo reductions caused by decreasing surface contributions; we will refer to these types of compensations as local compensations. These compensations occur primarily where the surface contribution reductions to albedo are the greatest, and we will discuss the NH cloud responses and their impact on the initial asymmetry response via local compensations in Section 3.2. Models also disagree on the amount of SH hemispheric mean albedo reductions, causing a divergence in modeled hemispheric albedo asymmetry after ‘Mid’ and leading to some models recovering towards their PI mean albedo asymmetry; we will refer compensations to the NH darkening offered by SH albedo reductions as remote compensations. To understand how clouds relate to the impact of reductions in SH extratropical and polar albedo among models, we will describe the model evolution in SH climate between ‘Mid’ and ‘End’ in Section 3.3. The agreement in modeled hemispheric albedo asymmetry responses in the initial response and the subsequent divergence of the asymmetry time series among models hints at processes that affect clouds and albedo occurring at different timescales.

It is important to note that we present the evolution of modeled albedo asymmetry relative to PI conditions to study its potential response to warming, and there is a large spread in PI mean hemispheric albedo differences among models (shown in Supplementary figure S1) (Jönsson and Bender, 2022; Diamond et al., 2022; Rugenstein and Hakuba, 2021).

### 3.2 Local compensation: NH cloud interactions with clear-sky darkening

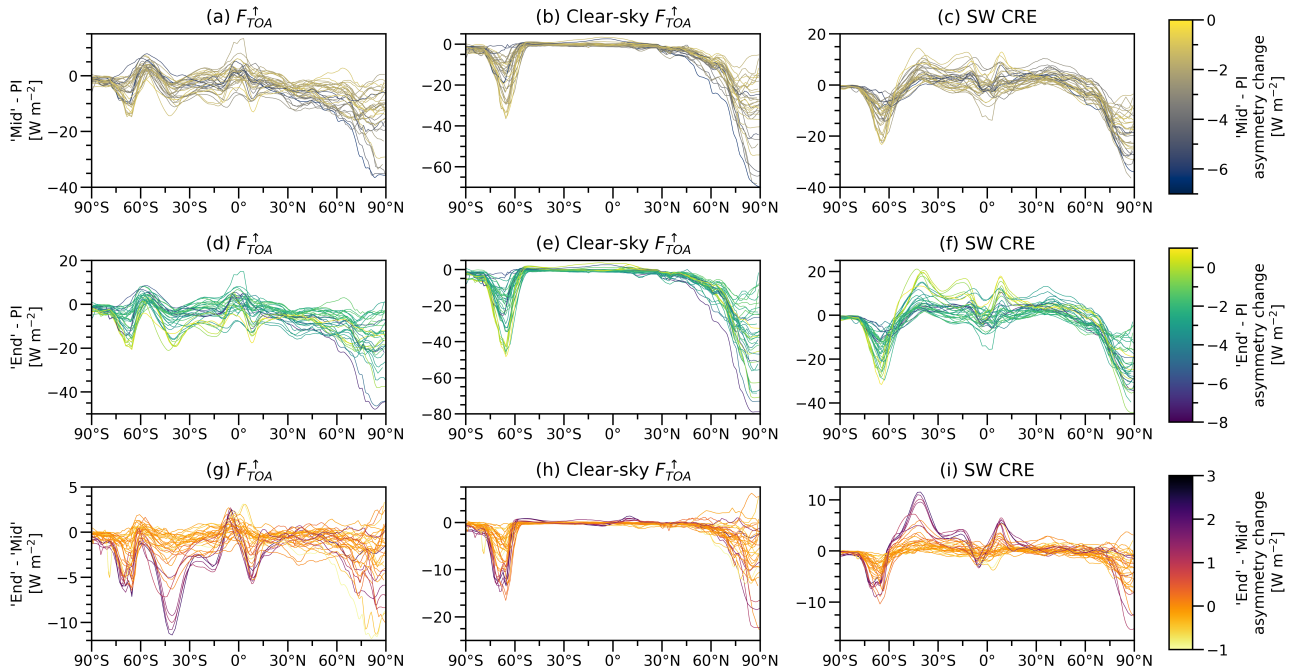

The initial response of NH darkening among models is primarily due to the clear-sky albedo reduction caused by decreased surface contributions to albedo as the NH cryosphere changes. Although the asymmetry response following the initial NH surface darkening is unanimous among models in terms of sign, there is spread in the magnitude of this asymmetry response. This spread is related to the impact of clouds on NH albedo, over which models disagree on whether they strengthen or dampen the NH clear-sky albedo reduction seen in the asymmetry time series. Figure 3 presents the differences in area-mean upwelling SW radiation at the TOA in all- and clear-sky conditions between ‘Mid’ and PI.

First, it is worthwhile to look at the cloud masking of Arctic surface albedo reductions resulting from the changes in the cryosphere in response to warming (Figure 3b). Poleward of 60° N, models agree that clouds reduce the impact of the loss of Arctic ice cover on Arctic planetary albedo, as has been detailed in Sledd and L’Ecuyer (2021), although they disagree on the magnitude of this cloud compensation for surface albedo darkening. However, the overall impact of clouds on NH albedo

**Figure 1.** Time series of 5-year running mean modeled all-sky (a) and clear-sky (b) asymmetry responses in abrupt-4xCO<sub>2</sub> simulations, and differences between ‘End’ and PI mean modeled all-sky albedo asymmetry plotted against (c) clear-sky albedo symmetry and (d) NH-SH hemispheric mean differences in TOA net radiation input (NET). The color scale of time series lines is representative of the total ‘End’ minus PI albedo asymmetry difference. Numbers in the scatter plot correspond to the model number as listed in Table 1.

155 varies between models, despite masking the surface albedo reduction in higher latitudes. Figure 3a shows that models agree on NH clear-sky albedo being reduced, but that the spread in mean NH SW CRE changes is high, being split between 17 models in which the clouds amplify the clear-sky albedo darkening and 16 in which they suppress some of it, dampening the overall NH planetary albedo reduction. Figure 2f shows that this is a result of compensation between CRE increases in the extratropics and more negative SW CRE in the Arctic.

**Figure 2.** Meridional profiles of differences in zonal mean all- and clear-sky  $F_{TOA}^{\uparrow}$ , as well as SW CRE between (a-c) ‘Mid’ and PI conditions, (d-f) ‘End’ and PI conditions, and (g-i) ‘End’ and ‘Mid’. Color scales represent the change in modeled mean hemispheric asymmetry between those periods.

160 While models exhibit strengthening negative SW CRE in the Arctic, most exhibit an evolution towards a less negative SW CRE in the NH subtropics and disagree on SW CRE changes in the NH midlatitudes, while clear-sky albedo does not change much in these latitudes. In this way, there is model disagreement in whether clouds would either amplify or reduce the NH albedo decrease caused by changes in the high-latitude clear-sky albedo during warming depending on both the the degree of strengthening negative SW CRE in the Arctic and the direction and strength of SW CRE changes in NH midlatitudes and  
 165 subtropics. The model disagreement in these NH cloud responses and their contributions to the planetary albedo leads to the spread in the strength of the initial response of the albedo asymmetry time series seen among models in Figure 1a. Figure 2 shows that most of these responses in the NH occur primarily by the end of the ‘Mid’ period and evolve less thereafter; changes after ‘Mid’ occur mostly at high latitudes.

One model family, EC-Earth3 (containing EC-Earth3-Veg and EC-Earth3-AerChem), exhibits continued NH albedo reduc-  
 170 tion. This is an extreme case of a lack of cloud compensations to NH surface albedo reductions in the Arctic, and continued global increases in SW CRE with warming. In this case, the overall impact is that the asymmetry in these models continues to strengthen over time as the NH polar albedo decreases beyond the ‘Mid’ period.

**Figure 3.** Mean differences in all- and clear-sky  $F_{TOA}^{\uparrow}$  as well as SW CRE in (a) the entire NH and (b) in the Arctic only (here  $> 60^\circ N$ ) between ‘Mid’ and PI conditions. Model numbers are as given in Table 1.

### 3.3 Remote compensation: SH extratropical cloud responses to warming

One way to maintain a hemispheric albedo symmetry after perturbing the clear-sky hemispheric albedo difference would be that, when one hemisphere darkens, the other darkens as well. As shown in Section 3.1, models agree on a relative darkening of the NH immediately after the onset of  $CO_2$  forcing. Following this, some models exhibit a return towards their PI mean asymmetry as SH cloud cover changes, reducing SH albedo. Figure 4a illustrates that SW CRE becomes less negative in the SH extratropics and midlatitudes, peaking at roughly  $45^\circ S$ . In this section, we henceforth use the difference in  $30-60^\circ S$  area mean SW CRE between the ‘End’ and ‘Mid’ periods as an indicator of the impact of cloud albedo contribution changes on TOA albedo in the SH extratropics among models. Comparing changes in  $30-60^\circ S$  mean SW CRE against cloud characteristics (Figure 4b-f) reveals that the primary cause for this spread are reductions in cloud fraction, which outcompetes increases in cloud water content and changes in cloud water phase partitioning (greater fraction of liquid water content) that would otherwise increase SW CRE (Mülmenstädt et al., 2021) in some models. Note also that SW CRE at higher latitudes ( $> 60^\circ S$ ) also becomes more negative consistently in models with SW CRE increases in the SH extratropics.

Among the models, we find a relationship between the evolution of the climate at high latitudes in the SH with SW CRE increases in the SH extratropics. Atmospheric moisture content increases in the SH (Figure 5a) as clouds are lost and the at-

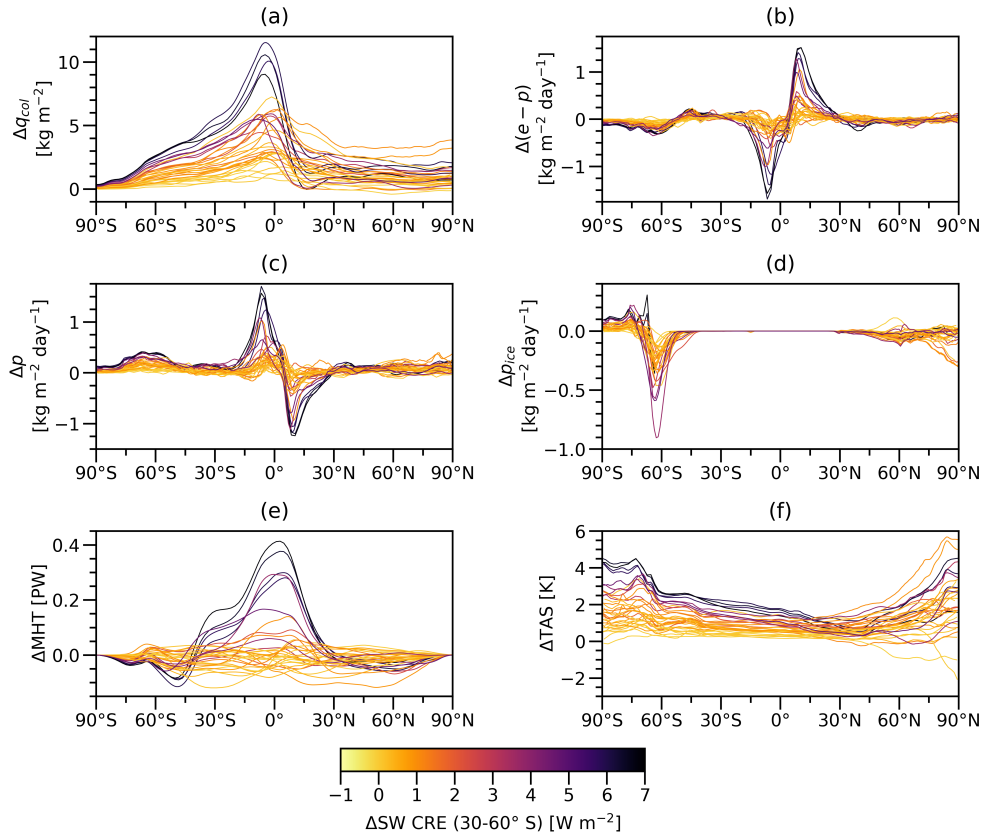

**Figure 4.** (a) Meridional profiles of differences in zonal mean SW CRE between ‘End’ and ‘Mid’ in models. The color scale depicts changes in 30-60° S area mean SW CRE between ‘End’ and ‘Mid’. Scatter plots show 30-60° S area mean differences between ‘End’ and ‘Mid’ SW CRE plotted against differences in (b) cloud fraction  $f$ , (c) in-cloud total water path CWP, (d) in-cloud liquid water path CLWP, (e) in-cloud ice water path CIWP, and (f) fraction of in-cloud ice to total water path  $f_{\text{CIW}}$  between ‘End’ and ‘Mid’. Markers denote models as they are numbered in Table 1.

mosphere is warmed. This leads to greater poleward moisture transport; the zonal mean evapotranspiration minus precipitation ( $e - p$ ) profiles (Figure 5b) imply that a net poleward transport of moisture away from the SH extratropics ( $\sim 30-50^\circ \text{ S}$ ) to the polar region ( $> 60^\circ \text{ S}$ ) continues to strengthen after ‘Mid’ in these models. Consequently, in models with greater SH extratropical cloud loss, total precipitation increases at high latitudes in the SH (Figure 5c). In the midlatitudes and sea ice zone ( $\sim 50-75^\circ \text{ S}$ ), this manifests increasingly as liquid precipitation while snowfall is reduced (Figure 5d).

The effect of the changes in the energy balance due to SH extratropical cloud reductions can be seen in the differences in MHT between the ‘Mid’ and ‘End’ periods (Figure 5e). In models with greater SH extratropical cloud loss, the increasing poleward moisture transport revealed by the  $e - p$  profiles implies a strengthening poleward moist AHT. In these models, stronger poleward moist AHT in the SH midlatitudes outpaces weakening poleward dry AHT to yield a strengthening poleward AHT (profiles of MHT and AHT, and changes thereof, are shown in Supplementary figure S2). Finally, near-surface air temperatures continue to rise throughout the SH, with significant polar amplification in the Antarctic seen in models that lose more SH extratropical clouds (Figure 5f).

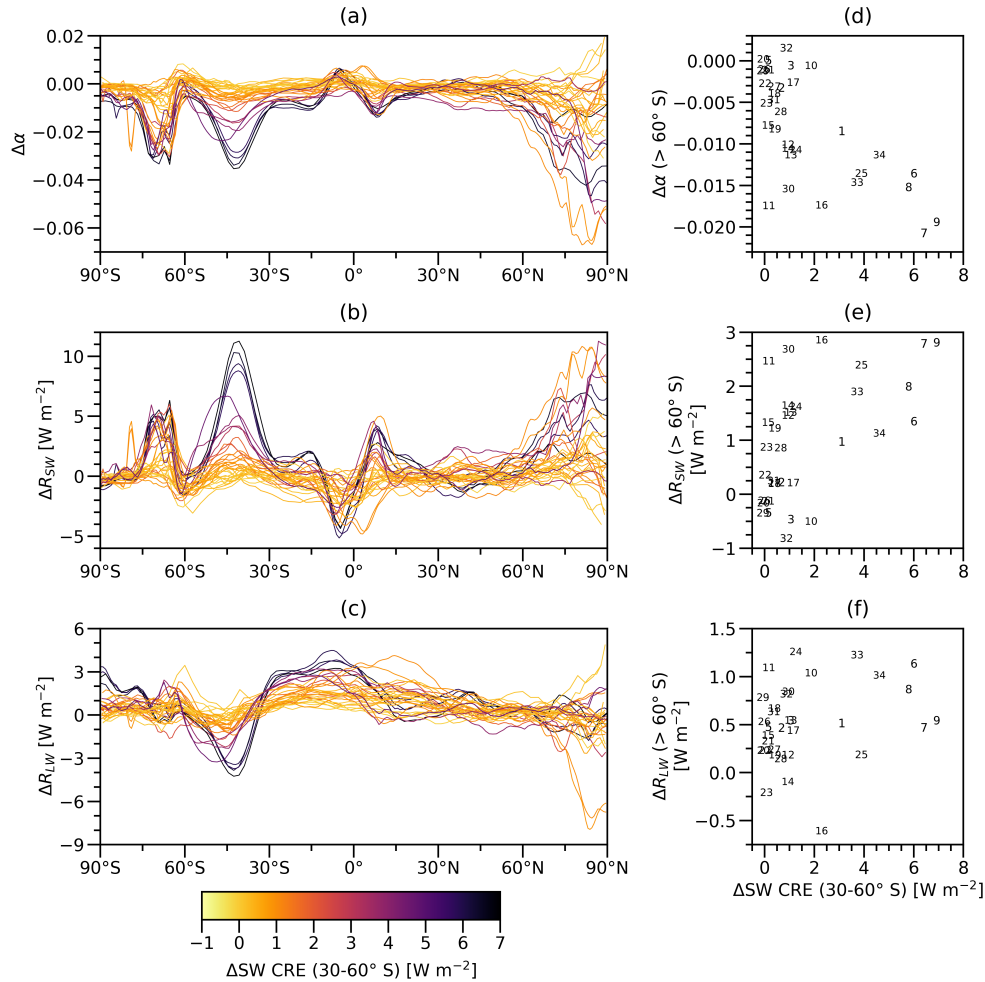

Taken together, the changes in poleward MHT and precipitation (Figure 5) as well as dynamical variables (shown in Supplementary figure S3) are indicative of a stronger poleward shift in the SH eddy-driven jet and SH midlatitude storm track in models where SH extratropical cloudiness declines more strongly after the ‘Mid’ period. As the SH midlatitude storm track shifts poleward, there is a slight strengthening of negative SW CRE over the Antarctic sea ice zone (Figure 4a) concurrent with

**Figure 5.** Meridional profiles of differences in zonal mean (a) atmospheric column water vapor content  $q_{col}$ , (b) evapotranspiration minus precipitation  $e - p$ , (c) total precipitation  $p$ , (d) ice-phase precipitation  $p_{ice}$ , (e) meridional heat transport MHT, and (f) near-surface air temperature TAS between ‘End’ and ‘Mid’. The color scale depicts differences in 30-60° S area mean SW CRE between ‘End’ and ‘Mid’.

increased liquid precipitation and decreased snowfall in the same latitudes. It is also worth noting that models with greater SH extratropical cloud reductions agree on a southward shift of the inter-tropical convergence zone (ITCZ) after the ‘Mid’ period that occurs concurrently with SH cloud reductions, seen in the profiles of precipitation and MHT (Figure 5c, e), which is expected due to the increase in absorbed solar radiation in the SH extratropics changing the hemispheric difference in net radiative heating (Geng et al., 2022).

Figure 6 shows how Antarctic warming manifests in models with greater SH extratropical cloud reduction through the onset of local positive feedbacks. Planetary albedo is reduced in the Antarctic sea ice zone (Figure 6a); this is most likely the result of increasing liquid-phase precipitation reducing the sea ice surface albedo, and decreasing snowfall that otherwise would stabilize sea ice albedo. This allows the sea ice albedo feedback to affect the SH polar climate in models where SH extratropical SW CRE increases more strongly; the result can be seen in increased SW radiative heating at the surface (Figure 6b, e). Furthermore, we find poor correlation between changes in total sea ice extent and SH extratropical SW CRE changes between the ‘End’ and

**Figure 6.** Meridional profiles of differences in zonal mean (a) planetary albedo  $\alpha$ , (b) surface SW heating  $R_{SW}$ , and (c) surface LW heating  $R_{LW}$  between 'End' and 'Mid'. The color scale depicts differences in 30-60° S area mean SW CRE between 'End' and 'Mid'. Scatter plots (d-f) depict the 30-60° S area mean differences in SW CRE between 'End' and 'Mid' plotted against differences in Antarctic (here > 60° S) area mean  $\alpha$ ,  $R_{SW}$ , and  $R_{LW}$ , respectively, between 'End' and 'Mid'.

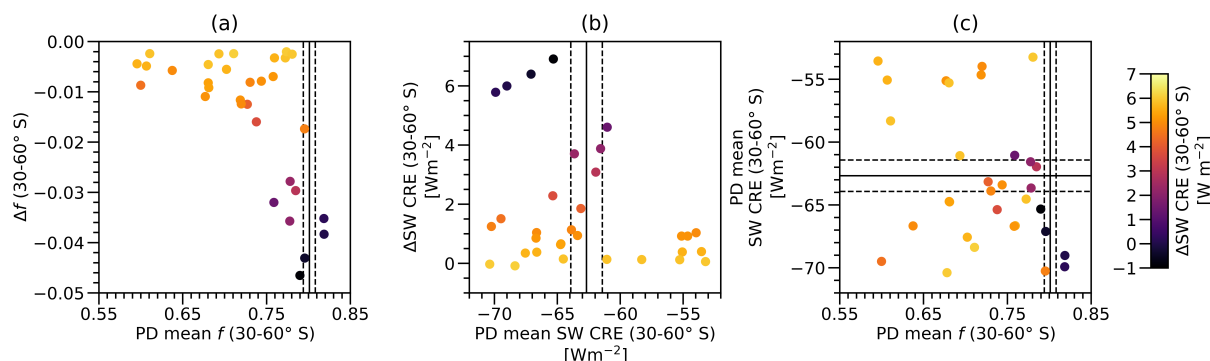

'Mid' periods (shown in Supplementary figure S4), indicating that the processes described here primarily affect the surface conditions of the Antarctic sea ice zone and not sea ice extent in the amount of simulation time presented here.

It is also important to note that these changes primarily affect the Antarctic sea ice zone, and not the Antarctic continent (poleward of roughly 75° S). As more moisture is transported poleward, the Antarctic continent sees greater snowfall (Figure 5d), which stabilizes surface albedo, and thus latitudes poleward of ~75° S see little change in albedo (Figure 6a). Higher LW heating at the surface can be seen at these latitudes (Figure 6c) due to increased atmospheric water vapor and higher air temperatures (Figure 5a, f). Beyond the SH polar region, owing to increasing SH temperatures and atmospheric water vapor,

surface LW heating is also increased in the SH tropics and subtropics in models where stronger SH extratropical cloud cover reductions occur (Figure 6c).

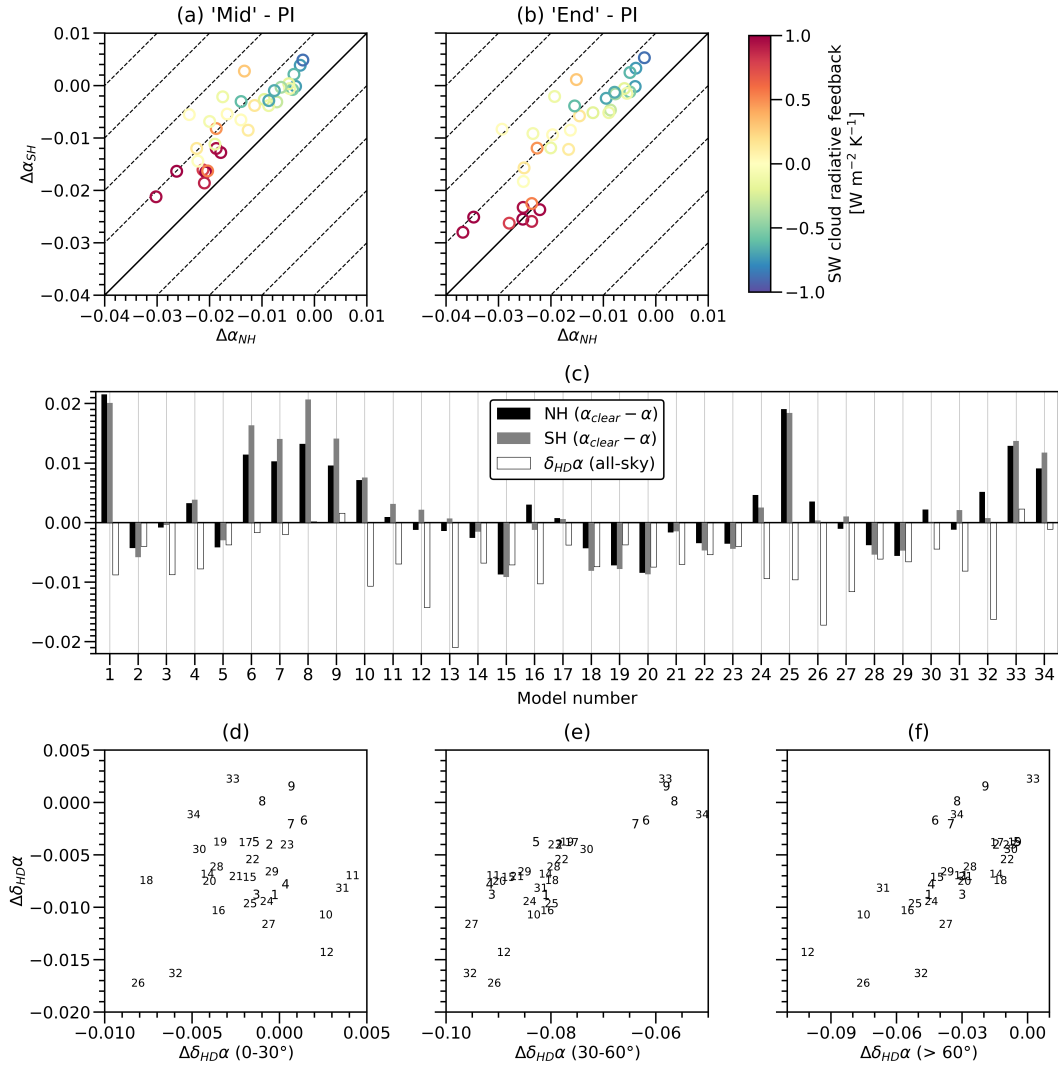

**Figure 7.** SH extratropical (30-60° S) mean (a) cloud fraction  $f$  and (b) SW CRE in PD conditions plotted against differences thereof between ‘End’ and ‘Mid’. In (c), PD mean SH extratropical  $f$  is plotted against PD mean SH extratropical SW CRE. Solid black lines represent CERES EBAF mean values over March 2000-February 2015, and dashed lines represent the bounds of one standard deviation in monthly mean anomalies. The color scale depicts differences in 30-60° S area mean SW CRE between ‘End’ and ‘Mid’.

PI and PD mean cloud fraction and SW CRE are close among all models (linear regressions yield  $R > 0.99$  for both); we therefore plot PD mean values of each against their responses to forcing in Figure 7 in order to compare model responses in models where cloud fraction and SW CRE are more similar to observations in the historical overlap period. The changes in SH extratropical cloud cover outlined in this section seem to have some dependency on the model state in an unforced climate, as models with the most cloud fraction in the SH extratropics in PI and PD conditions lose the most cloud fraction, although the impact on modeled SW CRE is inconsistent. Models with the highest cloud fraction in this region see some of the greatest reductions in cloud fraction (Figure 7a), but the relation between mean-state cloud fraction and cloud fraction loss is not linear; the relation between mean-state SW CRE and its response to forcing is even less consistent among models (Figure 7b). This illustrates that it is difficult to judge whether remote compensations by SH extratropical clouds to a perturbation in hemispheric albedo asymmetry are likely or not, as a wide range of forced SW CRE responses in the SH extratropics is seen where PD mean cloud fraction and SW CRE are closest to observations (Figure 7c). Thus, these measures are not enough to estimate which response in SH extratropical clouds is more realistic.

### 3.4 The relation between SW radiative feedback strength and the albedo symmetry

In the previous three sections, our results illustrate how responses in modeled hemispheric albedo differences to CO<sub>2</sub> forcing differ and diverge due to varying cloud responses in both hemispheres. Here, we will demonstrate how these cloud responses are related to the strength of the overall SW cloud radiative feedback.

In Figure 8a-b, we see that models that return to their pre-industrial mean asymmetry through continued SH albedo reductions have stronger positive SW cloud radiative feedback strengths, associated with a stronger global mean decrease in albedo.

**Figure 8.** Changes in the NH and SH hemispheric mean planetary albedo relative to their PI mean albedo ( $\Delta\alpha_{NH}$  and  $\Delta\alpha_{SH}$  respectively), plotted against each other on a ‘symmetry’ phase space for all models in the (a) ‘Mid’ and (b) ‘End’ periods. The thick diagonal line represents symmetry scaled to PI conditions, while each dashed line parallel to this represents a 1% hemispheric difference in albedo; models on the diagonal line remain close to their PI mean asymmetry. Estimates of model SW cloud radiative feedback strengths are given by the color of the marker. (c) Changes in hemispheric mean differences between all-sky and clear-sky albedo ( $\Delta\alpha_{clear} - \alpha$ ) in the NH and SH as well as changes in the hemispheric albedo asymmetry ( $\Delta\delta_{HD}\alpha$ ) between PI conditions and the ‘End’ period. Markers denote models as they are numbered in Table 1.

Many models with negative or weakly positive SW cloud radiative feedback strengths remain within a 1% difference in planetary albedo after warming through lower reductions in albedo in each hemisphere, but tend to exhibit a stronger NH than SH albedo decrease. For comparison, the CERES EBAF standard deviation in the albedo asymmetry time series between 2000-

2020 is  $0.4 \text{ W m}^{-2}$  ( $\sim 0.4\%$ ) (Jönsson and Bender, 2022), meaning that the perturbation in asymmetry due to strong forcing in  
 245 all models 150 years after the onset of abrupt  $\text{CO}_2$  forcing is close to the interannual variability seen in the past 20 years of  
 observations.

Figure 8c presents the ‘End’ minus PI anomalies in albedo asymmetry and hemispheric mean difference between clear- and  
 all-sky albedo  $\Delta(\alpha_{\text{clear}} - \alpha)$  (analogous to the SW CRE divided by the insolation at the TOA, with the same sign convention)  
 in each hemisphere as an illustration of the degree of cloud compensation impacts on albedo asymmetry; a negative difference  
 250 in the NH would yield local compensation to clear-sky NH albedo reductions, and a positive difference in the SH would yield  
 remote compensation to clear-sky hemispheric albedo asymmetry changes. Given the immediate clear-sky albedo reductions  
 outlined in Section 3.2, an effective configuration of  $\Delta(\alpha_{\text{clear}} - \alpha)$  that would maintain PI mean asymmetry would be weaker  
 or negative  $\Delta(\alpha_{\text{clear}} - \alpha)$  in the NH and positive  $\Delta(\alpha_{\text{clear}} - \alpha)$  in the SH. Models do not show consistency in the type of  
 compensation for the clear-sky albedo change induced by warming; a mixture of local NH cloud compensation and remote  
 255 compensation are at play in all models. When the difference between NH and SH  $\Delta(\alpha_{\text{clear}} - \alpha)$  is larger, asymmetry is more  
 effectively maintained. Among the models with the highest asymmetry changes relative to PI conditions, two (EC-Earth3-  
 AerChem and EC-Earth3-Veg) have both slightly positive  $\Delta(\alpha_{\text{clear}} - \alpha)$  in the SH and slightly negative  $\Delta(\alpha_{\text{clear}} - \alpha)$  in the  
 NH (neither local nor remote compensation). Finally,  $\Delta(\alpha_{\text{clear}} - \alpha)$  is generally in the same direction in both hemispheres  
 across models, indicating that changes in modeled SW CRE behave similarly globally when acting to amplify or dampen  
 260 clear-sky albedo reductions in response to warming.

## 4 Discussion

If a hemispherically asymmetric albedo response to warming is possible, intermediate ranges of total SW radiative feedback  
 strength estimates would be possible. However, if symmetry is to be maintained in a changing climate, hemispheric differences  
 in surface albedo changes must be compensated for by clouds in one of two ways: by local or by remote compensation. With  
 265 local compensation, surface albedo reductions are partially compensated for by cloud changes that mask the surface signal,  
 such as is the case to some degree in observed and modeled Arctic albedo responses to warming. With remote compensation,  
 the requirement that albedo in both hemispheres decline symmetrically necessarily means that the global albedo reduction  
 is greater. These two possibilities, local or remote compensation, would also mean that SW radiative feedback strengths are  
 either strongly positive or somewhat negative, respectively. There may, however, also be a combination of both processes  
 270 and interdependencies between them; the asymmetry response in EC-Earth3 family of models may exemplify how a balance  
 between local and remote compensations would be important if albedo symmetry were to be maintained, as in their case, a  
 lack of local compensation to NH clear-sky albedo reductions in combination with a lack of SH darkening yields the strongest  
 asymmetry disturbances relative to PI conditions among the models studied here.

Because of a lack of long-term measurements of Earth’s radiative energy system with which to study the evolution of Earth’s  
 275 hemispheric albedo symmetry throughout changes in the climate and anthropogenic forcings, detecting the strength and causal  
 sources of these compensations is currently very challenging. Hence, the lack of observational constraints or evidence for

the existence of a symmetry maintaining mechanism limits the possibility to evaluate model realism based on their degree of symmetry restoration. The lack of consistent pathways for symmetry restoration among the models limits the possibility to assess a single mechanism for keeping the symmetry. However, there is clearly an implication for the strength of cloud-climate feedbacks depending on whether a possible mechanism that maintains the hemispheric albedo symmetry involves cross-hemispheric communication or not.

While the tropical maximum in deep convective cloud cover following the position of the ITCZ has been suggested to offer some compensation to a hemispheric difference in albedo by shifting into the darker, warmer hemisphere (Voigt et al., 2013, 2014), tropical clouds have been understood not to have a major role in determining the hemispheric albedo symmetry, as the ITCZ and tropical maximum in cloud cover is located in the NH. Here we have also shown that in models, if a remote compensation to NH albedo reductions is accomplished by SH albedo reductions, the ITCZ will consequently move southward, in line with studies on changes in tropical precipitation under warming (e.g. Geng et al. 2022). A continued southward shift of the ITCZ may also occur if the SH extratropical cloud cover and Antarctic albedo reductions described in Section 3.3 reinforce hemispheric differences in net radiative heating and thus negate some of the remote compensation to asymmetry anomalies offered by SH albedo reductions. Although tropical clouds and albedo seem to play a secondary role in determining the the observed hemispheric albedo symmetry on time scales longer than a year (Bender et al., 2017; Datseris and Stevens, 2021; Jönsson and Bender, 2022), this should also be taken into account in understanding hemispheric albedo symmetry-maintaining mechanisms that involve the extratropics, as it can mean that some of the compensation offered by extratropical albedo reductions in one hemisphere can be buffered by tropical albedo increases, which may require more substantial high-latitude albedo reductions to maintain hemispheric albedo symmetry. However, model representations of tropical clouds, bias in the ITCZ position, and spurious, unrealistic ITCZ dynamics complicate projections of tropical clouds and albedo in a changing climate (e.g. Hwang and Frierson 2013; Zhang et al. 2019a; Tian and Dong 2020).

A remaining question is whether SH extratropical cloud reductions are to be seen in more models beyond the 150 years that are the required minimum simulation time for CMIP6 strong forcing experiments. Gjermundsen et al. (2021) note that in two related CMIP6 member models with very different EffCS, CESM2 and NorESM2, cloud radiative feedback strengths look similar after several centuries of strong forcing simulation, despite being much stronger at year 150 in CESM2 than in NorESM2. This is attributed to the different ocean component models, in which Southern Ocean deep convection slowing occurs more quickly in CESM2 than in NorESM2, allowing sea surface temperatures (SSTs) to increase more quickly and thus impact low cloud cover. Further illustrating the importance of the Southern Ocean deep convection in determining Antarctic climate are previous results based on a single model which show that SO deep convection also influences the occurrence of Antarctic warm events in a climate at equilibrium through processes similar to those presented in Section 3.3 (Pedro et al., 2016). It is possible that more models follow this pattern and therefore have similar SH albedo reductions on longer timescales following forcing than the 150 years presented here, and thereby exhibit remote compensation to the hemispheric albedo asymmetry anomalies induced by the warming, on longer timescales.

The fact that modeled cloud fraction and SW CRE are sensitive to SSTs in this region would point to changes in Southern Ocean SSTs being able to induce a SH albedo reduction as presented in Section 3.3. The overturning circulation that impacts

SSTs in this region reaches between hemispheres and thus could present a cross-hemispheric communicator of anomalous absorbed solar radiation caused by changes in cloud cover. Further work could also be done to remove model dependence; many of the models with greater SH extratropical cloud reduction are in the CESM2 family or contain shared components with CESM2, which points to model dependence in the SH warming processes laid out here.

As clouds in the SH extratropics are responsible for a large share of the positive shift in model estimates of SW cloud feedbacks (Zelinka et al., 2020) from CMIP5 to CMIP6, it is important to monitor the evolution of SH extratropical clouds as the climate warms; constraining the magnitude of this shift and the representation of SH extratropical clouds in models is made challenging due to a lack of observations (Ceppi and Hartmann, 2015; Gettelman et al., 2020). Changes in SH extratropical clouds in response to anthropogenic forcing would inevitably impact the hemispheric albedo symmetry, as they also play an important role in the mean cloud distribution that determines the observed albedo symmetry in the current climate. The fact that models with higher SH extratropical cloud fraction — and that are thereby in better agreement with observations — lose more clouds in response to warming could be taken as indication that a greater cloud loss, and hence more positive cloud feedback and remote compensation is more realistic; but on the other hand, the relation between unforced or historical mean SW CRE and the change in SW CRE in response to forcing is weak, leading to an inconsistent and weak constraint on remote compensations. Models may also have realistic cloud properties in this region for the wrong reason, and models with more cloud cover may also see greater changes simply due to having more clouds in the unforced state to lose (Kajtar et al., 2021). The link between mean state magnitude and forced response is ultimately not self-evident (McCoy et al., 2014; Zelinka et al., 2022; Kuma et al., 2022), and the time scales of the SH extratropical cloud changes involved may mean that albedo symmetry-restoring remote compensations do not act on the time span of the observations that we presently have (Frey et al., 2017; Gjermundsen et al., 2021).

## 5 Conclusions

Following the observation that Earth's albedo is persistently hemispherically symmetric throughout the most recent two decades of satellite observations, we investigated responses in hemispheric differences in albedo to CO<sub>2</sub> forcing, and their implications for cloud feedback, heat redistribution, and spatial patterns of warming. To do this, we made use of the evolution of hemispheric albedo differences in CMIP6 models when CO<sub>2</sub> concentrations are abruptly quadrupled.

In all models, NH albedo is immediately reduced due to albedo reductions in mid- to high latitudes following ice loss and cloud changes, causing the hemispheric difference in albedo to be SH-favored relative to PI conditions consistently among all models. However, models do not agree on the strength of this initial response. In some models, cloud cover increases in the NH to reduce the impact of clear-sky albedo reductions in the hemispheric mean, and in others, changes in cloud cover strengthens the all-sky albedo reductions. The former represents one way in which hemispheric albedo symmetry may be maintained: local compensations to albedo reductions.

Another possibility for maintaining hemispheric albedo symmetry involves remote compensations to hemispherically asymmetric albedo reductions: in some models, the SH mean albedo decreases after NH darkening when SH extratropical cloud

cover is reduced, causing some models' hemispheric albedo difference to return towards their respective PI mean asymmetry. Here, we have shown that changes in SH extratropical cloud cover are linked with Antarctic polar amplification and changes in Antarctic albedo. When cloud cover is reduced in the SH extratropics, the increased absorbed radiative energy is redistributed polewards, contributing to the spread in modeled Antarctic responses to CO<sub>2</sub> forcing.

These two pathways illustrate how mechanisms maintaining the hemispheric albedo symmetry impact the climate sensitivity through their implications for SW radiative feedbacks. Depending on the degree of local compensation (increasing total cloud contributions to albedo) and remote compensation (decreasing total cloud contributions to albedo), the implied SW cloud radiative feedback can be either negative or positive. Our results show that clouds may serve to suppress an asymmetric response in the hemispheric albedo difference to forcing so that the all-sky albedo is more hemispherically symmetric than clear-sky albedo, but may not necessarily fully compensate for a perturbed hemispheric albedo difference.

There is currently no explanation for a physical mechanism in the climate system maintaining Earth's observed hemispheric albedo symmetry — that the total albedo has been symmetric for the last few decades does not necessarily imply it has always been or will continue to be. It is therefore not possible to rule out models based on whether or not they restore their initial state of hemispheric asymmetry. The variety of responses among climate models, and the possible pathways illustrated for providing compensation for perturbed symmetry, can indicate where such mechanisms may be sought for in observed response to variations in GHG and aerosol forcing, and what such a mechanism would mean for clouds and cloud feedback.

*Data availability.* The CMIP6 model output used for this study can be accessed through the Earth System Grid Federation (ESGF).

*Author contributions.* A.R.J.: conceptualization, formal analysis, investigation, methodology, software, visualization, and writing (original draft preparation, reviewing, and editing). F.A.-M.B.: conceptualization, funding acquisition, methodology, project administration, supervision, and writing (review and editing).
