14  
15 **Abstract**

16 The hydroxyl radical (OH) is the main oxidant responsible for the removal of many reduced trace gases  
17 and the formation of secondary air pollutants. However, due to technical difficulties in measuring OH,  
18 the existing measurements of atmospheric OH concentrations are limited, and its sources and sinks are  
19 not well understood under low NO<sub>x</sub> conditions. In this study, we observed the OH concentrations using  
20 chemical ionization mass spectrometry at a coastal site in Hong Kong from October to November 2020.  
21 The average noontime OH concentration over the study period was measured at  $4.9 \pm 2.1 \times 10^6 \text{ cm}^{-3}$ .  
22 We found that a box model with comprehensive observational constraints reproduced the observed  
23 daytime OH concentrations when air parcels originated from the continental regions. However, this  
24 model overpredicted the observed daytime OH concentrations for coastal air parcels by 142% on  
25 average. The missing OH reactivity, which is defined as the OH loss from unmeasured trace gases, is  
26 proposed to be the cause of this overprediction. The estimated missing OH reactivity was found in the  
27 case of low concentrations of nitrogen oxides (NO<sub>x</sub>) and volatile organic compounds, as well as in aged  
28 air, and we hypothesize that there could be unmeasured chemical species that cause the model to  
29 overestimate OH in aged coastal air parcels. Further studies are needed to find out the exact cause of

1 the model overestimation and to identify the suspected unmeasured chemical species that contribute to  
2 the OH budget, in order to better quantify the formation of secondary air pollutants.

### 3 4 **1. Introduction**

5 The hydroxyl radical (OH) dominates atmospheric oxidative capacity and participates in nearly all  
6 sunlit tropospheric chemistry. The primary sources of the ambient OH radical include the photolysis of  
7 ozone (O<sub>3</sub>) and nitrous acid (HONO) and the ozonolysis of alkenes. The OH sinks are mainly the  
8 reactions of OH with trace gases, including carbon monoxide (CO), sulfur dioxide (SO<sub>2</sub>), nitric oxide  
9 (NO), nitrogen dioxide (NO<sub>2</sub>), methane, and other volatile organic compounds (VOCs, Fuchs et al.,  
10 2018). In reactions with CO and VOCs, peroxy radicals (HO<sub>2</sub> and RO<sub>2</sub>) are produced and then recycled  
11 back into OH in the presence of NO as a secondary OH source. This interconversion is closely related  
12 to photochemical smog production (Stone et al., 2012). The reaction of OH with SO<sub>2</sub> and NO<sub>2</sub> produces  
13 H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub>, contributing to new particle formation and the acidity of rain, fog, and aerosols. OH  
14 also plays an important role in the climate system through reactions with the greenhouse gas CH<sub>4</sub> and  
15 the sulfate aerosol precursor dimethyl sulfide (DMS)(Berresheim et al., 2002).

16  
17 Measuring ambient OH is challenging due to its high reactivity, short lifetime (< 1 s), and low  
18 environmental concentration (Stone et al., 2012). After decades of efforts, tropospheric OH radicals can  
19 now be detected following the development of laser-induced fluorescence (LIF)–fluorescence assay  
20 with gas expansion (Heard and Pilling, 2003), chemical ionization mass spectrometry (CIM, Eisele and  
21 Tanner, 1991), and open-path differential optical absorption spectrometry (Hausmann et al., 1997). The  
22 theory, advantages, and disadvantages of various measuring techniques have been discussed previously  
23 (Heard and Pilling, 2003; Mao et al., 2012). Using these techniques, multiple campaigns have been  
24 conducted to measure the atmospheric OH concentrations in different regions around the globe. Figure  
25 S1 and Table S1 summarise the previous field observations of OH radicals in various environments.

26  
27 The OH observations are often compared with model simulations to evaluate whether a model has  
28 included the major OH sources and sinks. A summary of the results of the most recent studies is shown  
29 in Table S1 with the simulation to observation ratios (R<sub>S/O</sub>). As concluded in previous reviews (Stone et

1 al., 2012; Rohrer et al., 2014; Lu et al., 2019), observed OH concentrations can generally be reproduced  
2 by box models under high NO conditions ( $\text{NO} > 1$  ppb), such as at urban sites or within polluted air  
3 masses (Shirley et al., 2006; Griffith et al., 2016; Slater et al., 2020). However, discrepancies between  
4 model predictions and observations have often been found under low NO conditions ( $\text{NO} < 1$  ppb). The  
5 model typically overpredicts OH concentrations in a low VOC environment and underpredicts them in  
6 a high biogenic VOC (BVOC) environment, as discussed below.

7  
8 The model overestimation of OH has been found in remote marine boundary layers and coastal, urban,  
9 and Arctic regions (Table S1), which is attributed to the overestimation of OH sources, missing OH  
10 sinks, or the uncertainties inherent in model simulation and observation. For example, model  
11 overestimation of OH has been found when dominant sources, such as HONO (in the Antarctic, Kukui  
12 et al., 2014a) and  $\text{HO}_2$  (in the coastal area Kanaya et al., 2007), are overestimated. In these cases, the  
13 overestimation of OH was resolved when these sources were better constrained in the model.  
14 Unmeasured VOCs have been proposed as the missing OH sinks, resulting in the overestimation of OH,  
15 e.g., in aged air in Idaho Hill (McKeen et al., 1997), in the marine boundary layer (MBL) of Mace  
16 Head (Carslaw et al., 1999; Berresheim et al., 2002), in the MBL in Tasmania (Creasey et al., 2003),  
17 in Antarctica (Mauldin III et al., 2010), and the urban area of California (Griffith et al., 2016). Other  
18 studies have shown evidence of missing OH sinks in various types of environments (Lou et al., 2010;  
19 Yang et al., 2016), e.g., in the clean forest (Hansen et al., 2014) and marine (Thames et al., 2020) areas,  
20 which is likely resulted from unmeasured organic compounds emitted from biogenic (Kaiser et al., 2016)  
21 or oceanic (Thames et al., 2020) sources and their oxidation products. A few studies have shown that  
22 the overestimations fall within measurement uncertainties of DOAS, CIMS (McKeen et al., 1997), and  
23 LIF, (Carslaw et al., 1999) while others have suggested a possible sampling loss of OH in CIMS  
24 (Mauldin III et al., 2010) or a possible calibration bias due to low relative humidity (CIMS, Mauldin III  
25 et al., 2001).

26  
27 Underestimations of OH by models have mostly been found in forest areas with high BVOC emissions  
28 and low NO conditions. Few recent studies also found the OH estimation in urban atmospheres when  
29 the NO level was below 1ppb (Whalley et al., 2018; Tan et al., 2017, 2019). These underestimations

1 have usually been attributed to missing OH sources (Tan et al., 2001; Lelieveld et al., 2008;  
2 Hofzumahaus et al., 2009; Whalley et al., 2011). To explain the missing sources in forested regions, a  
3 series of new OH regeneration reactions under low NO conditions were proposed based on chamber  
4 experiments that investigated the oxidation of isoprene by OH. This mechanism, known as the Leuven  
5 isoprene mechanism (LIM1; Peeters et al., 2014), includes unimolecular reactions (Peeters et al., 2009;  
6 da Silva et al., 2010; Fuchs et al., 2013; Novelli et al., 2020) and isomerization of isoprene and/or its  
7 products (Peeters and Müller, 2010; Fuchs et al., 2014). With the adoption of this mechanism, the  
8 simulated OH concentration increased by 20% – 30% in the forest region (Lew et al., 2020). Another  
9 breakthrough was the development of a new chemical scavenging technique in LIF instruments that  
10 were able to determine the interference to the instrument's background. Some studies have shown that  
11 the interference in LIF instruments can partly explain the previously observed high OH concentrations  
12 (Mao et al., 2012; Hens et al., 2014; Novelli et al., 2014; Feiner et al., 2016; Woodward-Massey et al.,  
13 2020). With the adoption of interference scavenging and the LIM1 improved mechanism, measurements  
14 using LIF in an Alabama forest (Feiner et al., 2016) and CIMS in Amazon forests (Jeong et al., 2022)  
15 agreed with the OH concentration predicted by the model. However, the models in other studies  
16 continued to underestimate OH with the improved mechanism (Tan et al., 2019; Lew et al., 2020).

17  
18 The industrialization of the Pearl River Delta (PRD) region of south China over the past three decades  
19 has been accompanied by high anthropogenic emissions of air pollutants (Lu et al., 2013), causing  
20 elevated concentrations of surface ozone (Wang et al., 2019b) and particulate matter (Yao et al., 2014).  
21 Measurements of OH in the PRD region that were taken using LIF at a forested site (Backgarden)  
22 indicated missing OH sources at this BVOC-rich site (Hofzumahaus et al., 2009; Lu et al., 2012). More  
23 recently, OH concentrations were measured at a suburban site in Shenzhen during the autumn of 2018  
24 (Wang et al., 2019a, 2021a) using a newly developed LIF instrument. The OH concentrations, which  
25 had an average value of  $5.3 \times 10^6 \text{ cm}^{-3}$  around noon, were briefly presented with no comparison to  
26 modeled OH.

27  
28 In the present study, we measured OH concentrations using quadrupole CIMS from October to  
29 November 2020 at a background site in Hong Kong. The study aimed to determine the OH

1 concentrations in coastal south China and to investigate whether they could be simulated by a state-of-  
2 the-art chemical model under different airflow conditions. We first give a brief description of the site  
3 and OH measurement procedure, including the working theory of CIMS, calibration, uncertainties, and  
4 modelling setup. We then present the overall measurement results for different air masses and compare  
5 them with those found in previous studies. After this, we simulate OH concentrations using a box model  
6 constrained by comprehensive observations and discuss possible reasons for the model–observation  
7 discrepancy. Our measurements add to the limited database of ambient OH radical concentrations, while  
8 our analysis sheds light on possible missing OH sinks under low NO<sub>x</sub> conditions.

## 9 10 **2. Methodology**

### 11 **2.1 The Hok Tsui Supersite**

12 The field campaign was conducted at the Cape D’Aguilar (also known as Hok Tsui, HT) Air Quality  
13 Supersite, which is operated by the Hong Kong Environmental Protection Department, between 6  
14 October and 24 November 2020. The HT Supersite (22°12'32" N, 114°15'12" E) is a coastal site located  
15 at the south-eastern tip of Hong Kong Island. The site is surrounded by ocean, vegetation, and a country  
16 road (Figure 1) and is around 15 km away from the nearest urban center. There is no strong  
17 anthropogenic emission source in the surrounding area apart from the ocean-going vessels traveling in  
18 nearby waters (Peng et al., 2022). Nonetheless, the site does occasionally receive polluted air masses  
19 from mainland China, including air masses from the highly urbanized PRD region (Li et al., 2018; Peng  
20 et al., 2022).

21  
22 We measured OH radicals, O<sub>3</sub>, NO<sub>x</sub>, CO, HONO, VOCs, oxygenated VOCs (OVOCs), relative humidity,  
23 temperature, NO<sub>2</sub> photolysis frequency ( $J_{\text{NO}_2}$ ), and aerosol size distribution. Table 1 summarises the  
24 measurement technique, resolution, and detection limits. The OH-CIMS was housed in an air-  
25 conditioned shelter in yard B together with the time-of-flight (ToF)-CIMS and ozone and NO<sub>x</sub> analyzers  
26 (Figure 1).  $J_{\text{NO}_2}$  was measured on top of the shelter. The other species and the aerosol size distribution  
27 were measured inside the main station building in yard A, which was located around 10 m away from  
28 yard B (Figure 1). The backward trajectory was calculated at 1-hour intervals on sampling days at an  
29 elevation of 60 m above ground level using the MeteoInfoMap software package (meteothink.org, Wang,

1 2014, 2019).

2

### 3 **2.2 OH radical measurements**

4 OH radical concentrations were indirectly measured using a custom-built quadrupole CIMS instrument  
5 (THS Inc, Atlanta). The THS CIMS was originally developed by (Eisele and Tanner, 1991) and  
6 improved upon in subsequent works (Eisele and Tanner, 1993; Tanner and Eisele, 1995; Tanner et al.,  
7 1997). The ambient OH concentrations were measured by first converting the OH (by addition of SO<sub>2</sub>)  
8 to sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) which was further converted to HSO<sub>4</sub><sup>-</sup> ion followed by its detection with a  
9 quadrupole mass detector.

10 A schematic diagram of our OH-CIMS instrument is shown in Figure 2. Ambient air was drawn into  
11 the stainless steel inlet with a turbulence-reducing scoop by the inlet pump. The central part of the air  
12 in the stainless steel inlet was then drawn into the sample inlet, where OH was converted into H<sub>2</sub>SO<sub>4</sub>  
13 by adding SO<sub>2</sub> to the sample flow (R1 to 3).

17 The conversion was ended by the addition of scavenger gases (C<sub>3</sub>F<sub>6</sub>) in the rear flow. The reaction time  
18 for OH conversion is 47ms which is short enough to mitigate the HO<sub>2</sub> and RO<sub>2</sub> recycling interference.

21 The converted H<sub>2</sub>SO<sub>4</sub> in the sample flow was then reacted with the excess NO<sub>3</sub><sup>-</sup> cluster in the sheath  
22 flow and converted into an HSO<sub>4</sub><sup>-</sup> ion cluster in the ionization chamber (R4).

24 The NO<sub>3</sub><sup>-</sup> reagent ion cluster (NO<sub>3</sub><sup>-</sup> · (HNO<sub>3</sub>)<sub>m</sub> · (H<sub>2</sub>O)<sub>n</sub>) with m and n mostly of 0-2 and 0-3  
25 (Berresheim et al., 2000) was generated by passing an HNO<sub>3</sub> containing sheath flow through a <sup>210</sup>Po  
26 ion source (R7 to 9).

1 Where  $e^-$  is emitted from the  $^{210}\text{Po}$  ion source. The  $\text{NO}_3^-$  and  $\text{HSO}_4^-$  ion clusters further dissociated  
2 in the collisional dissociation chamber (CDC), refocused in the ion guide chamber (IGC), and were then  
3 detected by the detector in the ion detection chamber (IDC).

6 The  $\text{HSO}_4^-$  and  $\text{NO}_3^-$  were detected by the peak intensities at  $m/z = 97$  ( $S_{97}$ ) and  $m/z = 62$  ( $S_{62}$ ). The  
7  $\text{HSO}_4^-$  ion concentration was determined based on relative signal strength (the  $S_{97}/S_{62}$  ratio) rather than  
8 absolute signal ( $S_{97}$ ) (Berresheim et al., 2000).

9  
10 Apart from ambient OH, some interference gases, such as ambient  $\text{H}_2\text{SO}_4$ , Criegee intermediates, and  
11 artificial OH produced by the ion source, can also be converted into  $\text{HSO}_4^-$  and contribute to the signal  
12  $S_{97}$ . To mitigate such interference, the scavenger gas ( $\text{C}_3\text{F}_6$ ) and  $\text{N}_2$  were added to the sample flow  
13 through electrically operated valves (see the pulsed flow in Figure 2) that automatically switched  
14 injection positions every 3 min. When a scavenger gas is added to the front injectors, ambient OH  
15 radicals are eliminated by the scavenger instead of reacting with  $\text{SO}_2$  due to the higher concentration  
16 (~100 times) and the faster reaction of  $\text{C}_3\text{F}_6$  than of  $\text{SO}_2$  in the sample flow (Dubey et al., 1996). This  
17 allows the background signal ( $\text{BS}_{97}$ ) contributed by the interference gases and instrument noise signal  
18 to be determined. When the pulsed flow scavenger gas is switched to the rear injector, the ambient OH  
19 radicals and interference gases react with  $\text{SO}_2$  to give the total signal ( $\text{TS}_{97}$ ). Then, the ambient OH  
20 signal can be obtained by subtracting the signal contributed by interference ( $\text{BS}_{97}$ ) from the total signal  
21 ( $\text{TS}_{97}$ ). The measured OH concentration ( $[\text{OH}]$ ) can be calculated using the following equation (E1):

$$22 \quad [\text{OH}] = \frac{1}{C} \times \frac{\text{TS}_{97} - \text{BS}_{97}}{S_{64}} \quad (\text{E1})$$

23 where  $C$  is the calibration factor obtained from calibration that was performed using the calibrator  
24 shown in Figure 2. The calibration is based on the production of OH radicals through the photolysis of  
25 water vapor by 184.9 nm light in the airflow through the calibrator (SR1). The OH concentration  
26 produced by the calibrator is calculated by photon flux ( $I$ ) and  $\text{H}_2\text{O}$  concentration in the airflow ( $\text{SE1}$ ).  
27 Calibration was carried out at least every two days during the campaign, as well as before and after any  
28 changes in settings. The difference in calibration factors was included in the calibration accuracy.

1 The detection limit was calculated by the background signal as shown by the equation in supplementary  
2 (SE3). The detection limit is approximately  $1.5 \times 10^5 \text{ cm}^{-3}$  (signal-to-noise ratio of 2) in the laboratory.  
3 Due to variations in the concentrations of  $\text{H}_2\text{SO}_4$  and other interference gases in the ambient air, the  
4 background signal during ambient measurement has a larger variation compared to the lab condition,  
5 resulting in a higher detection limit in the ambient condition. During the field study, the daytime and  
6 night-time average detection limits in this campaign were  $1.0 \times 10^6 \text{ cm}^{-3}$  and  $0.7 \times 10^6 \text{ cm}^{-3}$ , respectively.  
7 The overall calibration accuracy was estimated at 38%, by calculation that took into account the  
8 uncertainty of all of the parameters measured during the calibration process. The averaged overall  
9 uncertainty for this campaign is 44% for OH measurement with consideration of the calibration  
10 accuracy and the variations in m/z at 62 ( $\text{S}_{64}$ , 18%) and at 97 ( $\text{TS}_{97}$ - $\text{BS}_{97}$ , 13%) during observation (SE4  
11 and SE5). The technical details and specifications are in Table S2 and the detailed descriptions of CIMS  
12 optimization, calibration process, and calculation of detection limit are in the Supplementary  
13 Information.

### 14 **2.3 Box modeling**

15 The Framework for 0-D Atmospheric Modelling (F0AM) using the Master Chemical Mechanism  
16 (MCM) v3.3.1 (Wolfe et al., 2016) was used to simulate OH concentrations. MCM v3.3.1  
17 (<http://mcm.leeds.ac.uk/MCM>) is a near-explicit chemical mechanism that includes over 17,000  
18 elementary reactions of 6700 primary, secondary, and radical species (Jenkin et al., 2015). The isoprene  
19 degradation mechanisms, and in particular the mechanisms OH regenerated by  $\text{HO}_x$  recycling in low  
20  $\text{NO}_x$  condition, were improved in MCM v3.3.1. The MCM mechanism has been used in previous studies  
21 to investigate OH chemistry in different environments, including forests (Stone et al., 2011), urban areas  
22 (Slater et al., 2020), suburban areas (Tan et al., 2018), and coastal regions (Sommariva et al., 2004). In  
23 our study, observational data (shown in Table S1) were used to constrain the model. These data included  
24 VOCs, OVOCs,  $\text{SO}_2$ ,  $\text{NO}_x$ , CO,  $\text{O}_3$ , HONO, photolysis frequency of  $\text{NO}_2$  ( $J_{\text{NO}_2}$ ), and meteorological  
25 parameters (temperature, relative humidity, and pressure). The photolysis frequencies for other species  
26 were calculated by the “HYBRID” method in F0AM which is based on Tropospheric Ultraviolet and  
27 Visible (TUV v5.2) Radiation Model from National Center for Atmospheric Research. The Ozone  
28 column we used for TUV calculation was 240 DU (the Dobson unit) which is the average number from  
29 October to November 2020 for the Hok Tsui area according to the worldview website (EOSDIS

1 [Worldview \(nasa.gov\)](https://worldview.nasa.gov). The simulated photolysis frequencies were then scaled by the correction factor  
2 obtained from the comparison between observed and modeled  $J_{NO_2}$ . The first-order physical loss process,  
3 with a 24-hour lifetime for all species, was included in the model to represent physical processes (Wolfe  
4 et al., 2016; Chen et al., 2022). The physical loss process has a negligible influence on OH simulation  
5 because the OH concentrations are controlled by fast *in situ* chemistry.

6  
7 The heterogeneous uptake of HO<sub>2</sub> by aerosols was included in the model by assuming a pseudo-first-  
8 order loss of HO<sub>2</sub> (E2–E4; Jacob, 2000):

$$\frac{d[HO_2]}{dt} = -k_{HO_2}[HO_2] \quad (E2)$$

$$k_{HO_2} = \frac{V_{HO_2} \times S_a \times \gamma_{HO_2}}{4} \quad (E3)$$

$$V_{HO_2} = \sqrt{\frac{8RT}{\pi \times MM_{HO_2}}} \quad (E4)$$

9  
10  
11  
12 where  $k_{HO_2}$  is the first-order loss rate coefficient of HO<sub>2</sub> by aerosol uptake,  $\gamma_{HO_2}$  is the effective HO<sub>2</sub>  
13 uptake coefficient (0.1 for the base model run; Guo et al., 2019),  $V_{HO_2}$  is the mean molecular velocity  
14 of HO<sub>2</sub>,  $S_a$  is the aerosol surface area concentration measured by a scanning mobility particle sizing  
15 (SMPS), and  $MM_{HO_2}$  (= 17 g/mol) is the **molecular mass** of HO<sub>2</sub>. We assumed in the model that the  
16 products of heterogeneous HO<sub>2</sub> loss would not participate in further reactions (Guo et al., 2019).

17  
18 The observation data were averaged every 10 mins for the model input. Any missing values were  
19 calculated assuming linear interpolation. The measured concentrations of NO and NO<sub>2</sub> were used to  
20 constrain the model. Due to the clean condition of the coastal air, some of the reactive alkenes and long-  
21 chain alkanes were below detection limits. For the simulation of those compounds, we used  
22 concentrations that were half of the detection limits. The measured VOCs were further divided into  
23 those of anthropogenic origin (AVOCs) and biogenic origin (BVOCs). The AVOCs included alkanes  
24 (C<sub>2</sub>–C<sub>8</sub>), alkenes (C<sub>2</sub>–C<sub>6</sub>) benzene, and TEXs (toluene, ethylbenzene, and xylenes), which covered the  
25 dominant species originating from petroleum gas and industrial solvent evaporation (Tang et al., 2008),  
26 while the BVOCs included isoprene, terpene, pinene, and limonene. The majority (> 95%) of the  
27 measured OVOCs in this study were C<sub>1</sub>–C<sub>3</sub> aldehydes, ketones, and acids. For each run, a three-day  
28 spin-up was performed with constant photolysis and deposition to create a stable model environment

1 and to avoid the uncertainty of unconstrained species (Carslaw et al., 1999).

### 3. Results and Discussion

#### 3.1 Overview of observations

5 Figure 3 shows the time series of observed OH concentrations, along with the concentrations of other  
6 trace gases and the meteorological parameters, during the study period. The weather conditions featured  
7 relatively high temperatures, high relative humidity (RH), and strong solar radiation, similar to previous  
8 autumn observations at the same site (Li et al., 2018; Peng et al., 2022). The air temperature ranged  
9 from 20°C to 30°C and RH ranged from 40% to 96%. The photolysis frequency of NO<sub>2</sub> ( $J_{\text{NO}_2}$ ) peaked  
10 at  $8 \times 10^{-3} \text{ s}^{-1}$  around noon on sunny days and decreased to  $2 \times 10^{-3} \text{ s}^{-1}$  on cloudy days. The observed  
11 OH concentrations were mostly above the detection limit during the daytime but fell closer to the  
12 detection limit at night. The OH concentrations showed a distinct diurnal pattern and a positive  
13 correlation with  $J_{\text{NO}_2}$  and calculated  $J_{\text{O}_1\text{D}}$  ( $R^2 = 0.68$  and  $0.46$  for  $J_{\text{NO}_2}$  and calculated  $J_{\text{O}_1\text{D}}$ , respectively,  
14 Figure S2). The daily maximum OH concentration varied from  $2.1 \times 10^6 \text{ cm}^{-3}$  on 21 November,  
15 accompanying the lowest level of solar radiation, to  $15.4 \times 10^6 \text{ cm}^{-3}$  on 7 November during a pollution  
16 episode. The pollution episode began on the evening of 6 November and featured a maximum  
17 concentration of 174.0 ppb O<sub>3</sub>, 8.7 ppb NO, 22.7 ppb NO<sub>2</sub>,  $9.8 \text{ s}^{-1}$  total measured VOCs reactivity, and  
18  $5.8 \text{ s}^{-1}$  total measured OVOCs reactivity. The OH concentration peaked the next day (7 Nov). This  
19 suggests abundant OH sources and fast radical propagation under high-NO<sub>x</sub> and high-VOC conditions.

21 Figure 4 shows the average diurnal profiles of OH and other representative species. On average, the  
22 maximum OH concentration was  $4.9 \pm 2.1 \times 10^6 (1\sigma) \text{ cm}^{-3}$ . As shown in Table S1, the OH concentrations  
23 at our site were comparable to those reported in previous field studies conducted at tropical coastal sites.  
24 For example, the reported OH maximum concentration was  $4.5 \times 10^6 \text{ cm}^{-3}$  in the low-altitude remote  
25 tropical troposphere (Brune et al., 2020). In a study conducted in autumn at a suburban site in Shenzhen,  
26 approximately 50 km away from our site, an OH diurnal maximum concentration of  $5.3 \times 10^6 \text{ cm}^{-3}$  was  
27 observed (Wang et al., 2021b). The averaged night-time OH concentrations in this study was  $5.1 \pm 1.8$   
28  $\times 10^5 (1\sigma) \text{ cm}^{-3}$  which was comparable to the previous night-time results (below  $10 \times 10^5 \text{ cm}^{-3}$ ) measured  
29 at the PRD region (in Heshan, Tan et al., 2019, and in PKUSZ sites, Yang et al., 2022). The OH

1 concentration was slightly higher in the evening at  $6.8 \pm 1.1 \times 10^5$  ( $1\sigma$ )  $\text{cm}^{-3}$  than in the morning at  $3.7$   
2  $\pm 0.7 \times 10^5$  ( $1\sigma$ )  $\text{cm}^{-3}$  which might be due to the higher ozone concentration in the evening which leads  
3 to a higher OH production from alkene ozonolysis.

4  
5 Figure 4 also shows the average diurnal patterns of the other trace gases measured. As a primary source  
6 of OH, HONO, peaked in the morning at  $0.21 \pm 0.09$  ppb around 7:00 local time (LT), and  $\text{O}_3$  peaked  
7 in the afternoon at  $70 \pm 20$  ppb at around 16:00 LT. The average NO and  $\text{NO}_2$  concentrations reached a  
8 maximum of  $1.2 \pm 1.6$  ppb at around 10:00 LT and  $4.9 \pm 3.2$  ppb at around 18:00 LT, respectively.  
9 Isoprene showed a diurnal pattern similar to that of  $J_{\text{NO}_2}$  and OH, peaking at  $0.5 \pm 0.4$  ppb at noon. The  
10 average concentrations of all of the measured species during the campaign are shown in Table S3.

11  
12 Figure 5 shows the hourly backward trajectories over the whole campaign. Consistent with previous  
13 studies conducted at HT in the same season (Li et al., 2018; Peng et al., 2022), the air masses were  
14 dominated by continental air masses containing high concentrations of pollutants (Figure 5a) and less  
15 polluted coastal air masses (Figure 5c). In this study, we did not encounter oceanic air masses from the  
16 south. The average noontime OH concentration was  $5.0 \pm 2.2 \times 10^6$   $\text{cm}^{-3}$  in the continental air (Figure  
17 5b) and  $3.3 \pm 1.6 \times 10^6$   $\text{cm}^{-3}$  in the coastal air (Figure 5d).

### 18 19 **3.2 Model–observation comparison**

20 To investigate the performance of the MCM box model in simulating OH chemistry at our site, we  
21 selected 4 days featuring the continental air mass (8, 21, 22, and 23 Oct) and 4 days featuring the coastal  
22 air mass (25–27 Oct, 5 November) (Figure 6). We also selected 10 October as a specific case due to the  
23 shifting continental and coastal air masses within the same day during the daytime. These days were  
24 selected for model analysis because they comprised relatively complete chemical data that could be  
25 used to constrain the model. The below discussions focus on the comparison of the daytime results since  
26 the simulated night-time OH concentration was mostly within the measurement uncertainties and the  
27 night-time observations for Oct 08, 23, 27 and Nov. 5 were incomplete as shown in Figure 6.

#### 28 29 **3.2.1 Selected continental air mass cases**

1 Figure 6 shows the comparison between the simulated and observed OH concentrations for the selected  
2 cases in the continental and coastal air masses (4 days each). The simulated OH concentrations of the  
3 four continental cases (8 October and 21–23 October) were mostly within the OH measurement  
4 uncertainty ( $2\sigma$ ), with a daytime average  $R_{S/O}$  of 1.14 (Figure 7) and a range from 0.99 to 1.18 (Figure  
5 6). High  $\text{NO}_x$  ( $\sim 5$  ppb) and VOCs ( $\sim 17$  ppb) concentrations were measured on these days (Figure 7,  
6 Table S3). Therefore, in the continental polluted air mass, the existing MCM mechanism reproduced  
7 the observed OH concentrations well. On these days, the reaction between  $\text{HO}_2$  and  $\text{NO}$  was the  
8 dominant OH formation pathway (78%), followed by  $\text{O}_3$  photolysis (8%), HONO photolysis (6%), the  
9 reaction between ozone and  $\text{HO}_2$  (2%), and alkene ozonolysis ( $< 2\%$ ; Table 2 and Figure S3). These  
10 results are similar to the findings of previous studies in the PRD conducted during autumn under  
11 polluted conditions (Tan et al., 2019). The removal of OH occurs mainly through its reaction with non-  
12 methane hydrocarbons (NMHCs;  $\sim 63\%$ ),  $\text{CO}$  (20%),  $\text{NO}_2$  (9%), and  $\text{CH}_4$  (4%; Table 2)

13  
14 The simulated daytime average and peak  $\text{HO}_2$  concentration were  $2.1 \pm 1.2 \times 10^8 \text{ cm}^{-3}$  and  $4.5 \times 10^8$   
15  $\text{cm}^{-3}$ , respectively, for continental air masses (RUNBase, Figure S4). The peak  $\text{HO}_2$  value at our is lower  
16 than the result at a clean midlatitude forest area ( $10 \times 10^8 \text{ cm}^{-3}$ , Lew et al., 2020), and the average  
17 daytime value is higher than that measured at polluted urban sites in Beijing ( $0.3$  to  $0.4 \times 10^8 \text{ cm}^{-3}$ , Ma  
18 et al., 2019). The ratio between simulated  $\text{HO}_2$  and observed OH ( $\text{HO}_2_{\text{SIM}}/\text{OH}_{\text{OBS}}$ ) was 147 on the  
19 daytime average in continental cases.

20  
21 The simulated OH reactivity was  $8.1 \pm 1.0 \text{ s}^{-1}$  on average for continental air masses (Figure S5a), which  
22 is comparable to the OH reactivity measured at suburban sites which ranged from 5 to  $30 \text{ s}^{-1}$  but lower  
23 than that measured at the urban sites which ranged from 10 to  $100 \text{ s}^{-1}$  and mentioned by Yang et al.,  
24 (2016) and references therein.

### 25 26 3.2.2 Selected coastal air mass cases

27 In contrast to the continental air mass cases, the diurnal OH patterns in the coastal air mass category  
28 (25–27 October and 5 November) were not well reproduced by the model (Figure 6). The simulated  
29 results overestimated the observed OH concentration, with the daytime average  $R_{S/O}$  of 2.42 (Figure 7)

1 for these 4 days (range 2.08 to 3.11; Figure 6). The coastal air masses showed statistically significant  
2 ( $p < 0.05$ ) lower  $\text{NO}_x$  (-63%), AVOCs (-47%), BVOCs (-50%), OVOCs (-23%), and CO (-31%)  
3 concentrations compared with the continental cases (Figure 7, Table S3). The  $\text{HO}_2$  and NO reaction was  
4 still the dominant source (69%) of OH in the coastal air masses, like in the continental air mass cases,  
5 but in a lower proportion than on continental days due to the lower NO concentration (Table 2 and  
6 Figure S3). The other major OH sources were  $\text{O}_3$  photolysis (13.8%), HONO photolysis (7%), and the  
7 reaction between ozone and  $\text{HO}_2$  (4%).

8  
9 The simulated daytime average  $\text{HO}_2$  concentration was  $3.4 \pm 1.7 \times 10^8 \text{ cm}^{-3}$  for the coastal cases  
10 (RUNBase, Figure S4), which was  $\sim 1.2 \times 10^8 \text{ cm}^{-3}$  higher than the value in the continental polluted air  
11 mass. The simulated  $\text{HO}_2$  level is comparable to the measured value at a rural site in Heshan ( $3 \times 10^8$   
12  $\text{cm}^{-3}$ , Tan et al., 2019). The  $\text{HO}_2_{\text{SIM}}/\text{OH}_{\text{OBS}}$  was 218 in coastal cases, higher than the ratio in continental  
13 cases. This could be explained by the lower NO concentration in the coastal cases that slows the  
14 recycling reaction of  $\text{HO}_2$  back to OH (R4 and R5) (Sommariva et al., 2004; Shirley et al., 2006; Chen  
15 et al., 2010).

16  
17 The simulated OH reactivity was  $4.7 \pm 0.58 \text{ s}^{-1}$  on average for the coastal cases (Figure S5b), which was  
18 lower than that of the continental polluted air mass ( $8.1 \pm 1.0 \text{ s}^{-1}$ ). As discussed below in Section 3.3,  
19 low OH reactivity could have been the cause of the model's overestimation of OH concentrations in the  
20 coastal cases. The model's overestimation of OH in coastal air masses indicates gaps in our knowledge  
21 about the OH budget in relatively clean conditions with low  $\text{NO}_x$  and VOCs.

### 23 3.2.3 The 10 October case day

24 During the day on 10 October, our site received continental air masses between sunrise and noon and  
25 coastal air masses between noon and sunset. This served as another case that could be used to check the  
26 model's performance on continental versus coastal air masses within the same day. On 10 October, the  
27  $R_{\text{S/O}}$  changed from 1.20 in the morning to 2.59 in the afternoon, driven by the air mass drift during  
28 continuous measurement without interruption (Figure 8). As with the continental and coastal results  
29 shown above, the afternoon of 10 October showed significantly ( $p < 0.05$ ) lower concentrations of NO

1 (–50%), NO<sub>2</sub> (–68%) and the reactivity of AVOCs (–42%), BVOCs (–27%), and OVOCs (–12%)  
2 compared with the morning (Table S3). With lower NO, the fraction of OH produced from HO<sub>2</sub> and NO  
3 reaction was also lower in the afternoon (65%) than in the morning (73%; Table 2 and Figure S3).  
4 Similarly, the simulated total OH reactivity was lower in the afternoon ( $7.6 \pm 2.3$  s<sup>–1</sup> on average) than  
5 in the morning ( $10.3 \pm 1.6$  s<sup>–1</sup> on average; Figure S5c). The simulated HO<sub>2</sub> was  $3.6 \pm 2.4 \times 10^8$  cm<sup>–3</sup> in  
6 the morning when continental air mass dominated and was  $5.6 \pm 1.9 \times 10^8$  cm<sup>–3</sup> in the afternoon when  
7 coastal air mass dominated (RUNBase, Figure S4). The HO<sub>2,SIM</sub>/OH<sub>OBS</sub> was 142 in the morning and up  
8 to 476 in the afternoon. Again, higher HO<sub>2</sub> concentration and HO<sub>2,SIM</sub>/OH<sub>OBS</sub> ratio were shown with  
9 low NO concentration.

### 11 3.3 Discussion on the model–observation discrepancy

12 As discussed in the introduction, the model’s overestimation of OH could have been caused by multiple  
13 factors, including uncertainties in OH measurements and modelling, overestimation of OH sources, and  
14 underestimation of OH sinks. Below, we discuss possible their roles in the study.

#### 16 3.3.1 Uncertainties in OH measurement and simulation

17 The OH measurement uncertainties have been calculated as described in Section 2.2 and are shown as  
18 the error bars in Figures 5 and 6. The model’s overestimation of OH in coastal air masses exceeded the  
19 measurement uncertainties (Figures 6 and 7), and thus, the measurement uncertainty is unlikely to be  
20 the main reason for the discrepancy.

21  
22 Model uncertainties in our study include the uncertainties in photolysis frequencies correction,  
23 uncertainties in the constrained VOCs concentrations when they were below detection limits, and  
24 uncertainties from not considering halogen chemistry. On the first possibility, we acknowledge that the  
25 correction factor for photolysis frequencies due to cloud presence may be different for different species  
26 (Walker et al., 2022), thus, using a single correction factor (based on J<sub>NO2</sub>) may introduce uncertainty in  
27 the model simulations. We think such uncertainty should not be significant because the weather was  
28 mostly sunny in the coastal cases. Regarding the uncertainty from the VOCs input, we conducted a  
29 sensitivity test to show that the treatment of VOCs that were below the detection limits should have a

1 negligible effect on OH simulation (RUN<sub>VOC0</sub> and RUN<sub>VOCDL</sub> in Figure S4). We did not include halogen  
2 chemistry in our study as we wanted to compare our results with previous modelling work most of  
3 which did not consider halogen chemistry. Our other studies at the same site that did consider the  
4 halogen chemistry show a 4% increase in OH concentration from Cl chemistry (Peng et al., 2022) and  
5 2.8% from Br chemistry (Xia et al., 2022), which would even increase the model-measurement  
6 in the coastal air mass discrepancy.

### 8 **3.3.2 Overestimation of OH sources**

9 Our calculated OH budgets show that the main sources of OH in the coastal air masses were the HO<sub>2</sub> +  
10 NO reaction (69%), O<sub>3</sub> photolysis (14%), HONO photolysis (7%), and the reaction between ozone and  
11 HO<sub>2</sub> (4%). In the simulation, NO, HONO, and O<sub>3</sub> were constrained by observations. Could HO<sub>2</sub> be  
12 overestimated which would cause overprediction of OH?

13  
14 The main HO<sub>2</sub> sources are the VOCs oxidation by OH and the photolysis of OVOCs. In our study,  
15 VOCs and OVOCs were more likely under-measured than over-measured, which would underpredict  
16 HO<sub>2</sub> rather than overpredicting it. In addition, not including the halogen chemistry would under-  
17 simulate HO<sub>2</sub> at this site (Peng et al., 2022; Xia et al., 2022).

18  
19 We next examine the possibility of the underestimation of HO<sub>2</sub> sinks as the cause of the overprediction  
20 of OH. The major sinks of HO<sub>2</sub> include the reaction of NO to recycle OH, self-reaction to form H<sub>2</sub>O<sub>2</sub>,  
21 and heterogeneous loss by aerosol uptake. The first and second pathways have been considered in the  
22 MCM. The heterogeneous uptake of HO<sub>2</sub> onto aerosol was also included in our simulations with an  
23 uptake coefficient of 0.1. We conducted a sensitivity run by increasing the aerosol uptake of HO<sub>2</sub>  
24 (RUN<sub>γ<sub>MAX</sub></sub>, Figure S4). Even when we set the uptake coefficient to unity (which is unlikely large), the  
25 simulated HO<sub>2</sub> concentration would decrease by 34% and the simulated OH R<sub>S/O</sub> would decrease to  
26 1.73 from 2.42 in the base case. This indicates that the heterogeneous uptake of HO<sub>2</sub> is not the cause of  
27 the overestimation of OH in the coastal case. In summary, the discrepancy in modelled and observed  
28 OH in coastal cases is unlikely to be due to the overestimated HO<sub>2</sub>.

### 3.3.3 Possible missing OH reactivity.

Based on the above discussions, we propose that the model's overestimation of OH could have been caused by unmeasured species that were not included in the model as OH sinks. We attempt to estimate the magnitude of possible OH sinks and investigate which factors could be important to these sinks. We added an **artificial loss** reaction into the model with the reactivity of  $k_{miss}$  ( $s^{-1}$ ) and assumed that the reaction product would not participate in further reactions. Assuming a pseudo-steady state of OH during the daytime ( $P = k[OH]$ ),  $k_{miss}$  was calculated as follows:

$$k_{miss} = \frac{P_{constrain}}{[OH_{obs}]} - \frac{P_{constrain}}{[OH_{sim}]} \quad (E9)$$

where  $P_{constrain}$  is the model's calculated OH production rates, with OH constrained by observations;  $[OH_{obs}]$  is the observed OH concentration; and  $[OH_{sim}]$  is the OH concentration simulated in RUNBase. After introducing the OH sink with  $k_{miss}$  into the model, the model better reproduced the observed OH concentrations on the coastal case days, with daytime  $R_{S/O}$  close to unity (RUNKmiss Figure S6). The average daytime  $k_{miss}$  for the coastal cases was  $5.0 \pm 2.6 s^{-1}$ , which larger than the total calculated reactivity in coastal cases ( $4.7 \pm 0.58 s^{-1}$ ). **The calculated  $k_{miss}$  could be a lower limit of the possible missing source as the products from the reactions of OH with unknown species are most likely to further react with the missing source to produce  $RO_2$  and  $HO_2$  and recycle back to OH.**

We next explored the dependence of  $k_{miss}$  on different trace gases. Figure 9a shows the correlation between  $k_{miss}$  and NO concentration for the nine case days (including 10 October) between 09:00 and 15:00. At  $NO > 0.5$  ppb,  $k_{miss}$  is close to zero. At  $NO < 0.5$  ppb,  $k_{miss}$  tended to increase with decreasing NO. Similarly,  $k_{miss}$  approached zero at high concentrations of  $NO_2$  ( $> 2.5$  ppb), TEXs ( $> 0.25$  ppb), and AVOCs ( $> 5$  ppb; Figure 9) and increased with decreasing concentrations of  $NO_2$ , TEXs, and AVOCs. High  $k_{miss}$  also typically occurred at low toluene/benzene ratios and low  $C_2H_2/CO$  ratios (Figure 9), which are indicators of an aged air mass (Xiao et al., 2007; Kuyper et al., 2020).

**Therefore, while we cannot completely rule out other possibilities,** we argue that the aged coastal air masses could have contained unmeasured species such as oxygenated organic molecules (OOMs; Nie et al., 2022) and ocean-emitted gases (Thames et al., 2020) that contributed to the missing OH reactivity, causing the model to overestimate OH concentrations on the coastal case days.

#### 4. Summary and conclusion

In this study, we measured OH concentrations using CIMS at a coastal site in Hong Kong in the autumn of 2020 to gain insights into the atmospheric oxidative capacity and to evaluate the performance of a box model in the coastal atmosphere. The daily maximum OH concentration ranged from 2.1 to  $15.4 \times 10^6 \text{ cm}^{-3}$  over the whole campaign, with an average of  $4.9 \pm 2.1 \times 10^6 \text{ cm}^{-3}$ . The air masses were categorized into two groups based on their backward air trajectories: (1) continental air masses, which contained high concentrations of  $\text{NO}_x$  and VOCs, and (2) coastal air masses, which contained low concentrations of  $\text{NO}_x$  and VOCs. The observed OH concentration in the continental air parcels was on average 52% higher than in the coastal air parcels. The F0AM box model with comprehensive observational constraints generally reproduced the observed OH in the continental cases during the daytime, with a simulated/observed OH ratio ( $R_{S/O}$ ) of 1.14 on average. However, the model significantly overestimated OH concentrations in the coastal cases, with an  $R_{S/O}$  of 2.42 on average during the daytime. While we cannot completely rule out other possibilities, we incline to attribute this overestimation to a missing OH reactivity in the aged coastal air parcels that were not accounted for in the model. The lower limit of the missing OH reactivity was estimated at  $5.0 \pm 2.6 \text{ s}^{-1}$  on average between 09:00 and 15:00 and was especially larger under low  $\text{NO}_x$ , low AVOCs, and aged air conditions. We hypothesize that unknown products from AVOC oxidation or unknown OH-reacting gases emitted from oceans could contribute to the missing OH reactivity in aged coastal air masses. The overestimation of OH in the model could cause an overestimation of the formation of secondary aerosols, such as sulfate and nitrate, while the impacts would be even more complicated if it is due to missing chemical species which participated in ozone formation. Further studies are necessary to pin down the exact cause(s) of the OH overestimation by concurrently measuring  $\text{HO}_2$  and OH reactivities, VOC oxidation products, and ocean-emitted trace gases.

**Data availability.** All of the data used to produce this paper can be obtained by contacting Tao Wang ([two.wang@polyu.edu.hk](mailto:two.wang@polyu.edu.hk)).

**Supplement.** The online supplement for this article is available at:

1 **Author contributions.** TW initially conceived the project. TW and ZW planned and organized the  
2 overall field campaign at Hok Tsui. ZZ conducted the OH measurements using CIMS, with  
3 contributions from TW and ZW. YC performed the aerosol size distribution measurements. YQ  
4 performed the OVOC measurements using PTR-MS. MX and YC performed the HONO measurements  
5 using ToF-CIMS. YW assisted with HONO calibration. ZZ performed the box model analysis and  
6 sensitivity test with contributions from EX and QC. ZZ, TW, and QC analyzed the data and interpreted  
7 the results, with contributions from MX. ZZ, TW, and QC wrote the paper. All of the authors reviewed  
8 and commented on the paper.

9 **Competing interests.** One author (Tao Wang) is a member of the editorial board of Atmospheric  
10 Chemistry and Physics. The peer-review process was guided by an independent editor, and the authors  
11 have no other competing interests to declare.

## 12 **Acknowledgments**

13 We thank David Tanner, Dr. Wei Pu, and Dr. Weihao Wang for developing the OH CIMS. We are also  
14 grateful to the Environmental Protection Department of Hong Kong, for loaning the CIMS instrument  
15 and providing access to its station and data on trace gases, and to the Hong Kong Observatory, for  
16 supplying meteorology data.

## Figures and Tables

Figure 1. The location of the Hok Tsui Air Monitoring Supersite in Hong Kong, South China.

The map is from © Google Earth.

Table 1. Measuring instruments and measured species in the field campaign

Species	Instruments	Time Resolution	Detection Limit	Accuracy (1 $\sigma$ )
NO, NO <sub>2</sub>	Chemiluminescence/photolytic converter (Thermo, Model 42i)	1 min	60 ppt	NO: $\pm 5.2\%$ NO <sub>2</sub> : $\pm 15.2\%$
OH	Nitrate-quadrupole chemical ionization mass spectrometer (CIMS)	10 s	Lab: $1.5 \times 10^5 \text{ cm}^{-3}$ Daytime: $1 \times 10^6 \text{ cm}^{-3}$	$\pm 44\%$
Ozone	Ozone analyzer, model 49i, Thermo Scientific	1 min	0.5 ppb	$\pm 6.0\%$
JNO <sub>2</sub>	Filter Radiometer, Metcon	1 min	$4 \times 10^{-5} \text{ s}^{-1}$	$\pm 10\%$
HONO	Iodide-Tof-CIMS, Aerodyne Inc	1s	0.2 ppt	$\pm 15\%$
SO <sub>2</sub>	Pulsed Fluorescence SO <sub>2</sub> Analyzer (Thermo, Model 43i)	1 min	1 ppb	$\pm 6.1\%$
CO	Gas Filter Correlation CO Analyzer (Thermo, Model 48i)	1 min	40 ppb	$\pm 7.4\%$
NH <sub>3</sub>	Chemiluminescence NH <sub>3</sub> Analyzer (Thermo, Model 17i)	2 mins	1 ppb	$\pm 8\%$
Particle number size distribution	Scanning mobility particle sizer, TSI	5 mins	1 particle $\text{cm}^{-3}$	$\pm 10\%$
VOCs	GC-MS/FID (GC955 Series 611/811, Syntech Spectras)	1 hour	$\sim 10 \text{ ppt}$	$\pm 20\%$
	PTR-MS (PTR-QMS 500, IONICON Analytik, Austria)	5 mins	20 ppt	$\pm 20\%$
OVOCs	PTR-Tof-MS, IONICON Analytic;	1 s	$\sim 10 \text{ ppt}$	$\pm 15\%$

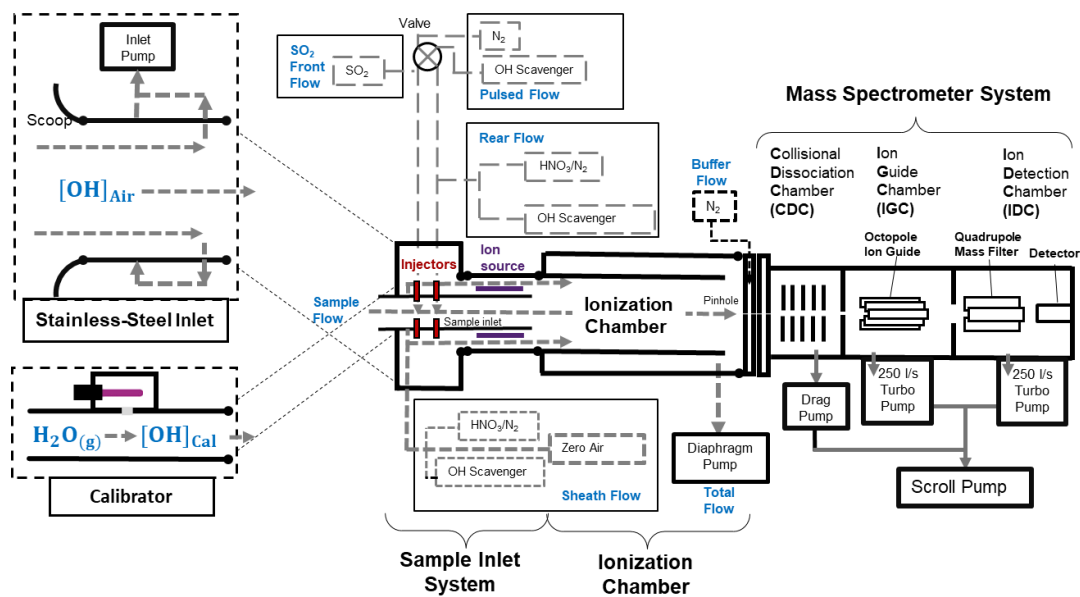

Figure 2. Schematics of the CIMS system which consists of a stainless-steel inlet, a sample inlet, an ionization chamber, a mass spectrometer system, and a calibration unit. The CIMS measures the ambient OH concentration when connecting to the stainless-steel inlet whereas, during calibration, the calibration unit is connected to the CIMS instead. Details of the setup, calibration and optimization of the CIMS can be found in the Supplementary.

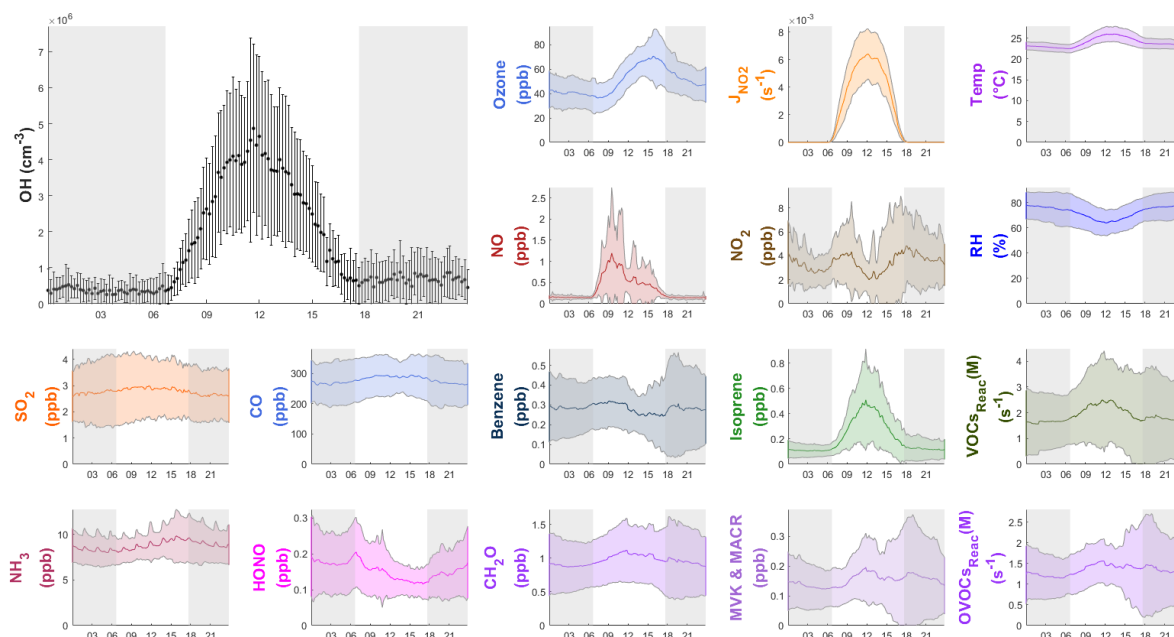

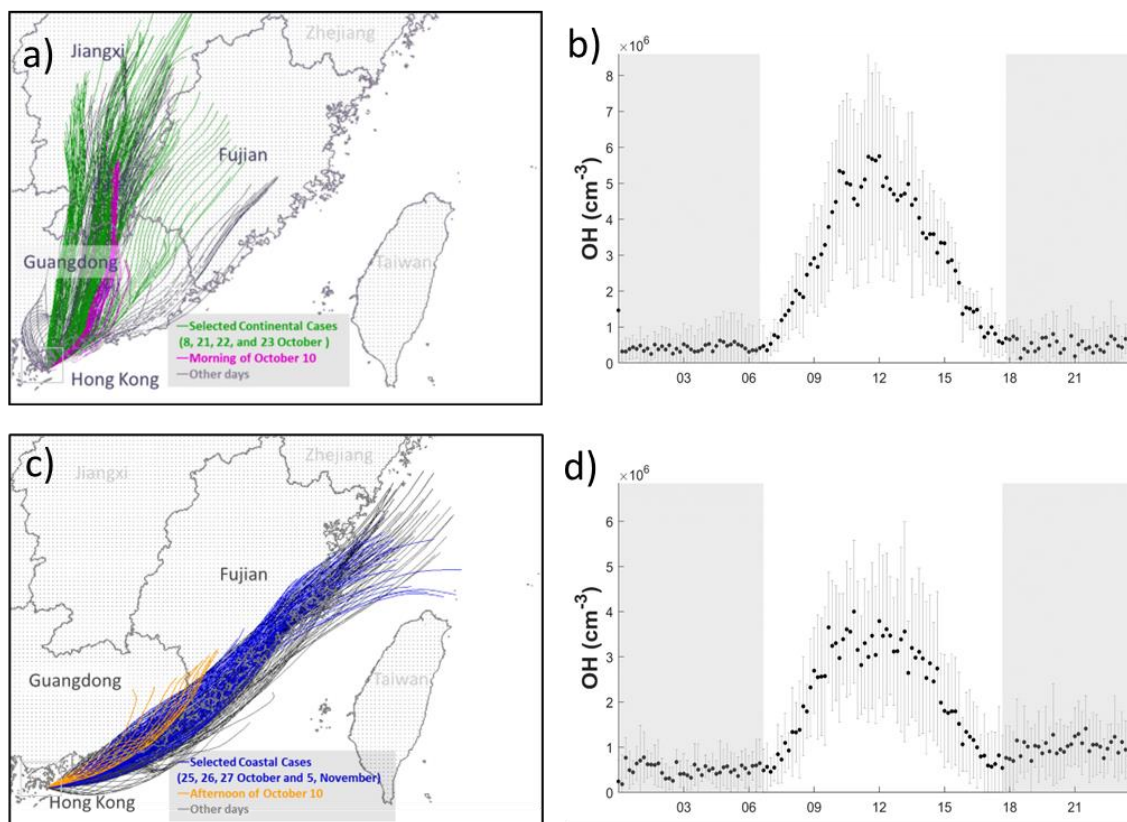

Figure 3. Time series of OH between 7 October and 23 November with measured weather conditions (temperature and RH), OH primary sources (ozone and HONO),  $\text{NO}_x$  (NO and  $\text{NO}_2$ ), reactivity of measured VOCs and OVOCs ( $\text{VOCs}_{\text{Reac}}(\text{M})$  and  $\text{OVOCs}_{\text{Reac}}(\text{M})$ ), and photolysis frequency ( $J_{\text{NO}_2}$ ). All measurement data shown are 10 min averages. The gaps of the data were due to the calibration or instrument maintenance. The black lines separate the non-continuous days during measurement. The grey shaded area denotes night-time. The time zone was local time (+8 UTC) for the x-axis.

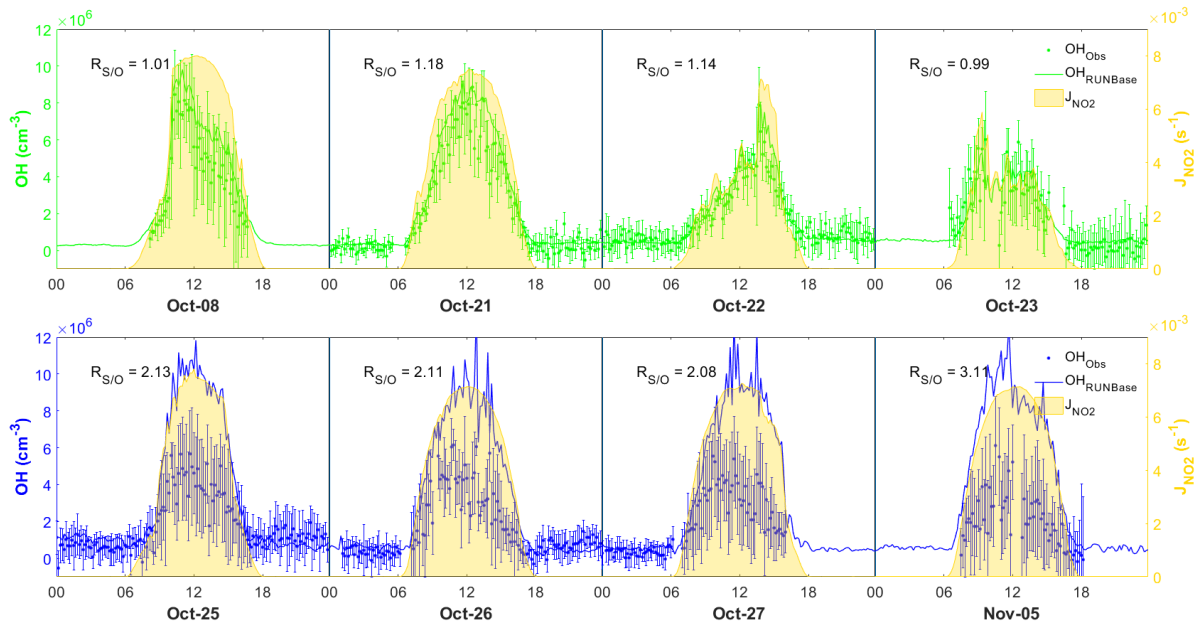

1  
 2 Figure 4. Diurnal profiles of the average ( $\pm 1\sigma$ ) concentrations of OH, other chemical species, **the**  
 3 **measured VOCs reactivity and OVOCs reactivity ( $\text{VOCs}_{\text{Reac}}(\text{M})$  and  $\text{OVOCs}_{\text{Reac}}(\text{M})$ ), and**  
 4 meteorological parameters ( $T$ ,  $\text{RH}$ ,  $J_{\text{NO}_2}$ ) during the field campaign. The grey shaded area denotes night-  
 5 time. **The error bars and shaded error bars are the standard deviation of the averaged data.**

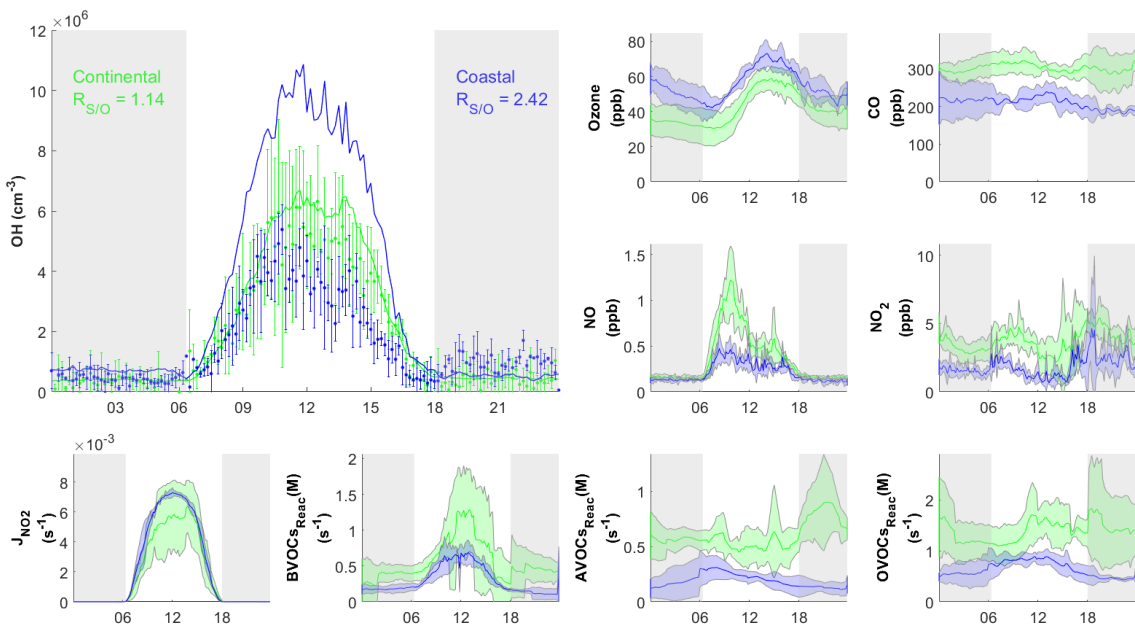

6  
 7 Figure 5. 24 h back trajectories of the continental (a) and coastal (c) cases over the whole measurement

1 period. The selected days for coastal, continental, and mixed cases are labelled in different colours. (b)  
 2 and (d) show the average concentration of OH with standard deviation in continental and coastal air  
 3 masses, respectively. The error bars and shaded error bars are the standard deviation of the averaged  
 4 data.

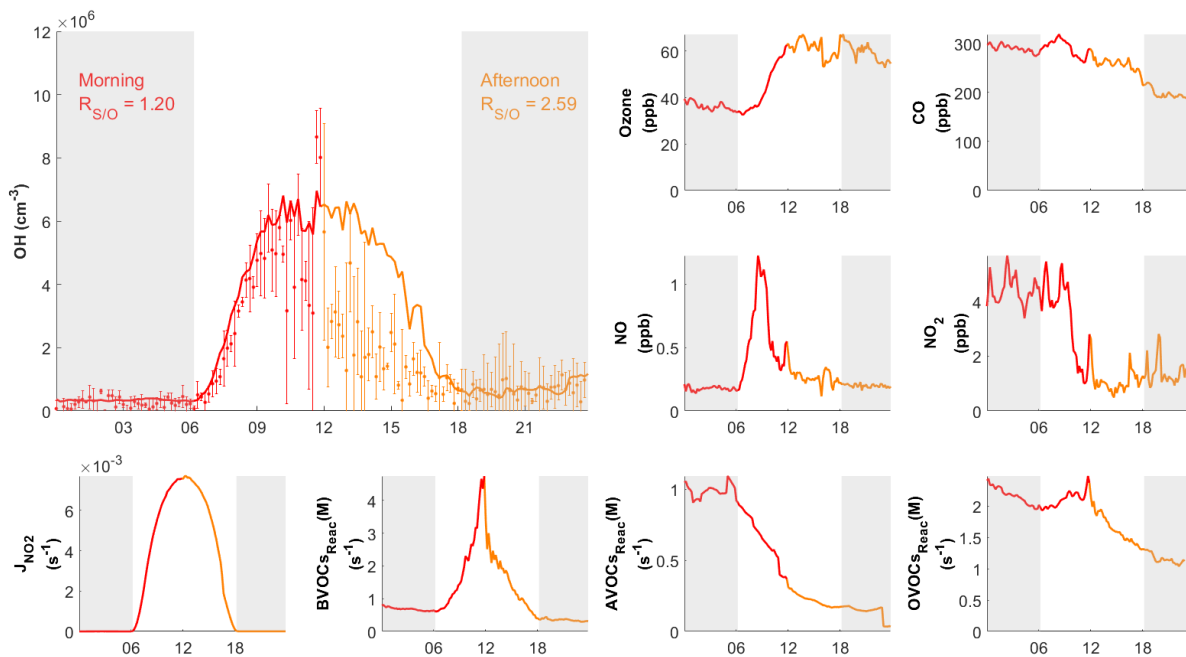

6  
 7 **Figure 6.** Comparison between observed (dots) and simulated (lines) OH in the four continental cases  
 8 (top panel) and the four coastal cases (lower panel), also showing measurement uncertainty (error bars)  
 9 and  $J_{NO_2}$  measurement (yellow shades). The time zone was local time (+8 UTC) for the x-axis.

10

1 Figure 7. Diurnal profiles of average concentrations of measured (dots) with standard deviation and  
 2 simulated (RUNBase, line) OH concentration, important trace gases and the measured BVOCs, AVOCs,  
 3 OVOCs reactivity (BVOCs<sub>Reac</sub>(M), AVOCs<sub>Reac</sub>(M) and OVOCs<sub>Reac</sub>(M)) for selected cases in continental  
 4 (green) and coastal (blue) air masses. The grey shaded area denotes night-time. The error bars and  
 5 shaded error bars are the standard deviation of the averaged data.

7  
 8 Figure 8. Diurnal profiles of measured (dots) with measurement uncertainty (error bars) and simulated  
 9 (RUNBase, line) OH on 10 October 2020, with other chemical species and the measured BVOCs,  
 10 AVOCs, OVOCs reactivity (BVOCs<sub>Reac</sub>(M), AVOCs<sub>Reac</sub>(M) and OVOCs<sub>Reac</sub>(M)). The air mass drifted  
 11 from continental (red) in the morning to coastal (orange) in the afternoon. The grey shaded area denotes  
 12 night-time. The time zone was local time (+8 UTC) for the x-axis.

13  
 14

1 Table 2. OH budgets for the selected continental and coastal cases, morning and afternoon of 10  
 2 October.

Continental Case		Coastal Case		Oct 10 Morning		Oct 10 Afternoon	
Production							
HO <sub>2</sub> + NO	77.66%	HO <sub>2</sub> + NO	69.02%	HO <sub>2</sub> + NO	73.17%	HO <sub>2</sub> + NO	65.11%
O <sup>1</sup> D + H <sub>2</sub> O	7.98%	O <sup>1</sup> D + H <sub>2</sub> O	13.80%	O <sup>1</sup> D + H <sub>2</sub> O	10.73%	O <sup>1</sup> D + H <sub>2</sub> O	15.04%
HONO + hv	5.78%	HONO + hv	7.32%	HONO + hv	8.65%	HONO + hv	7.16%
HO <sub>2</sub> + O <sub>3</sub>	1.97%	HO <sub>2</sub> + O <sub>3</sub>	3.60%	HO <sub>2</sub> + O <sub>3</sub>	1.70%	HO <sub>2</sub> + O <sub>3</sub>	3.80%
DM23BU2ENE + O <sub>3</sub>	1.59%	ME2BUT2ENE + O <sub>3</sub>	1.40%	H <sub>2</sub> O <sub>2</sub> + hv	0.52%	H <sub>2</sub> O <sub>2</sub> + hv	1.63%
Other	5.02%	Other	4.85%	Other	5.23%	Other	7.25%
Loss							
CO	19.91%	CO	23.39%	C <sub>5</sub> H <sub>8</sub>	15.96%	C <sub>5</sub> H <sub>8</sub>	15.38%
NO <sub>2</sub>	9.38%	C <sub>5</sub> H <sub>8</sub>	8.17%	CO	14.68%	CO	13.72%
C <sub>5</sub> H <sub>8</sub>	9.09%	C <sub>2</sub> H <sub>5</sub> CHO	7.44%	CH <sub>3</sub> CHO	8.76%	C <sub>2</sub> H <sub>5</sub> CHO	10.64%
C <sub>2</sub> H <sub>5</sub> CHO	7.96%	CH <sub>3</sub> CHO	6.97%	C <sub>2</sub> H <sub>5</sub> CHO	8.31%	CH <sub>3</sub> CHO	7.52%
CH <sub>3</sub> CHO	7.94%	NO <sub>2</sub>	6.27%	NO <sub>2</sub>	5.70%	HCHO	3.44%
CH <sub>4</sub>	3.68%	CH <sub>4</sub>	5.91%	CH <sub>4</sub>	3.04%	NO <sub>2</sub>	3.33%
HCHO	2.79%	HCHO	2.50%	HCHO	3.03%	CH <sub>4</sub>	3.06%
ACR	1.41%	O <sub>3</sub>	2.04%	ACR	1.65%	ACR	1.71%
HOCH <sub>2</sub> CHO	1.36%	H <sub>2</sub>	1.71%	HOCH <sub>2</sub> CHO	1.61%	HOCH <sub>2</sub> CHO	1.71%
Other	36.48%	Other	35.61%	Other	37.27%	Other	39.50%

3 Notes: The H<sub>2</sub> concentration were constrained as 550 ppb in the model simulation.

4 The H<sub>2</sub>O<sub>2</sub> were simulated by model with averaged concentration at 0.95 ppb.

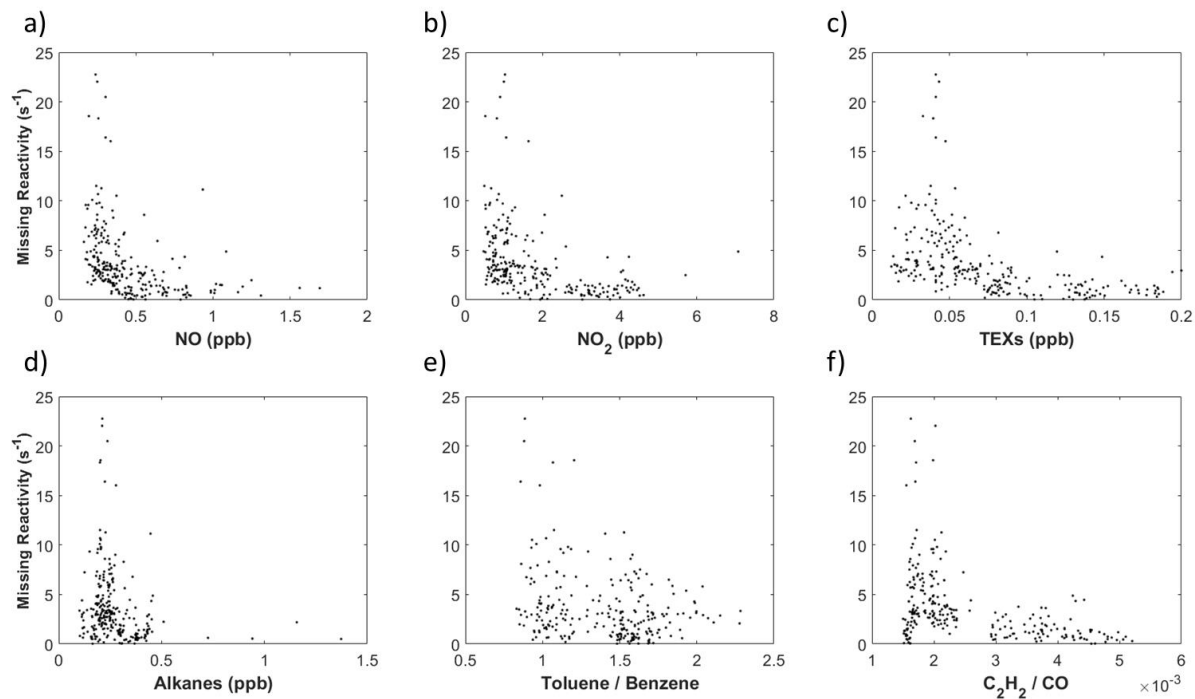

5 ACR- acrolein HCHO: Formaldehyde

6 C<sub>5</sub>H<sub>8</sub>: Isoprene HOCH<sub>2</sub>CHO: Glycolaldehyde

7 C<sub>2</sub>H<sub>5</sub>CHO: Propanol CH<sub>3</sub>CHO: Acetaldehyde

8 ME2BUT2ENE: 2-Methyl-2-butene DM23BU2ENE: 2,3-Dimethyl-2-butene

9 Other represents the group of the species contribute less than 2% to the total OH reactivities. Most of  
 10 them were the intermediate species produced by the reaction of OH with VOCs.

## 2 Notes:

3 ISOP: Isoprene.

- 1 AIOFM: Laser- induced fluorescence instrument by the Anhui Institute of Optics Fine Mechanics, Chinese Academy of Sciences.
- 2 Mean: Campaign average concentration or ratio.
- 3 Peak: Campaign maximum concentration or ratio.
- 4 Peaks (Mean): Maximum concentration or ratio for the averaged diurnal or averaged cases.
- 5 Mean (Range): Daily average concentration or ratio range for the campaign or cases.
- 6 Peaks (Range): Maximum concentration or ratio range for the campaign or cases
- 7 w/ and w/o: Considered or did not consider the specific mechanism, species, or interference.
- 8 ~: The result is based on the figure or description, and the exact number is not mentioned in the article.
- 9 N/A: Not available in the article
- 10 \*: The HO<sub>2</sub> result includes some RO<sub>2</sub> species.

## Calibration

The calibration was performed by applying the calibrator shown in Figure 3 to the CIMS. The calibration flow passes through the water bubbler and carries H<sub>2</sub>O. When the humid calibration flow is exposed to the Pen Ray mercury lamp (Analytik Jena, UVP Pen Ray), the OH radicals produced by H<sub>2</sub>O photolysis as shown below:

The OH concentration ([OH]) produced by the calibrator is calculated by SE1.

$$[OH] = [H_2O] * \sigma_{H_2O} * \Phi * It \quad (\text{SE1})$$

[H<sub>2</sub>O] is the water concentration in the calibration flow which is calculated from the temperature, saturated water vapor pressure, and relative humidity.  $\sigma_{H_2O}$  ( $= 7.14 \times 10^{-20} \text{ cm}^2$ ; (Cantrell et al., 1997) is the photolysis cross-section of water vapor, while  $\Phi$  represents the photolysis quantum yield and was assumed to be 1 (Kürten et al., 2012). The photon flux ( $It$ ) was determined using the chemical actinometry method. This method measures the mixing ratio of N<sub>2</sub>O and its photolysis products to determine the product  $It$  value of the lamp in the calibrator while the N<sub>2</sub>O photolysis and H<sub>2</sub>O photolysis require the same photon intensity (184.9 nm). The reactions and equations of  $It$  determination were presented by (Kürten et al., 2012). In this study, the  $It$  values were measured before and after the field campaign and no significant difference was found.

By calculating the [OH]<sub>CAL</sub> produced by the calibrator, the signal response to OH ( $TS_{97} - BS_{97}$ ), and reagent ion ( $S_{62}$ ), the calibration factor ( $C$ ) can be calculated by following the equation which was transformed from E1.

$$C = \frac{1}{[OH]_{CAL}} \times \frac{TS_{97} - BS_{97}}{S_{64}} \quad (\text{SE2})$$

## Detection limit

The detection limit can be calculated as follows,

$$DL = \frac{1}{C} \times \frac{n * \sigma_{BS97}}{S_{64}} \quad (\text{SE3})$$

Where DL is the detection limit in 10<sup>6</sup> molecule/cm<sup>3</sup>,  $C$  is the calibration factor, and  $n$  is the ratio of signal to noise S/N.  $\sigma_{BS97}$  represents the standard deviation of the signal intensity of HSO<sub>4</sub><sup>-</sup> at 97 m/z when the scavenger was added through front injectors, and  $S_{64}$  represents the

1 signal intensity of  $\text{NO}_3^-$  at 64 m/z. Figure 8 shows the concentrations of OH radicals and the  
2 corresponding detection limit (S/N=2, average time=6 minutes) in the laboratory. The detection  
3 limit was quite stable over the whole day and ranged from  $0.08$  to  $0.20 \times 10^6$  molecule  $\text{cm}^{-3}$ ,  
4 with an average value of approximately  $0.15 \times 10^6$  molecule  $\text{cm}^{-3}$ .

### 6 **Uncertainty calculation**

7 The uncertainty of the instrument is calculated by the rules for propagation for the uncertainty.

8 Propagation Rules for Addition ( $y = x_1 + x_2$ ): 
$$e_y = \sqrt{e_{x_1}^2 + e_{x_2}^2} \quad (\text{SE4})$$

9 Propagation Rules for Multiplication ( $y = x_1 \times x_2$ ): 
$$\frac{e_y}{y} = \sqrt{\left(\frac{e_{x_1}}{x_1}\right)^2 + \left(\frac{e_{x_2}}{x_2}\right)^2} \quad (\text{SE5})$$

10 Where  $e_y$ ,  $e_{x_1}$ ,  $e_{x_2}$ , are the absolute uncertainty for  $y$ ,  $x_1$ , and  $x_2$ .

### 12 **Calibration Uncertainties**

13 The calibration uncertainty is calculated by the uncertainties of all the parameters involved in  
14 the SE2 which includes the uncertainty of calculated OH radicals concentration and the  
15 precision of the measurements of signal at 64 m/z and 97 m/z. Due to the equation SE1, the  
16 uncertainty of OH radical ( $[\text{OH}]_{\text{CAL}}$ ) will further be contributed by the uncertainty of  $It \sim 36\%$ ,  
17  $\sigma_{\text{H}_2\text{O}}$  ( $\sim 5\%$ ),  $\phi_{\text{H}_2\text{O}}$  ( $< 1\%$ , Cantrell et al. 1997), and calculated water concentration based on the  
18 measured Temperature and relative humidity ( $\sim 10\%$ ). The precision of the measurements  
19 signal at 64 m/z and 97 m/z ( $\frac{TS_{97} - BS_{97}}{S_{64}}$ ) of the CIMS instrument ( $2\sigma$ ) was 11% (for 6 min  
20 integration time). Considering all the above uncertainties and calculated by the rules (SE3 and  
21 SE4), the overall uncertainty for the calibration factor can be calculated by the well-known  
22 uncertainty formula. The uncertainty for the calibration factor was about 38% in this study.

### 24 **Sensitivity optimization**

25 The sensitivity (S) of the CIMS instrument to the OH radicals depends on the conversion  
26 efficiency of OH to  $\text{H}_2\text{SO}_4$  in the chemical conversion region ( $E_{\text{Conv}}$ ), the ionization efficiency  
27 of  $\text{H}_2\text{SO}_4$  to  $\text{HSO}_4^-$  in chemical ionization region ( $E_{\text{Ion}}$ ), and the ion-transmitted efficiency of  
28  $\text{HSO}_4^-$  from sample inlet to mass spectrometer system ( $E_{\text{Trans}}$ ):

$$S \sim E_{\text{Conv}} \cdot E_{\text{Ion}} \cdot E_{\text{Trans}}$$

$E_{\text{Conv}}$  is dependent on the reaction time and the  $\text{SO}_2$  concentration of the conversion reactions (R1-3). However, the conversion time has to be relatively short ( $<1\text{s}$ ) to avoid the interference of  $\text{HO}_2$  recycling as mentioned by Berresheim et al. (2000).  $E_{\text{Ion}}$  is affected by the flow dynamics, which determines the mixing of flows, and the electric field inside the ionization region, which forces the  $\text{NO}_3^- \cdot (\text{HNO}_3)_m \cdot (\text{HO}_2)_n$  primary ions to the center of the region for  $\text{H}_2\text{SO}_4$  ionization.  $E_{\text{Trans}}$  is related to the  $\text{N}_2$  buffer and induces an electric field in the pinhole area. On the other hand,  $E_{\text{Trans}}$  is proportional to the transmission of the neutral molecule and particles from sampling air to the mass spectrometer system which deteriorates the measurement and damages the mass spectrometer. Thus, the optimization should take both transmission efficiency and protection function into consideration.

In this study, the CIMS was optimized before the field campaign. The detailed specification was shown in Table S1. To maximize the  $E_{\text{Conv}}$ , 5 sccm  $\text{SO}_2$  was added from the front injectors to the sample flow and the  $[\text{SO}_2]$  was around 12 ppm in the sample flow. The sample flow was 3727 sccm and the sample flow rate was 55 cm/s which means the reaction time for OH conversion is around 47 ms.

The reaction time affects the positive bias of OH arising from  $\text{HO}_2 + \text{NO}$  in the inlet. To estimate this bias, Tanner et al., (1997) calculated the OH produced by the  $\text{HO}_2$  recycling reaction under different NO conditions (from  $< 60$  ppt to 1-2 ppb) in the inlet by a box model. Their results showed that the positive bias of less than  $0.5 \times 10^6 \text{ cm}^{-3}$  with a 60 ms conversion time, and the bias does not increase with the increase of NO concentration. Thus, the conversion time of 47 ms in our study should further reduce such positive bias.

Compared to  $\text{C}_3\text{F}_6$ , propane ( $\text{C}_3\text{F}_8$ ) has a higher elimination rate. However, the purity of the  $\text{C}_3\text{F}_8$  from most of the suppliers is not high enough for elimination of the artificial OH, we thus chose  $\text{C}_3\text{F}_6$  due to its stable quality. These parameters taking the  $E_{\text{Conv}}$  and the  $\text{HO}_2$  interference mentioned above into consideration. Similarly, the sample/sheath flow ratio was adjusted to 0.3 and the voltages different between sample and sheath flow were adjusted to 48 V to achieve the maximum  $E_{\text{Ion}}$ . Finally, the buffer flow was 440 sccm and the Pinhole voltage difference was 30 V for a better  $E_{\text{Trans}}$  and to prevent neutral molecules enter the mass

1 spectrometer system as the same time.

1 Notes:

2 The concentration unit is presented in the bracket in the 'Species Abb.'.

3 The unit for other species is in ppb.

4 \* Species measured by GC-MS and constrained by the model

5 \*\* Species measured by PTR-MS and constrained by mode.

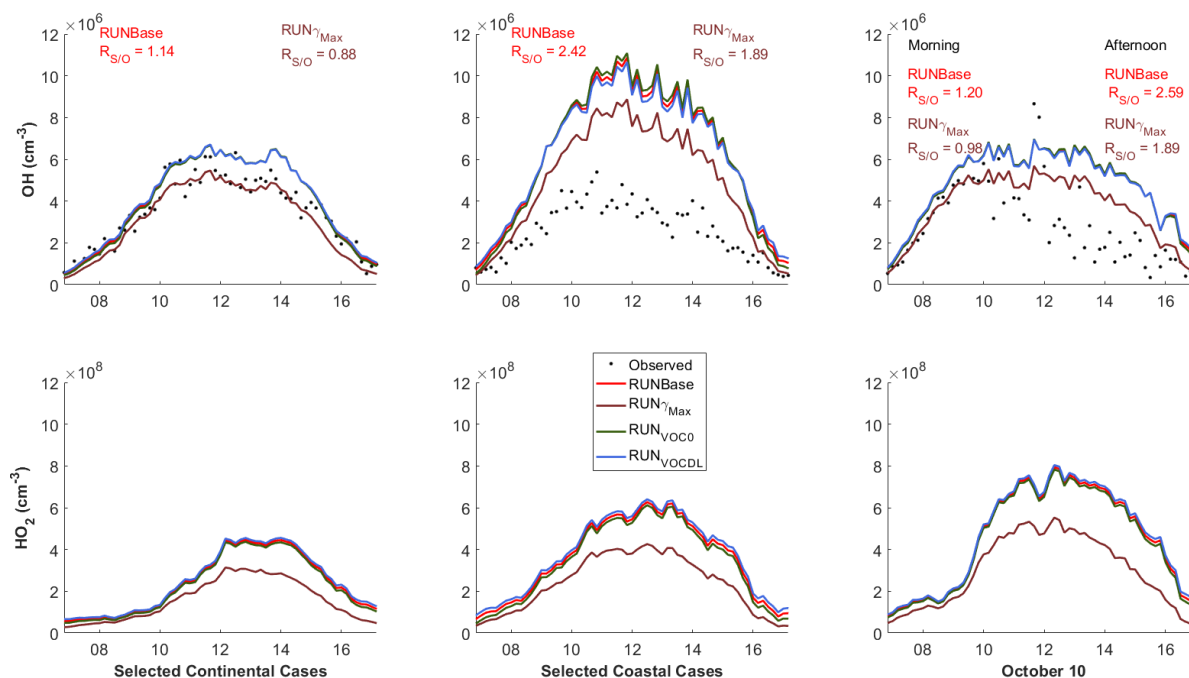

6 † Species measured by instrument specified in Table 1.

7 & Different VOCs functional groups.

8

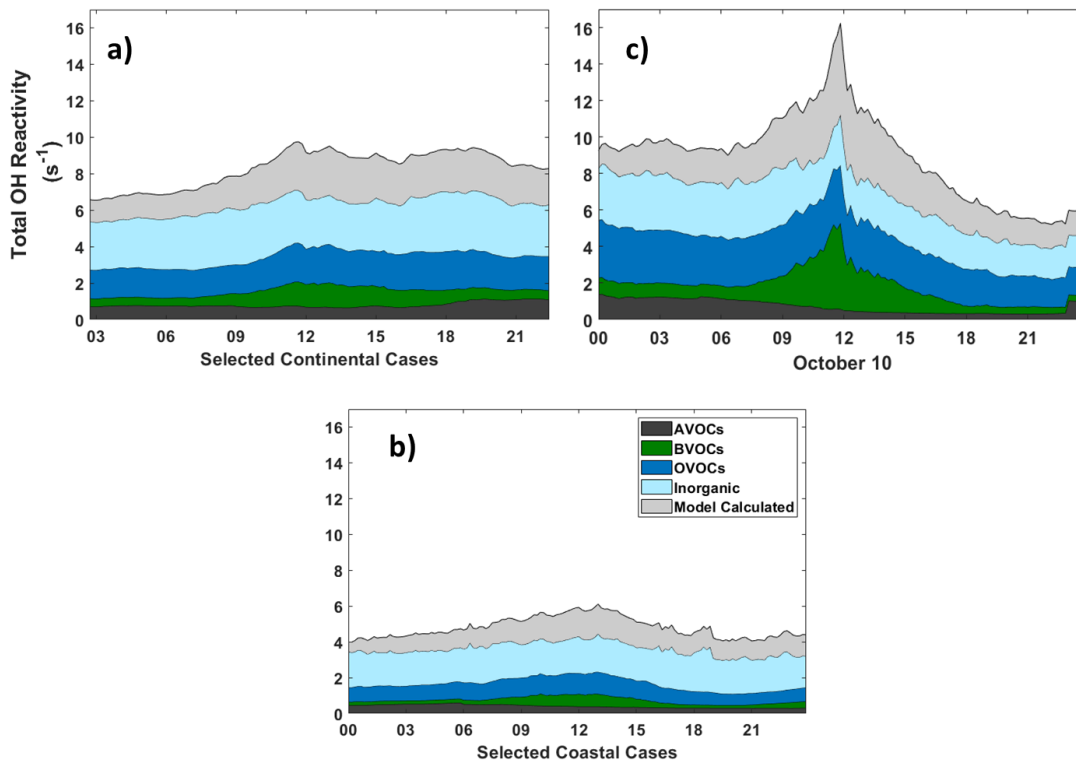

1  
 2 Figure S3. OH radical budgets for the continental cases, coastal cases, and 10 October. Where  
 3 DM23BU2ENE and ME2BUT2ENE represent 2,3-Dimethyl-2-butene and 2-Methyl-2-butene  
 4 respectively.

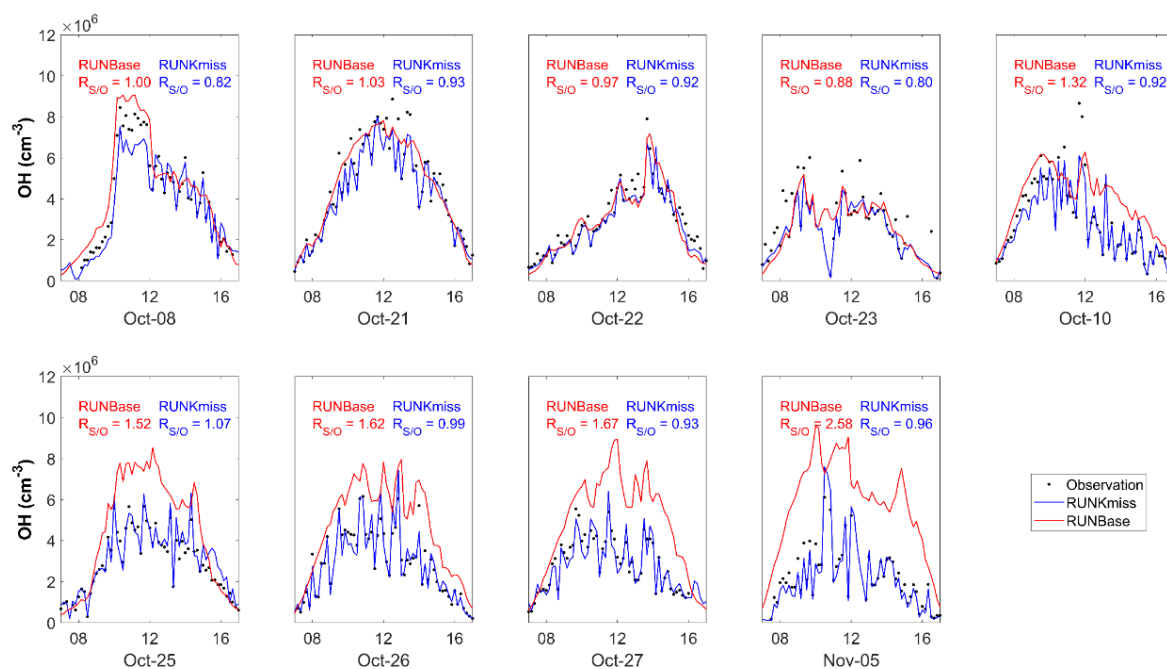

6  
 7 Figure S4. Sensitivity tests for the simulated OH and HO<sub>2</sub> in continental and coastal cases and on 10  
 8 October. RUN<sub>γMAX</sub> shows the simulated results for the maximum heterogeneous uptake effect of HO<sub>2</sub>  
 9 ( $\gamma = 1$ ). The RUN<sub>VOC0</sub> and RUN<sub>VOCDL</sub> show the simulated results that constraints "0" and the detection

1 limit value as the concentration of VOCs when their concentration were below detection limits.

2  
3 Figure S5. Simulated reactivity for continental cases (a), coastal cases (b), and 10 October (c). The  
4 AVOCs, BVOCs, OVOCs, and Inorganic demonstrates the reactivity calculated from the measured  
5 species and the Model Calculated represents the reactivity calculated by the derived species simulated  
6 by model.

7

8

1 **Figure S6.** Nine-day comparison between observed OH and simulated OH with (RUNBase) and without  
2 (RUNKmiss) addition reactivity.
