14
15 **Abstract.** Forest dynamics need to be considered when estimating the global carbon budget. The
16 alteration of forest structure and function under a changing climate and expanding human activity
17 could lead to a reduction of forest canopy cover and a spread of lower-biomass ecosystems in
18 warm and dry regions. Non-structural carbohydrate (NSC) acts as a storage buffer between carbon
19 supplied by assimilation and carbon consumed by, inter alia, respiration, reproduction, and pests.
20 Estimation of NSC concentrations in a tree is very important for accurate projection of future
21 forest dynamics. We developed a new NSC module for incorporation into a spatially explicit,
22 individual-based, dynamic global vegetation model (SEIB-DGVM) to validate the simulated NSC
23 dynamics with observations. NSC pools were simulated in three plant organs: leaves, trunk, and
24 roots. The seasonal dynamics of the NSCs varied among plant species, and the sizes of the NSC
25 pools inferred from observations differed between the boreal, temperate, and tropical climates.
26 The NSC models were therefore validated for each of the three climatic regions at both point and
27 global scales to assess the performance of the models. The modeled NSCs showed good
28 agreement in seasonality with the observed NSCs at four sites—Canada (boreal), Austria and
29 Switzerland (temperate), and Panama (tropical)—and in mean values for three climate zones
30 derived from the global NSC dataset. The SEIB-DGVM-NSCv1.0 is expected to enable
31 simulation of biome shifts caused by the changes of NSC dynamics worldwide. These dynamics
32 will contribute to changes of not only the global carbon cycle but also of forest structure and
33 demography at a global scale.

36 **1 Introduction**

37

38 Permanent shifts in forest vegetation dynamics have already been observed and are expected to
39 accelerate under future changes of climate globally (McDowell et al., 2020). Forest dynamics are
40 changing due to anthropogenic drivers, such as rising temperatures and CO₂ partial pressures, and
41 are affected by transient disturbances such as wildfires, droughts, biotic attacks, and land-use
42 changes. The dependence of tree recruitment and growth on anthropogenic drivers and transient
43 disturbances could lead to an increase of tree mortality rates in warm and dry regions (Stevens-
44 Rumann et al., 2018; Xu et al., 2017). These changes will cause forests to become shorter and
45 younger. The result will be a net reduction of forest canopy cover and a shift toward low-biomass
46 ecosystems. Furthermore, higher tree mortality will have a negative impact on global ecosystem:
47 lower biological diversity and altered hydrological and carbon cycles (Adams et al., 2013).
48 Understanding the drivers of vegetation dynamics requires accurately simulating the effect of
49 climate change on global terrestrial biogeochemistry.

50 To increase their chance of survival, trees control their carbon resources and strategically
51 allocate them to growth, respiration, storage, reproduction, and defense (Hoch et al., 2003;
52 Hartmann et al., 2018). When the atmospheric partial pressure of CO₂ increases, trees can allocate
53 surplus carbon to either growth or carbon storage (Hoch et al., 2003; Huang et al., 2020). Changes
54 in tree carbon allocation patterns have been shown to exert large effects on constituents of the
55 terrestrial carbon cycle (Klein and Hoch, 2015). Clarification of the importance of carbon
56 allocation has revealed that non-structural carbohydrates (NSCs) draw much from the other
57 carbon resources because they are the most significant carbon compounds involved in the life
58 processes of trees (He et al., 2020).

59 The NSC is comprised of starch and sugars, which are mobilized mainly for growth and
60 metabolism when sink strength exceeds source activity (Gough et al., 2010; Richardson et al.,
61 2013; Chuste et al., 2020; Herrera-Ramírez et al., 2020). During photosynthesis, freshly
62 assimilated carbon is transported as triose phosphate from the chloroplast to the cytosol, where
63 sucrose is synthesized from it. Some of the sucrose is then changed into starch in the chloroplast,
64 and the starch is consumed to maintain growth and metabolism at times when recently assimilated
65 carbon is not available to the plants (Dietze et al., 2014). Plants that seasonally shed leaves need
66 to rely on stored carbon for maintenance during the leafless season. NSCs play an important role
67 as substrates for the synthesis of compounds in plants and as energy sources for metabolic
68 activities (Hartmann et al., 2018). Moreover, NSCs include key compounds that are used to buffer
69 physiological stress when energy from photosynthesis does not satisfy metabolic demands
70 (Gough et al., 2010; Sala et al., 2012) because carbohydrates such as starch can be easily
71 mobilized and reallocated (Hartmann et al., 2018).

削除: temporal

削除: drivers

削除: , a decrease of wild animal habitat,

削除: , and increased vulnerability to sudden invasions by
exotic species

削除: little recently assimilated carbon is available

79 In long-lived plants, the ability to store carbon is a key to survival at times when
80 photosynthetic rates are low because of shade, drought, and disturbance (Martínez-Vilalta et al.,
81 2016). As a result, the amount of NSC storage or remobilization depends on the balance between
82 the supply and demand of assimilated carbon and accounts for a large fraction of the annual carbon
83 budget of plants (Richardson et al., 2013). When carbon allocation patterns favor storage over
84 growth, tree growth is limited (Wang et al., 2021). Hence, the dynamics of stored carbon pools
85 can be considered an indicator of the carbon balance of the plant.

86 The decline of stomatal conductance during a drought reduces photosynthetic carbon
87 assimilation and thus decreases the amount of NSC (McDowell et al., 2008; Adams et al., 2017).
88 Although an imbalance of the NSC pool could mechanistically trigger plant mortality, few
89 ecological models predict tree mortality resulting from the role of NSC associated with climate
90 change (Adams et al., 2013; McDowell, 2011). Simulations of the NSC dynamics of plants will
91 elucidate the effects of different drivers on forested ecosystems (Gough et al., 2010).

92 Because the frequency, duration, and severity of droughts are expected to increase globally,
93 the damage to plants through rising temperatures, water vapor pressure deficit, and associated
94 water loss will also increase (IPCC, 2014; Sevanto and Dickman, 2015). Trees can be killed
95 directly by drought, i.e. vial desiccation, or indirectly by associated increases of insect or pathogen
96 attacks. Indirect effects that cause tree mortality include girdling by bark beetles and defoliation
97 events. The frequency and severity of this indirect biotic disturbance from insects and insect-
98 pathogen complexes have been increasing (McDowell et al., 2020; Seidl et al., 2017). According
99 to multiple observational and experimental studies, the resulting imbalance between NSC demand
100 and supply leads to carbon starvation, which is one of the mechanisms that contribute to drought-
101 induced mortality (McDowell, 2011).

102 Dynamic global vegetation models (DGVMs) are often used to represent vegetation dynamics
103 as well as biogeochemical cycles and to simulate the transition of the vegetation structure in
104 response to climatic changes via modeling of competition and disturbance (Hickler et al., 2004;
105 Krinner et al., 2005; Braakhekke et al., 2019). In DGVMs, plant species are classified into plant
106 functional types (PFTs) based on their eco-physiological traits. However, most DGVMs
107 oversimplify individual plant competition by using average values of traits for each PFT (Smith
108 et al., 2001). Most of such models miss the effects of local competition for light, which must be
109 considered when modeling gap population dynamics among individual trees (Sato et al., 2007).

110 In contrast, the Spatially Explicit, Individual-Based, Dynamic Global Vegetation Model
111 (SEIB-DGVM; Sato et al., 2007) can simulate the growth of individual trees on numerous
112 replicate patches and enable observation of how single, large trees can influence nearby trees.
113 Plants in different patches do not interact with each other in terms of physical resources such as
114 light and water. In each patch, the growth and mortality of each tree, and competitive interactions

上へ移動 [3]: The decline of stomatal conductance during a drought reduces photosynthetic carbon assimilation and thus decreases the amount of NSC (McDowell et al., 2008; Adams et al., 2017). Although an imbalance of the NSC pool could mechanistically trigger plant mortality, few ecological models predict tree mortality resulting from the role of NSC associated with climate change (Adams et al., 2013; McDowell, 2011). Simulations of the NSC dynamics of plants will elucidate the effects of different drivers on forested ecosystems (Gough et al., 2010).↵

削除: ,

133 between individual trees are calculated based on environmental conditions. Transient changes in
134 vegetation distribution and dynamics can therefore be examined (Sato et al., 2007). Because the
135 amount of stored NSC depends on the size of individual trees and because the SEIB-DGVM can
136 simulate individual trees, we chose the SEIB-DGVM to estimate the NSC dynamics of plants.

削除: , and mortality of each tree

削除: .

137 SEIB-DGVM has been used to simulate a transient change in the distribution and function of
138 vegetation on the African continent in conjunction with the ranges of dispersal of trees and to
139 address factors that had a strong impact on the transient change (Sato and Ise, 2012). Use of the
140 SEIB-DGVM has enabled reconstruction of the geographical distributions of plant productivity
141 and thermo-hydrology based on observations in eastern Siberia and partial representation of the
142 effect of topography on the abundance of trees in larch forests (Sato et al., 2020). The SEIB-
143 DGVM was coupled with an earth system model (MIROC-ESM; Watanabe et al., 2011).

削除:

144 However, the original SEIB-DGVM lacks the ability to compute NSC levels in trees, which
145 means it cannot simulate the plant death caused by an imbalance in the NSC pool, as well as
146 indirect impacts like insect infestations and defoliation. This also hinders the ability to investigate
147 the effects of various drivers on forest ecosystems, such as the intensification of drought, and
148 limits the development of the MIROC-ESM for simulating the global carbon cycle.

削除: a flagship E

削除: Because the amount of stored NSC depends on the size of individual trees and because the SEIB-DGVM can simulate individual trees, we chose the SEIB-DGVM to estimate the NSC dynamics of plants.

149 The objectives of the research were to 1) incorporate a module to simulate NSC dynamics in
150 the SEIB-DGVM and 2) validate the simulated NSC dynamics with observational data at both
151 point and global scales. We therefore created a new function in the SEIB-DGVM to represent the
152 NSC dynamics of individual trees. How NSC is produced, stored, and distributed among different
153 plant organs under environmental stress is poorly understood (Jones et al., 2019; Rademacher et
154 al., 2021; Wang et al., 2021). Our enhanced model improves the physiological simulation of the
155 leaf life cycle and enhances understanding of how NSC affects the distribution of vegetation,
156 gross primary production (GPP), and net primary production (NPP), as well as tree dynamics (age,
157 height, and trunk diameter) at global scales in the future. By adjusting the NSC accumulation
158 rates of individual trees and the threshold of NSC-induced mortality during drought, the model
159 can simulate the timing, location, and percentage of trees that die in response to moderate drought.
160 Furthermore, the model can increase our understanding of the role of NSCs.

削除: , and carbon stocks

削除: carbon reserve

162 2 Model

164 2.1 Spatially Explicit Individual-Based Dynamic Global Vegetation Model (SEIB-DGVM)

166 The SEIB-DGVM (v3.02; http://seib-dgvm.com/data/seib_code302.zip; Sato et al., 2016) is a
167 carbon budget model that simulates the establishment of individual trees, competition between
168 trees, and the death of individual trees according to input climate data. The default settings follow

179 the structure of a three-dimensional virtual forest on a 30 m × 30 m stand of trees with 1 m × 1 m
 180 simulation grid cells. In each grid cell, a tree belonging to one of 14 woody plant functional types
 181 (PFTs) is assigned depending on conditions, in addition to one of 2 grass PFTs. All physical and
 182 physiological processes are calculated at daily time steps, trunk growth is estimated monthly, and
 183 vegetation dynamics and disturbance such as wildfire and heat stress are assessed annually.
 184 Because of the lack of field observations at the time the model was developed, there is no
 185 mechanism to control the NSC in leaves and roots in the original SEIB-DGVM, and only the NSC
 186 in trunks is simulated after adjusting the available organic matter for reproduction and respiration.
 187 The original SEIB-DGVM therefore cannot represent NSC-induced effects on forest ecosystems
 188 realistically without accounting for the NSC in leaves and roots.

190 2.2 NSC components

192 2.2.1 NSC pool

193 The new NSC pools are separated into three organs of an individual tree: leaves, trunk, and roots.
 194 In the original SEIB-DGVM, the NSC in trunks is supplemented to 250 g dry matter (DM) from
 195 the litter after seed establishment and is based on the existing leaf biomass after the first 30 days
 196 of the growing season. It is used for foliation after the dormant phase and metabolic processes
 197 such as the synthesis of a storage organ and remobilization of the nutrients within it. In the new
 198 model, the carbon newly assimilated via photosynthesis goes into three NSC pools. The NSC
 199 pools can be later mobilized for growth and respiration as follows (Fig. 1).

$$201 \Delta NSC_t = NPP_t = \Delta NSC_{trunk,t} + \Delta NSC_{leaf,t} + \Delta NSC_{root,t}, \quad (1)$$

202 when $NSC_{trunk,t-1} < NSC_{trunk,max(t)}$, $NSC_{leaf,t-1} < NSC_{leaf,max(t)}$, and $NSC_{root,t-1} < NSC_{root,max(t)}$,

$$205 \begin{cases} \text{parent } NSC_{trunk,t} = \min(NSC_{trunk,max(t)}, \Delta NSC_t), \\ NSC_{leaf,t} = \min(NSC_{leaf,max(t)}, \Delta NSC_t - NSC_{trunk,t}), \\ NSC_{root,t} = \min(NSC_{root,max(t)}, \Delta NSC_t - NSC_{trunk,t} - NSC_{leaf,t}), \end{cases} \quad (2)$$

206 when $NSC_{trunk,t-1} < NSC_{trunk,max(t)}$, $NSC_{leaf,t-1} < NSC_{leaf,max(t)}$, and $NSC_{root,t-1} > NSC_{root,max(t)}$

$$209 \begin{cases} \text{parent } NSC_{trunk,t} = \min(NSC_{trunk,max(t)}, \Delta NSC_t), \\ NSC_{leaf,t} = \min(NSC_{leaf,max(t)}, \Delta NSC_t - NSC_{trunk,t}), \\ NSC_{root,t} = NSC_{root,max(t)}, \end{cases} \quad (3)$$

251
252 where t is the calculation day, $t-1$ is the previous day, NSC_{organ} is the amount of NSC in each organ,
253 and $NSC_{organ, \max(t)}$ is the maximum amount of NSC in each organ on day t .

254 The NSC pools of the organs displays unique seasonality for each climatic zone. The NSC
255 seasonality of each organ varies among tree species mainly because the climate and surrounding
256 environment influence the capacity and utilization of NSCs in plants. To take into consideration
257 the fact that field observations of NSC covered whole seasons and that various plant species were
258 scarce, we classify NSC seasonality into three types: tropical, temperate, and boreal. Observations
259 from temperate forests showed that the NSC seasonal cycles were similar among the organs and
260 peaked around late spring–summer, although the NSC_{organ} differed in size (Hoch et al., 2003;
261 Richardson et al., 2013; Woodruff and Meinzer, 2011; Gruber et al., 2012). In contrast, the NSC
262 concentrations in the leaves of boreal trees peak in June (Sveinbjörnsson et al., 2010), and NSCs
263 in the fine roots increase until summer and then decline toward mid-summer and fall because of
264 the initiation of root growth (Landhäusser and Lieffers, 2003). All 14 woody PFTs of the SEIB-
265 DGVM are sorted into one of three NSC types, and carbon assimilated via photosynthesis was
266 allocated to the NSC pool of each organ in temperate and boreal PFTs as follows.

$$267 \quad 268 \quad 269 \quad 270 \quad NSC_{organ, \max} = (a + b \times \text{daily GPP}) \times \text{Biomass}, \quad (10)$$

271 where the organ is either a leaf, trunk, or root, a is the minimum value, and b is the seasonality
272 parameter.

273 Tropical species have a different NSC seasonality from temperate and boreal species. The
274 NSC of leaves display a concave upward seasonal pattern that reaches its minimum in late spring–
275 early summer (Würth et al., 2005), which is a dry season when leaf production and flowering
276 deplete NSC pools. Singh and Srivastava (1986) have observed that the NSC of roots is at a
277 minimum level from July to September because the NSC pool is drained to enable survival of the
278 rainy season during that period. The amount of NSCs then increases toward winter, when the fine
279 root biomass declines. Hence, Eq. (10), which is used for temperate and boreal forests, is
280 inadequate for simulation of tropical forests because the NSC depends less on the seasonality of
281 photosynthesis in the tropics. The size of the NSC pool of tropical species therefore accumulates
282 as follows.

$$283 \quad 284 \quad 285 \quad 286 \quad NSC_{organ, \max} = (a + b) \times \text{Biomass}, \quad (11)$$

287 where the organ is either the leaf, trunk, or root, a is the minimum value, and b is the seasonality
288 parameter.

删除: First, the surplus carbon that remains after respiration is assigned to the NSC trunk pool using Eq. (1). As long as the trunk biomass increases relative to that on the previous day, the overflowing carbon moves primarily into NSC_{leaf} , secondarily into NSC_{root} , and finally into the growth of leaves, the trunk, and roots. The sum of the NSCs in the leaves, trunk, and roots (the total NSC) is maximized for each climate region (Table 1). If the total NSC exceeds this upper limit, the surplus is directly consumed for the growth of each organ.

Table 1. Maximum volume of NSC pool

... [1]

300 First, the surplus carbon that remains after respiration is assigned to the NSC_{trunk} using Eq.
 301 (1). Once NSC_{trunk} has reached its maximum capacity, the rest of assimilated carbon moves
 302 primarily into NSC_{leaf} , secondarily into NSC_{root} . Finally, any remaining carbon is allocated to the
 303 growth of leaves, the trunk, and roots. The sum of the NSCs in the leaves, trunk, and roots (the
 304 total NSC) is maximized in relation to total biomass for each climate region (Table 1). In cases
 305 where the total NSC exceeds this upper limit, the surplus is directly consumed for the growth of
 306 each organ.

Tropical	9% of total biomass	Würth et al. (2005)

309
 310 **2.2.2 NSC expenditure**

311
 312 **2.2.2.1 Respiration**

313 Normally, photosynthetically assimilated carbon is used for maintenance respiration without
 314 entering the NSC pool. When the assimilated carbon is insufficient for maintenance respiration,
 315 the NSC compensates for the shortage. The NSC loss is allocated to each organ as follows.

削除: carbon storage system

削除: inadequate

317
 318 $NSC_{leaf,t} = NSC_{leaf,t-1} - R_{a,t-1} \times c_{leaf}$ (12)

319 $NSC_{trunk,t} = NSC_{trunk,t-1} - R_{a,t-1} \times c_{trunk}$ (13)

320 $NSC_{root,t} = NSC_{root,t-1} - R_{a,t-1} \times c_{root}$, (14)

321
 322 where autotrophic respiration (R_a) is the difference between assimilated carbon and maintenance
 323 respiration and c is the allocation factor for NSC utilization ($c_{leaf} + c_{trunk} + c_{root} = 1$). If the total
 324 NSC equals the carbon shortfall, the NSC of all organs becomes zero. If an NSC_{organ} is insufficient
 325 to provide the allocated share of R_a , the other organs will supply the difference: the NSC_{leaf} is
 326 supplemented first from the NSC_{trunk} , and if that is not enough, from the NSC_{root} . Similarly, if any
 327 of the other NSC_{organ} pools is unable to cover local shortages, the NSC pools of the remaining
 328 organs will balance the supply and demand. When the total NSC is not enough to pay for the
 329 charges, a 1% of reduction in the biomass of all of the living organs occurs. The removed biomass
 330 of sapwood is transformed into heartwood, while the removed biomass of other organs is placed
 331 into the litter pool. The allocation factors of NSC utilization depend on the climatic region (Table

削除: The allocation factors of NSC utilization depend on the climatic region (Table 2).

削除: t

削除: will be consumed

347

348 **2.2.2.3 Turnover**

349

350 Part of the NSC pools of leaves and roots is transformed into litter at the same fractional rates as
 351 in the turnover of general carbon pools for leaves and roots. This turnover is calculated at daily
 352 steps, regardless of the phenology phase.

353

354 **2.2.2.4 Establishment**

355

356 The establishment process is performed on the last day of each simulation year in the SEIB-
 357 DGVM. The characteristics of the PFT are determined by five bioclimatic parameters: (1) the
 358 maximum temperature in the coldest month; (2) the maximum growing-degree day; (3) the
 359 minimum growing-degree day; (4) the minimum photosynthetically active radiation; and (5) the
 360 duration of drought. All new trees, independent of their PFT, start with a sapwood diameter of
 361 0.01 m and heartwood diameter of 0.00 m. Initially, these new trees have no leaves or fine roots.

362 Their carbon cycle is therefore maintained by initial values of 250 g DM of assimilated carbon
 363 and 250 g DM of NSC ($NSC_{leaf} = 10$ g, $NSC_{trunk} = 190$ g, and $NSC_{root} = 50$ g) from the litter pool.

367 Observational NSC data for model validation were derived from Martínez-Vilalta et al. (2016),
 368 who reviewed 296 papers and summarized NSC dynamics in forests. Their data include total

379 NSCs in leaves, trunks, and roots of mature terrestrial plants from observations over at least four
 380 months. The new model was first validated at the point scale. After confirming that the model can
 381 accurately simulate at the point scale, it was then validated at the global scale. These data were
 382 used for both point-scale and global-scale model validations. For the point-scale simulation,
 383 several field sites were selected, which NSC data were available for all organ. At each site, the
 384 seasonality of the NSC was measured for at least four months. The modeled outputs were then
 385 compared to the observed data, which were calculated using local climate data on a grid that
 386 corresponds to the field site. For the global-scale simulation, global mean NSC values derived by
 387 using all observed data from the relevant climate zones. The modeled outputs calculated using
 388 0.5°×0.5° gridded climate data were then compared to these values.

390 2.3.1 Validation at a point scale,

392 2.3.1.1 Site descriptions

394 Four countries were used to validate the simulated NSC content in the plant organs: boreal
 395 (Canada), temperate (Austria and Switzerland), and tropical (Panama). We used local climate data
 396 from meteorological stations gap-filled by corrected gridded climate reanalysis data as the input
 397 at these sites. We ran the NSC module including the SEIB-DGVM with the location and climate
 398 provided and compared the model output with the observation data.

399 The boreal site is located near Alder Flats, Alberta, Canada (52°58'N, 114°59'W) in 2000. The
 400 site was dominated by boreal winter deciduous plants such as *Populus tremuloides* (Landhäusser
 401 and Lieffers, 2003). One of the temperate sites is located in the timberline ecotone at Mt.
 402 Patscherkofel to the south of Innsbruck, Austria (47°13'N, 11°27'E) in 2008 (Gruber et al., 2011).
 403 Temperate conifer species such as *Pinus cembra* were the dominating tree species. The other
 404 temperate site is at the Mont Noble, Canton Valais, Swiss Central Alps (46°12'N, 7°30'E) and was
 405 dominated by temperate conifers (*P. cembra* L.; Hoch et al., 2003) in 2000. The tropical site is
 406 located at the Parque Natural Metropolitano near Panama City, the Republic of Panama in 1996
 407 (85°8'N, 79°34'W; Würth et al., 2005). The site has mixed cover with 17 dominant species,
 408 including *Cecropia longipes* and *Anacardium excelsum*.

410 2.3.1.2 Input climate data

412 The SEIB-DGVM requires ten climatic variables as environmental drivers: air temperature, soil
 413 temperature at a depth of 50 cm (soil layer 1), soil temperature at a depth of 100 cm (soil layer
 414 2), soil temperature at a depth of 150 cm (soil layer 3), precipitation, shortwave radiation,

455 longwave radiation, wind velocity, specific humidity, and diurnal range of air temperature. The
456 input climate data were prepared by harmonizing a global reanalysis gridded climate dataset, the
457 WATCH Forcing Data ERA-Interim (WFDEI, 0.5×0.5 degrees, 1979–2016,
458 Weedon et al., 2018), and the climate generated by the SEIB generator (Tei et al., 2017), which
459 is the monthly observation-based climatic datasets produced by Climatic Research Unit (CRU
460 TS4.00, 0.5×0.5 degrees, 1901–2015, Harris et al., 2014) supplemented with the National
461 Centers for Environmental Prediction/National Center for Atmospheric Research
462 (NCEP/NCAR) daily climate datasets (Kalnay et al., 1996) for 1950, with local climatology
463 recorded at meteorological stations near the sites. Local climatology in Panama is measured at
464 the Parque Natural Metropolitano Canopy Crane meteorological station (1995–2019). The
465 climatology in Austria (1979–2008) and Switzerland (1979–2000) was derived from the closest
466 meteorological station to the field site under the European Climate Assessment (Klein et al.,
467 2002, <https://www.ecad.eu>). WFDEI data were used for the climatology in Canada, except for
468 precipitation data, which are measured in the Meteorological Service of Canada (1979–1984,
469 https://climate.weather.gc.ca/historical_data/search_historic_data_e.html).

470 The reanalysis of daily WFDEI and SEIB climate data included daily records, which were
471 corrected by regression models to local climate data. For temperature, humidity, and shortwave
472 radiation values, local climatology were used directly and the daily WFDEI data supplemented
473 by simple linear regression. Precipitation data and wind speeds were first adjusted to monthly and
474 then annual averages and then scaled as a correction. WFDEI precipitation data were scaled after
475 adjusting to the annual climatological precipitation of 995 mm in 2008 for Austria and 630 mm
476 in 2000 for Switzerland. Longwave radiation was calculated using harmonized temperatures and
477 humidities above (Brutsaert, 1975). Missing values were estimated via linear interpolation.
478 Because soil temperature data were unavailable for local sites and for WFDEI, soil layer
479 temperatures were calculated using the SEIB generator by regressing soil layer 1 on atmospheric
480 temperature, soil layer 2 on layer 1, and layer 3 on layer 2. In Austria, humidity data were available
481 from 2005. The WFDEI data were therefore used to estimate missing data via linear interpolation.
482 In Canada, no observational data were available, except for temperature and precipitation.
483 Precipitation in Canada was scaled with WFDEI data after adjusting to the total climatological
484 precipitation for 1979–1984, shortwave radiation was taken from the WFDEI, and humidity data
485 were harmonized in the same way as the humidity data in Austria.

486

487 **2.3.1.3 Simulation scheme**

488

489 To reach equilibrium conditions of the biomes, plant, and soil carbon pools, a 1000-year spin-up
490 simulation was performed by looping the climate data and atmospheric CO₂ concentrations

491 between 1979–2000. Building on the final conditions of the spin-up simulations, continuous
492 simulations corresponding to 1979–2001 in Canada, 1979–2008 in Austria, 1979–2000 in
493 Switzerland, and 1979–1995 in Panama were carried out, and the NSC dynamics were compared
494 with field data.

495

496 2.3.2 Validation at a global scale

497

498 In the global-scale simulation, the NSC seasonality in the SEIB-DGVM was validated using
499 CRU/NCEP/MIROC integrated data (0.5×0.5 degrees, 1850–2100, Tei et al., 2017, Watanabe et
500 al., 2011) as climatic input. SEIB-DGVM-NSC ver 1.0 is expected to simulate on future scenarios,
501 thus the different climate data that cover longer period than that of section 2.3.1.2. are used for
502 validation at a global scale. The SEIB-DGVM categorizes plant species into 16 PFTs for global-
503 scale simulations.

504 The outputs of the SEIB-DGVM include two boreal biome types (evergreen and deciduous
505 forests), three temperate biome types (conifer, broad-leaved evergreen, and deciduous forests),
506 and two tropical biome types (evergreen and deciduous forests), whereas the observations
507 included two boreal biome types (conifer and deciduous forests), three temperate biome types
508 (conifer, evergreen, and deciduous forests), and two tropical biome types (evergreen and
509 deciduous forests). The model outputs and observation data were compared for each climate zone.
510 Global climate data were available from 1850 to 2005. The first 30 years (1850–1880) were
511 therefore looped for a 1000-year spin-up simulation. After the spin-up, simulations were run for
512 the period 1850–2005. The NSC dynamics from the period 1975–2005 were used for model
513 validation.

514

515 2.4 Parameterization of NSC functions

516

517 Hoch et al. (2003) have reported that the NSC_{leaf} of temperate trees [sampled near the village of](#)
518 [Hofstetten in Switzerland](#) varies between 7%–20% of the total leaf DM. They determined the
519 seasonal mean of the NSC_{trunk} in sapwood of temperate deciduous trees and temperate evergreen
520 trees to be $4.7\% \pm 0.1\%$ of DM and $1.8\% \pm 0.1\%$ of DM, respectively. There were no significant
521 seasonal differences. The mean NSC_{root} was less than 1.5% of the root DM [for forests in Austria](#)
522 throughout the whole season (Gruber et al., 2012), and the total NSC of temperate trees was
523 around 4%–5% of the DM during the growing season (Gruber et al., 2011). For tropical trees
524 [collected in Parque Natural Metropolitano in Panama](#), the NSC_{trunk} and NSC_{root} were 8%–10% of
525 their biomass, whereas the NSC_{leaf} fluctuated within 5%–9% of leaf biomass (Würth et al., 2005).
526 Landhäuser and Liefers (2003) have reported that the NSC_{root} of boreal trees [in Canada](#), which

削除: For the validation, we used all available NSC data from the given climate zone.

削除:

530 is used to support leaf flush and root growth, is 3%–4% of their root mass. The stemwood NSC_{trunk}
 531 concentration is ~18 mg g⁻¹ of the DM for sample forests collected by Ameri flux tower (Carbone
 532 et al., 2013). Because of limited observational data, the parameters of the NSC processes were
 533 derived mostly from the values observed at each site used for point-scale validation, and the
 534 maximums of simulated NSCs were corrected so that they were in the range of measured NSCs.

535 First, the parameter a in Eq. (10) controls the base amount of photosynthetically fixed carbon
 536 mobilized for the NSC pools. The parameter b in Eq. (10) controls the seasonal fluctuations of
 537 the NSCs from the parameter a . In temperate zones, the value of b differs before and after July, so
 538 that NSC peaks around mid-summer. In contrast, in tropical zones, the amount of NSC in leaves
 539 and trunks decreases throughout the spring–summer.

540 The same parameter a and b were basically used for global-scale validation as for point-scale
 541 validation. However, because the NSCs are influenced by environmental conditions at the field
 542 sites, the observed global mean values used for global-scale validation were different from the
 543 values used for setting parameters for point-scale validation. Therefore, some adjustments were
 544 made to certain parameters to align with the values used in the global-scale validation. Tables 3
 545 and 4 show the parameters used for validation. Parameter values unrelated to the NSC module
 546 remain at the default values of the SEIB-DGVM (Sato et al., 2007).

656

657

670 **3 Results**

671

672 **3.1 Seasonality of NSC at the point scale**

673

674 **3.1.1 Boreal**

675 In Canada, the fact that the dominant PFT in the simulations was boreal deciduous trees was
676 consistent with observations at the site in Canada. The model simulated an increase in the NSC
677 of leaves from 80 mg g⁻¹ to 203 mg g⁻¹, whereas the observed NSC values were 89 mg g⁻¹ in May
678 and 185 mg g⁻¹ in August (Fig. 2a). The modeled NSCs in leaves therefore captured the increasing
679 trend during the growing season, but the simulations overestimated the maximum NSC a little.
680 The observed NSCs in trunks fluctuated from 90 mg g⁻¹ to 192 mg g⁻¹ during a year with no
681 specific seasonal trend (Fig. 2e). The model outputs in trunks were in the range 56–76 mg g⁻¹.
682 Although the observed fluctuations exceeded the modeled outputs, the modeled outputs were
683 within one standard deviation of the observations. The range of the observed NSCs in roots was
684 97–138 mg g⁻¹, whereas the range of the modeled NSCs was 117–132 mg g⁻¹ (Fig. 2i). However,
685 the observations peaked in August 2001 and in October 2002. The modeled NSCs of roots differed
686 from the observed NSCs because the former peaked during August in both years. Overall, the
687 simulated NSCs agreed well with the observed data (Fig. 3; RMSE = 69.92 mg g⁻¹, $r = 0.21$).

688

689 **3.1.2 Temperate**

690

691 In Austria, the fact that the dominant PFT in the simulations was temperate conifer forests was
692 consistent with observations at the site in Austria. The modeled NSCs in leaves accumulated until
693 July with a maximum of 142 mg g⁻¹. This pattern was similar to the observed seasonality of the
694 NSCs, which peaked at 150 mg g⁻¹ (Fig. 2b). The modeled NSCs in trunks were stable in the
695 range 19–26 mg g⁻¹, and the observations were within the range 18–38 mg g⁻¹, with no specific
696 seasonality (Fig. 2f). The modeled values were interspersed between the observations. The
697 modeled NSCs in roots varied in a curvilinear manner from 18 to 26 mg g⁻¹, a range that was
698 similar to the range of the observed NSCs, 13–32 mg g⁻¹ (Fig. 2j). The seasonality and magnitudes
699 of the modeled NSCs were consistent with observations (Fig. 3; RMSE = 9.52 mg g⁻¹, $r = 0.95$).

700 In Switzerland, the dominant PFT in the simulations corresponded to the temperate conifers
701 observed at the field site. The NSCs in the tree leaves accumulated during early spring and reached
702 up to 222 mg g⁻¹ (Fig. 2c). The decrease of the NSCs after July to a minimum of 135 mg g⁻¹ was
703 similar to the decline of the observed NSCs to a minimum of 124 mg g⁻¹. The modeled NSCs in
704 trunks fell in the range 13–16 mg g⁻¹, which was overlapped with the range of the observed NSCs
705 in trunks, 15–33 mg g⁻¹ (Fig. 2g), and the modeled NSCs all fell within one standard deviation of

716 the observations. The modeled NSCs in roots increased gradually from 45 to 62 mg g⁻¹, which is
717 similar to the observed range of observations, 48–64 mg g⁻¹ (Fig. 2k). The simulations captured
718 the amounts and seasonal patterns of the NSCs in the different organs and produced results that
719 compared well with observations (Fig. 3; RMSE = 25.83 mg g⁻¹, $r = 0.91$).

720

721 **3.1.3. Tropical**

722

723 **In Panama**, while a wide range of woody species was found at the Panama site, in the simulation
724 the tropical evergreen PFT became dominant. The simulations showed that the NSCs in leaves
725 were stored during winter and were then gradually consumed from July to October, when they
726 reached a minimum of 52 mg g⁻¹ (Fig. 2d). The observed NSCs in leaves likewise decreased from
727 69 to 48 mg g⁻¹ between August and October. The model therefore followed the observed
728 seasonality of the leaf NSCs. The modeled NSCs in trunks fell in the range 35–73 mg g⁻¹ (Fig.
729 2h). The slight decrease of the modeled NSCs in trunks during the summer was not apparent in
730 the observations. However, the simulated values fell within the range of the observed NSCs, 27–
731 97 mg g⁻¹. The simulated NSCs in roots fell in the range 23–55 mg g⁻¹; the observed NSCs ranged
732 from 43 to 70 mg g⁻¹ (Fig. 2l). Despite the weak correlation between simulated and observed
733 NSCs, the model results were within the acceptable margin of error (Fig. 3; RMSE = 20.75 mg
734 g⁻¹, $r = 0.08$).

735

736 **3.2. Comparison of annual mean NSC concentrations at a global scale**

737

738 For validation at a global scale, the mean annual NSCs from the **new** model were compared with
739 the observed mean annual NSCs in boreal, temperate, and tropical regions (Table 5). The model
740 simulated the amounts of NSCs in forest tree trunks in all climate regions with high accuracy. The
741 modeled NSCs in the trunks of trees in boreal forests averaged 47.48 ± 18.35 mg g⁻¹, which
742 compared favorably with the observed average of 76.67 ± 23.68 mg g⁻¹. In temperate forests, the
743 modeled NSCs of trunks averaged 44.78 ± 6.82 mg g⁻¹, which was close to the observed average of
744 51.59 ± 22.63 mg g⁻¹. The modeled NSCs of trunks in tropical forests averaged 66.68 ± 18.79 mg g⁻¹,
745 which was close to the average of the observations, 106.23 ± 32.52 mg g⁻¹. Although the modeled
746 NSCs in leaves of temperate and tropical forests were close to observed values, the modeled NSCs
747 in leaves of boreal forests underestimated the observed values. Moreover, the modeled NSCs in
748 roots of tropical forests were smaller than the observed NSCs. Overall, the simulated NSCs of all
749 organs of forest trees in all climate regions agreed reasonably well with observations (Fig. 4;
750 RMSE = 66.75 mg g⁻¹, $r = 0.17$). The model could simulate the NSCs with high accuracy, with
751 the exception of the NSCs of tree leaves in boreal forests and of tree roots in tropical forests (Fig.

删除: 4

删除: Panama

删除: W

删除: Seasonality

756 4; RMSE = 34.15 mg g⁻¹, r = 0.71). The original SEIB-DGVM only calculated NSCs in the trunks
 757 of trees with, an average value of 63.70 ± 44.64 mg g⁻¹ in boreal forests, 20.87 ± 15.91 mg g⁻¹ in
 758 temperate forests, and 16.61 ± 10.22 mg g⁻¹ tropical forests. Although the NSC in trunks of boreal
 759 forests from the original SEIB-DGVM was close to observation, the old model underestimated
 760 the NSC in trunks of temperate and tropical forests. The simulated NSCs from the original SEIB-
 761 DGVM in all climate regions were found to be poorly less correlated with observations (Fig. 4:
 762 RMSE = 55.37 mg g⁻¹, r = 0.01).

766
 767 **3.3 Woody biomass and total NSCs on a global scale**
 768

769 The average of the total GPP simulated from the new model during 1976–2005 was 123 PgC
 770 year⁻¹. The model estimated the mean total woody biomass to be 282 PgC year⁻¹ in boreal zones,
 771 100 PgC year⁻¹ in temperate zones, and 337 PgC year⁻¹ in tropical zones globally during 1976–
 772 2005. In boreal zones, the new model estimated the mean concentration of total NSCs to be 4.98%
 773 ± 1.87% of total woody biomass, while the original SEIB-DGVM estimated it to be 6.37% ±
 774 4.46% of total woody biomass (Fig. 5). The new model's estimation of the percentage of NSCs to
 775 total woody biomass in North America and North Russia was lower than the original SEIB-
 776 DGVM. In temperate zones, the mean concentration of total NSCs was 4.67% ± 0.54% of total
 777 woody biomass from the new model, while 2.09% ± 1.59% from the original SEIB-DGVM. The
 778 NSCs in the temperate forests of Asia and South America accounted for a larger fraction of total
 779 biomass in the new model compared to the original SEIB-DGVM. Total NSCs of tropical forests
 780 in South America and Africa from the new model were 6.19% ± 1.66% of their total woody
 781 biomass, the original SEIB-DGVM estimated it to be 1.66% ± 1.02% of the total biomass. The
 782 new model estimated a larger percentage of NSC to total biomass across tropical regions compared to
 783 the original SEIB-DGVM.

削除: .

790 Mean values of the simulated total NSCs relative to total woody biomass from the new model
 791 were close to previous estimates for temperate and tropical forests (Table 6). The total NSCs of
 792 temperate, broad-leaved, evergreen forests from the new model were $4.63\% \pm 0.50\%$, which
 793 corresponded to the woody biomass reported by Smith et al. (2018). Furthermore, in the new model,
 794 the total NSCs of temperate conifer forests were $4.72\% \pm 0.58\%$ of total woody biomass, which was
 795 close to the figure of 4% reported by Körner (2003). While, the original SEIB-DGVM calculated the
 796 total NSCs of temperate broad-leaved evergreen forests to be $2.64\% \pm 1.24\%$, and the total NSCs of
 797 temperate conifer forests were $5.30\% \pm 2.68\%$ of the total woody biomass, which closely matched
 798 the observations. However, the original SEIB-DGVM only considered NSCs in the trunks, whereas
 799 the new model allocates the total NSC into three organs, resulting in a close match to the observed
 800 total NSC. According to Würth et al. (2005), the percentages of woody biomass contributed by
 801 NSCs are 4%–8% in tropical forests. The new model calculated to be $4.66\% \pm 1.28\%$ in tropical
 802 deciduous forests, and $7.11\% \pm 1.08\%$ in tropical evergreen forests. In contrast, the total NSCs of
 803 tropical deciduous forests from the original SEIB-DGVM were $1.66\% \pm 1.35\%$ and the total
 804 NSCs of tropical evergreen forests were $1.66\% \pm 0.71\%$, which were different from the observed
 805 values. These observed percentages are close to our simulated values from the new model.

844 **4 Discussion**

845

846 ~~At the point scale, the modeled NSCs for boreal forests in Canada were close to the observed~~
847 ~~NSCs. The seasonality of the modeled NSCs in leaves was consistent with observations.~~
848 ~~However, the seasonality of NSC in roots differed from the observations because there were~~
849 ~~insufficient observations in boreal regions that enabled assessment of the seasonality of NSCs in~~
850 ~~all organs. The seasonality of NSCs in roots is therefore still unclear. In temperate zones, the~~
851 ~~model simulated the observed NSCs very accurately. The simulated NSCs of temperate forests~~
852 ~~were close to observed values in Austria and Switzerland. The simulations showed that the~~
853 ~~NSCs in leaves were consumed in winter for bud flush, and the leaves accumulated NSCs~~
854 ~~during the growing season. This pattern corresponded to the seasonality reported in Asaadi et al.~~
855 ~~(2018) and Furze et al. (2019). In the tropical zones, the model also captured a seasonality of~~
856 ~~NSCs that was similar to observations. The NSC concentration in the canopy of tropical forests~~
857 ~~decreased from June to August to satisfy increased maintenance demands (Signori-Müller et al.,~~
858 ~~2022; Würth et al., 2005). The simulated NSCs in leaves followed a similar pattern from June to~~
859 ~~August, and the simulated NSCs in leaves, trunks, and roots were close to observed values.~~

削除: On

削除: a

860 ~~At the global scale, the new model simulated NSC values in each organ of all climate~~
861 ~~regions that agreed with the observed data, except for the leaves of boreal forests and roots of~~
862 ~~tropical forests. As for the total NSCs of biome types, the modeled total NSCs of all temperate~~
863 ~~and tropical biomes matched the observed ranges well. In contrast, the original SEIB-DGVM~~
864 ~~only calculated NSC in trunks, and the modeled NSC in trunks of temperate and tropical forests~~
865 ~~were underestimated compared to observations. Total NSCs of tropical biomes were lower than~~
866 ~~observations, while those of temperate biomes were close to observations, but the original~~
867 ~~SEIB-DGVM did not assign the total NSC into leaves and roots. Therefore, these findings~~
868 ~~reveal that the new model can simulate NSC more accurately than the original SEIB-DGVM. In~~
869 ~~the original SEIB-DGVM, the NSC in trunks depended on the existing leaf biomass, which~~
870 ~~could not be applied to all biome types and climate zones, especially tropical forests. In the new~~
871 ~~model, the NSC_{organ} is determined by the biomass of the organ and photosynthesis in some~~
872 ~~climate zones. The new function, which was validated at the point scale, could therefore~~
873 ~~perform well on a global scale. The NSCs in trunks, which contain the greatest amounts of~~
874 ~~carbon in trees, were simulated accurately in all climate regions. The new function could~~
875 ~~therefore calculate the total NSCs in trees with great accuracy.~~

書式を変更: 下付き

876 The model with the new function calculated the global GPP to be $123 \text{ PgC year}^{-1}$, which is
877 close to the previous estimates of $106.2 \pm 2.9 \text{ PgC year}^{-1}$ by Zheng et al. (2020) and 130 ± 1.6
878 PgC year^{-1} by Madani et al. (2020). Moreover, the simulated mean total woody biomass for boreal
879 forests was $282 \text{ PgC year}^{-1}$, which is within the range of $249\text{--}295 \text{ PgC year}^{-1}$ reported by Pan et

削除: storage

書式変更: インデント: 最初の行: 6.3 mm

888 al. (2011). The simulated woody biomass of 100 PgC year⁻¹ for temperate forests was within the
889 observed range of 59–139 PgC year⁻¹ (Hui et al., 2020) and a little lower than the range of 113–
890 125 PgC year⁻¹ for other temperate forests (Pan et al., 2011). The calculated total woody biomass
891 of 337 PgC year⁻¹ for tropical forests was within the range of 212–340 PgC year⁻¹ reported by
892 Hui et al. (2020) and was not very different from the estimates of 378–564 PgC year⁻¹ by Pan et
893 al. (2011), and 200–300 PgC year⁻¹ by Mitchard (2018). Furthermore, the total NSCs relative to
894 total biomass output from the new function for temperate and tropical biome types agreed with
895 previous research. The total NSC of boreal biome types could not be compared with observations
896 due to lack of data.

897 The new model ~~allows for simulation of~~ various biotic effects on terrestrial ecosystems by
898 calculating the NSC dynamics within each plant organ. The NSCs stored in the trunk and roots
899 ~~help to~~ compensate for the deficit of CO₂ uptake in trees under stress, and the NSC stored in roots
900 is potentially indispensable for tree recovery after disturbances (Herrera-Ramírez et al., 2020).
901 ~~Therefore,~~ the NSC changes in the trunk and roots ~~provide~~ better indicators of carbon source–
902 sink relationships under elevated CO₂ conditions ~~and are more closely related~~ to the carbon
903 balance of plant bodies (Körner, 2003). ~~While the original SEIB-DGVM was unable to simulate~~
904 ~~biotic effects due to the lack of consideration for NSCs in all organs,~~ simulation of the dynamics
905 of NSC in the three compartments in this research contributes to ~~a better~~ understanding plant
906 growth and the response of carbon dynamics in each organ to increasing atmospheric CO₂.

907 ~~Carbon starvation may also be one of the causes of plant death during drought when~~
908 ~~photosynthesis decreases and water stress increases (McDowell et al., 2008). If reduced~~
909 ~~photosynthetic rates cannot supply enough carbon for NSC accumulation during drought, there~~
910 ~~will be greater canopy dieback in the next season (McDowell, 2011; Chen et al., 2017). The new~~
911 ~~model can simulate the dieback of long-lived temperate and tropical forests during drought,~~
912 ~~because it can represent the total NSC in plant bodies at a global scale. Additionally, insect pests~~
913 ~~have a significant impact on forest ecosystems, especially in temperate biomes, and their~~
914 ~~outbreaks have increased with climate change (Canelles et al., 2021). To recover from defoliation~~
915 ~~caused by insect pests and avoid decreased growth rates and lower survival rates, plants allocate~~
916 ~~carbon for NSC defense mechanisms. The new model accurately simulates the amount of total~~
917 ~~NSCs in temperate biomes, and therefore, it can be used to estimate the impact of insect pests on~~
918 ~~a global and future scale.~~

919 The new model introduced NSC compartments in leaves, trunk, and roots that were validated
920 at the point and global scales. Use of the model developed here enabled simulation of the
921 environmental effects on forests resulting from the changing amount of NSC in each organ. The
922 simulations depicted ~~the amount of NSC in the trunk at a global scale especially well, which~~
923 ~~constitutes a significant portion of the total NSC.~~ The model could thus be used as an indicator of

削除: Carbon starvation may also be the main cause of plant death during drought when photosynthesis decreases and water stress increases (McDowell et al., 2008). If reduced photosynthetic rates cannot supply enough carbon for NSC accumulation during drought, there will be greater canopy dieback in the next season. Plants therefore prioritize NSC storage, even when no excess carbon is available (Hartmann et al., 2020). At times, plants are unable to allocate carbon for this NSC defense mechanism, and their reduced ability to recover from biotic attacks such as defoliation caused by insect pests leads to decreased growth rates, less restoration of NSC, and lower survival rates. These processes may culminate in broad-scale tree mortalities (McDowell, 2011, ... [23])

削除: the

削除: NSC changes in the trunk especially well.

972 the carbon cycle in terrestrial ecosystems to understand the effect of climate change. Simulation
973 of photosynthetic carbon allocated into NSC storage in leaves, trunks, and roots enables a more
974 dynamic simulation of the carbon cycle between terrestrial ecosystems and the atmosphere. ▲

975 However, there were still some limitations to this research. We considered two potential
976 limitations that could lead to some discrepancies between the modeled and measured NSC values.
977 First, the relatively coarse spatial resolution of 0.5°×0.5° gridded climate data at the global scale
978 could not depict the details of local climates derived from observations. ▼These differences were
979 especially important in the case of temperature and short radiation, which play a key role in NSC
980 dynamics. Temperature surrounding plants is a key factor for the rate of plant growth (Hatfield
981 and Prueger, 2015). And different plant species has a specific temperature range. The short
982 radiation is used for a calculation of photosynthesis rate. These differences of two parameters
983 between 0.5°×0.5° gridded climate data and local climate data affect the ability of the trees to
984 accumulate NSCs.

985 ▼Second, the scarcity of ground-measured NSC seasonality prevented us from having more
986 average information on NSC concentrations, especially in the tropical and boreal regions, where
987 there were fewer available data. The NSC seasonality differs between biome types, but because
988 it is difficult to measure NSC dynamics, there is a lack of long-term data for each biome type.
989 Hence, we adjusted the new NSC process and its related parameters based on climate zones rather
990 than biome types, in our study. The fact that the NSC allocation was further influenced by
991 environmental conditions caused the allocation patterns to change within the same biome type.
992 The NSC allocation to roots was favored over aboveground allocations when soil resources were
993 lacking, and tree size was considered an important determinant of carbon allocation as well as
994 aridity (Hartmann et al., 2020). As we used data from different measurement sites for global-scale
995 validation, we could not account for the potential influence of varying surrounding conditions on
996 the data collected. In addition to the above factors, the number of samples and duration of
997 observations differed between the various studies. These differences led to no explicit NSC
998 seasonality. These potential sources of error in the field measurements jeopardized the model
999 performances.

削除:

削除: precipitation and soil properties, which play a key role
in NSC dynamics. Lowering of the water level in soils
causes damage to the hydraulic conductivity of the phloem
tube, which leads to a decline of phloem conductance at the
stem level (Dannoura et al., 2018; Sevanto, 2014). This
cessation of phloem transport could change the allocation of
photosynthetic products to plant growth and affect the ability
of the trees to accumulate NSCs (Dannoura et al., 2018).⁴

削除: parameters were tuned to simulate the same
seasonality for all the biome types in a given climate zone

削除: Because we pooled data for each organ from different
measurement sites for global-scale validation, environmental
effects on the data could not be measured.

1000

1001 5 Conclusions

1002

1003 In this study, a new NSC model was incorporated into the SEIB-DGVM to understand the effect
1004 of NSC allocation on global forest dynamics through competition and establishment among
1005 individual trees. The new module calculated the NSC dynamics of three organs—leaves, trunk,
1006 and roots—and the general NSC seasonality based on ground measurements was determined for
1007 biome types in three climate zones: boreal, temperate, and tropical. The NSC seasonality was

1022 validated at four sites: Canada (boreal), Austria and Switzerland (temperate), and Panama
1023 (tropical). The mean values of simulated NSC concentration agreed reasonably well with
1024 observed data on a global scale.

1025 The model enabled us to simulate the biotic effects resulting from insufficient NSC caused
1026 by factors such as carbon starvation and insect pests that are otherwise difficult to measure in
1027 terrestrial ecosystems globally. The difference of the NSC dynamics in the organs under
1028 elevated CO₂ conditions highlighted the importance of modeling the organs separately when
1029 studying environmental stresses. As more observation data about NSC dynamics become
1030 available, the model can be further improved and can contribute to the simulations of the
1031 passive biome shifts that may occur globally.
