11 **Abstract.** Frozen layers within the subsurface of rock glaciers are generally assumed to act as aquicludes or aquitards. So far,
12 this behavior has been mainly defined analyzing the geochemical characteristics of spring waters. In this work, for the first
13 time, we experimentally confirmed this assumption by executing an infiltration test in a rock glacier of the Southern Alps,
14 Italy. Time-lapse electrical tomography (ERT) technique was adopted to monitor the infiltration of 800 liters of salt-water
15 spilled on the surface of the rock glacier. 24 hours ERT monitoring highlighted that the injected water was not able to infiltrate
16 into the underlying frozen layer.

17 1 Introduction

18 In alpine regions, groundwater originating from moraines and rock glaciers is highly contributing to the streamflow (Wagner
19 et al. 2016). Therefore, a key factor in the hydrological modeling of alpine catchments is the determination of the hydraulic
20 properties of these landforms. The subsoil hydrodynamic of moraines, talus and hillslope aquifers is relatively well known,
21 but the hydraulic behavior of rock glaciers and their impact on the hydrology of alpine catchments are relatively less defined
22 (Pauritsch et al., 2017 and references therein). The hydrological and the geochemical monitoring of spring waters emerging
23 downslope of active rock glaciers have been used to investigate runoff processes, the presence and role of frozen layers in
24 alpine catchments (e.g., Krainer et al., 2007; Carturan et al., 2016). In active or ice-rich intact rock glaciers, continuous frozen
25 layers are typically considered as aquicludes (Giardino et al., 1992). Krainer et al. (2007) separated a subsurface flow
26 component, derived from snow-ice melting and rainwater, and a deeper and longer stored aquifer at the bottom of Reichenkar
27 active rock glacier (Austrian Alps). Harrington et al. (2018) defined the inactive Helen Creek rock glacier (Alberta, Canada)
28 as an unconfined aquifer, as the limited ground ice distribution is unlikely to act as a pure aquiclude. These investigations
29 suggest that rock glaciers host complex and heterogeneous aquifers with a layered internal structure. Nevertheless,
30 geochemical surveys have not the ability to accurately define the aquifer's structure (e.g., layers thickness, discontinuities, and
31 lateral/vertical heterogeneities) if not integrated with geophysical surveys.

32 To verify and confirm the hydraulic behavior of the frozen layer, an infiltration experiment combined with electrical resistivity
33 tomography (ERT) time-lapse measurements has been performed on the Sadole rock glacier (Southern Alps, Italy). Controlled
34 irrigation experiments combined with ERT time-lapse measurements were successfully applied to study the vadose zone
35 (Cassiani et al., 2006), or rarely in more challenging hillslope catchments (Cassiani et al., 2009). The Sadole rock glacier
36 infiltration experiment represents the first attempt to adopt this monitoring technique to the mountain permafrost environment
37 and, considering the promising results, can be used as reference to improve future tests and better characterize the hydraulic
38 properties of the frozen subsoils.

39 **2 Site description**

40 The Sadole rock glacier is located in the Sadole Valley, in the Eastern part of the Trento Province (North-East Italy, Fig.1A).
41 The rock glacier ranges between 1820 m a.s.l. and 2090 m a.s.l. and it is a complex periglacial landform that derives from the
42 confluence of three different lobes (Fig.1B). This periglacial landform occupies the floor of two coalescent glacial cirques.
43 Steep rock walls and sharp crests almost entirely bound these cirques, with the exception of the Sadole Pass that was likely a
44 glacial transfluence saddle during the last glaciation. Slope deposits are found between the rock walls and the rock glacier
45 rooting areas. These deposits have gravitational or mixed gravitational/debris-flow/avalanche origin and are predominantly
46 active. From a geological point of view, the rock glacier is composed of magmatic rocks (riodacitic ignimbrites) that belong
47 to the Athesian Volcanic Group, a late-Paleozoic (Permian) volcanic succession. The Sadole rock glacier has been classified
48 as ‘relict’ in the inventory of Trento Province (Seppi et al., 2012), in agreement with the guidelines provided by the IPA Action
49 Group (RGIK, 2022). Despite this, the general convex morphology and the low water temperature of its spring, ranging
50 between 1.0 and 1.8°C in the ablation season, suggested that this rock glacier may preserve permafrost (Carturan et al., 2016
51 and references therein). In addition, ice outcrops have been observed in mid-summer two meters below the surface, in a pit
52 dug during the 1st World War (green dot in Fig.1B). Therefore, several ERT transects (blue, violet, and brown lines in Fig.1B)
53 have been collected in summer 2021 on the rock glacier, confirming the presence of a discontinuous frozen layer (see “deep”
54 high resistivity areas in Figs.1D-E). Soil temperature sensors (red dots in Fig.1B) have been installed in different location of
55 the rock glacier bodies. Finally, to evaluate the hydraulic behavior of the frozen layer, an infiltration experiment with ERT
56 time-lapse measurements has been realized in middle June 2022. The ERT monitoring transect (red line in Fig.1C) has been
57 located in the same area of the ERT surveys 2021, considering the maximum slope gradient, and specifically settled to detect
58 how the injected water flows in the area where the frozen layer is present, and how it flows where the frozen layer ends.

59 **3 Methods**

60 **3.1 Experiment principles**

61 ERT surveys are performed to detect the electrical properties of the ground. The method can be used for monitoring time-
62 dependent subsurface processes by repeating periodically the measurements using the same electrode array (Binley, 2015).
63 This ERT data acquisition method is defined as “ERT time-lapse technique”, and can be performed with controlled irrigation
64 experiments (Cassiani et al., 2006; Cassiani et al., 2009). In these tests, a large amount of salt-water is released into the subsoil
65 system, and the propagation of the injected water is investigated using the ERT time lapse survey. An ERT dataset is collected
66 before the injection, at a time called time zero (t_0). Subsequently, as the salt water propagates into the ground, new datasets
67 are periodically acquired at defined time steps (t_1, t_2, \dots, t_n). The changes of electrical properties in the subsoil, due to the
68 injected water flow, are usually not clearly highlighted by comparing the individual inverted resistivity models. To enhance
69 the variation from one-time step to the next, only the inverted model t_0 is represented in terms of absolute resistivities, while
70 the other time steps are plotted in terms of percentage variations of resistivity with respect to the t_0 model (Binley, 2015).

71 **3.2 Data acquisition**

72 An ERT survey line of 72 electrodes, spaced 1.5 meters from each other (total length of 106.5 meters), has been centered with
73 respect to the discontinuous frozen layer detected in ERT surveys 2021. The injection point has been placed in the middle of
74 the array. The measurements have been performed with a Syscal Pro georesistivimeter (Iris Instruments), using a dipole-dipole
75 configuration with different skips (1, 3, 5 and 7 - the skip represents the number of electrodes skipped to create a dipole), and
76 a stacking range between 3 and 6 with 5% error threshold. The chosen configuration allowed to collect direct and reciprocals
77 measurements and to estimate a reliable experimental error for the acquired datasets (Binley, 2015). The position,
78 characteristics of the survey line, and the acquisition scheme, were defined to better highlights the flow of the injected water.

79 The chosen array in fact guarantees a good resolution in the shallower part of the subsurface thanks to the relatively short
80 spacing and low skips but at the same time a large penetration thanks to the total length of the array and higher skips.
81 Furthermore, a very large number of measuring points (2594) have been acquired to increase the possibility of detecting
82 resistivity variations in the subsurface due to water flow. Thanks to this high number of measured points, the characteristics
83 of the array, and the acquisition scheme, we tried to increase the reliability of our models even in areas where the sensitivity
84 is notoriously low (e.g. the bottom and the edges, Binley, 2015).

85 The ERT data quality in rock glacier environments is usually low due to the high contact resistances between electrodes and
86 boulders (Hauck & Kneisell, 2008). To partially overcome this problem, and increase the amount of injected current (Pavoni
87 et al., 2022), we inserted the electrodes between the boulders using sponges soaked with saltwater (Fig.2A). The sponges have
88 been wetted at the beginning of each measurement during the ERT time lapse survey, to reach (approximately) homogeneous
89 contact resistances for each collected dataset. Collecting measurements with different contact resistances could lead in fact to
90 changes in resistivity models not linked to the flow of the injected water.

91 The water for the experiment has been collected during the previous months, using ten 100-liter bins. The bins have been
92 placed on the Sadole rock glacier, in the point selected for the water injection, in the early spring, when snow cover was still
93 present (Fig.B). They were filled with snow and covered with nylon sheets pierced at their center to collect rainwater. This
94 way, in mid-June the bins were completely filled with a mixture of snowmelt and rainwater. Before the experiment, 3 kg of
95 NaCl were added to each bin to obtain a salt-water solution. After collecting the t_0 dataset, 8 bins were emptied one after the
96 other, injecting 800 liters of salt-water into the subsurface system (Fig.2C). Four datasets have been acquired in the first hour,
97 followed by four datasets at hourly intervals, and a last dataset collected 24 hours after water injection. No rain or uncontrolled
98 water contribution happened during the experiment.

99 **3.3 Data processing**

100 The acquired datasets have been filtered removing quadrupoles with a stacking error higher than 5%, and a reciprocal error
101 higher than 20%. Only the common quadrupoles saved in all the filtered datasets have been used to perform the inversion
102 process of each dataset. The inversion modeling has been performed using the Python-based software ResIPy (Blanchy et al.,
103 2020), and an expected data error of 20% has been set according to the reciprocal check (Binley, 2015). Once a common
104 unstructured triangular mesh has been created, all the acquired datasets have been independently inverted. Only the t_0 initial
105 model was plotted in terms of absolute electrical resistivity values (logarithmic scale), while the other models (t_n) obtained
106 with the ERT time-lapse survey were plotted as percentage variations in resistivity compared to the initial model t_0 . In order
107 to avoid emphasizing changes in the high resistivity zone, the percentage changes in resistivity were calculated using
108 logarithmic values. Since we defined an expected data error of 20%, tiny resistivity changes in the inverted tomograms are
109 considered not reliable to highlights the flow of the injected water. Therefore, in the time-lapse models, negative resistivity
110 variations lower than 10% are plotted in light gray color. Finally, to detect the frozen layer boundary in t_0 model, we applied
111 the steepest gradient method (Chambers, 2012). This method, as suggested by forward modeling analysis, is the most reliable
112 to evaluate the thickness of the active layer (Herring et al., 2022).

113 **4 Results**

114 Figure 3A shows the resistivity section at t_0 . The high resistivities ($\rho > 30 \text{ k}\Omega\text{m}$) close to the surface are linked to the voids
115 among coarse debris and blocks, typical in rock glacier environments (Hauck and Kneisel, 2008). Below the top high resistivity
116 layer, lower values of resistivity ($\rho < 10 \text{ k}\Omega\text{m}$) are found and can be associated with a decrease in porosity and grain size of the
117 deposit, and a possible increase in humidity. At the south-west and north-east edges of the section this low resistivity layer
118 reaches the bottom of the model. On the other hand, in the central part of the model ($30 < x < 70 \text{ m}$) a clear change is detected at
119 a depth of about 10 meters. Below this boundary, the resistivity rapidly increases ($\rho > 50 \text{ k}\Omega\text{m}$), highlighting the presence of a

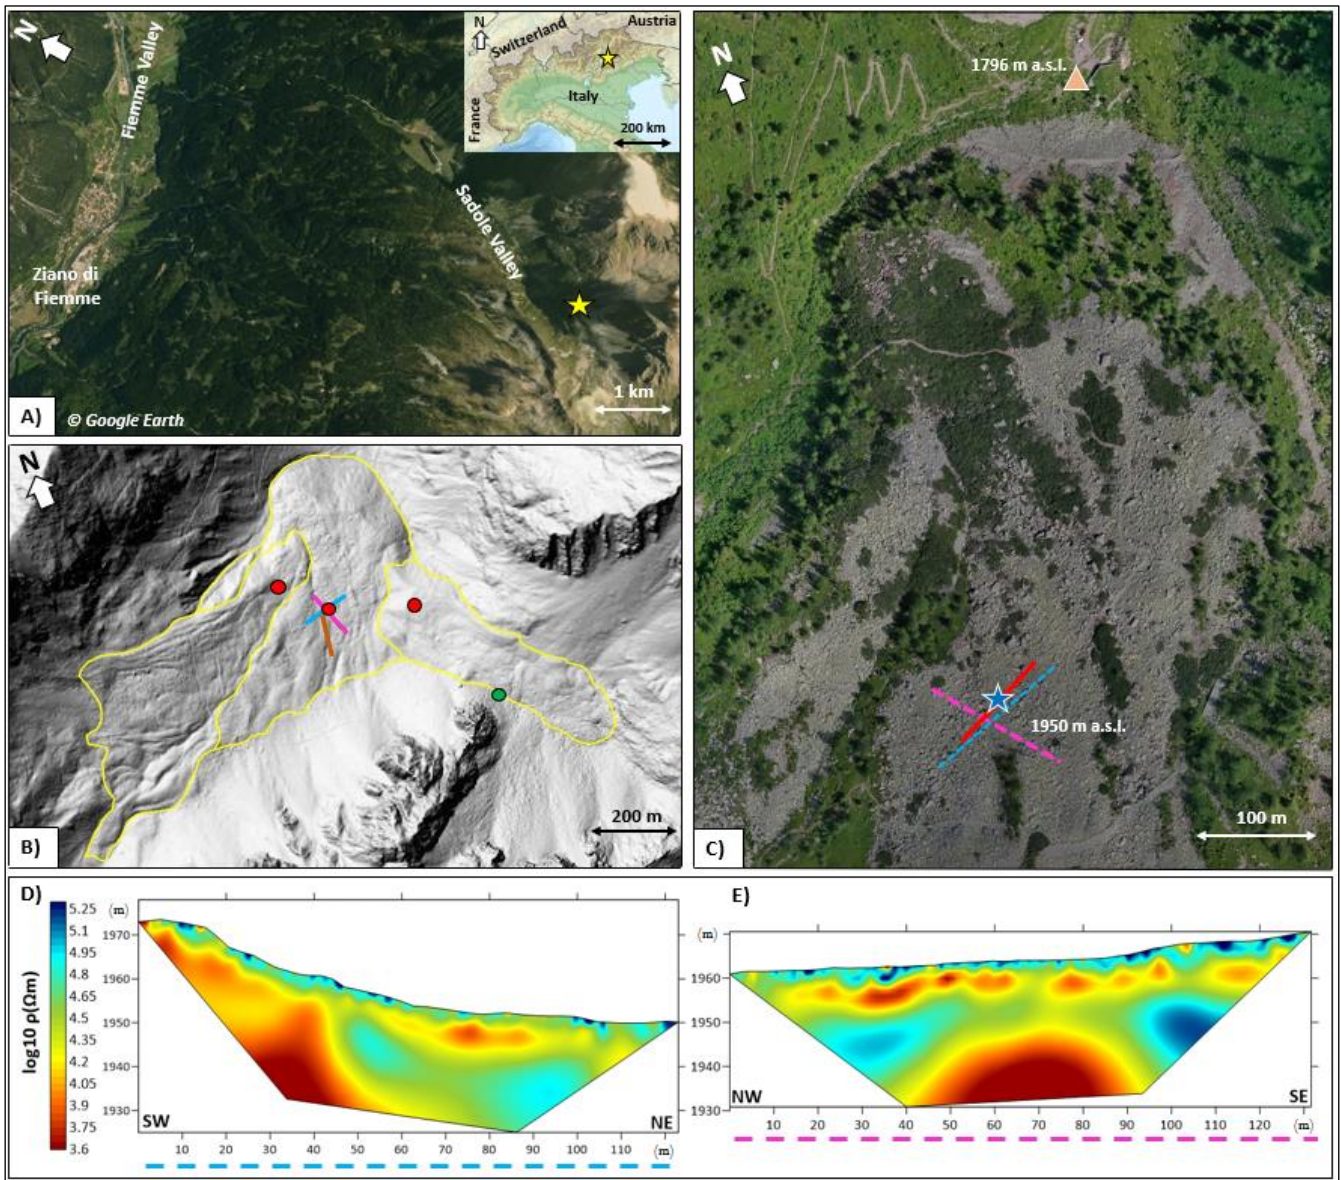

120 frozen layer (Hauck and Kneisell, 2008). By applying the steepest gradient method in the vertical direction, we defined 55
121 $k\Omega m$ as the upper boundary of the permafrost layer and the same value has been used to define its lateral termination.
122 In Fig. 3B high negative resistivity variations ($>20\%$) show a quick vertical infiltration of the injected water up to a depth of
123 10 meters within the first 15 minutes after the injection. This wet area persisted below the injection point until the last survey
124 t_{10} (Fig.3M), even if it seems to slowly shrink from one data acquisition to the next. Negative resistivity variations in Figs.
125 3B-E indicate a downslope subsurface flow in the north-east direction above the identified frozen layer. Where the frozen layer
126 ends ($x \approx 70$ m), the water clearly appears to be able to propagate deeper vertically. Concerning the upslope area ($x < 30$ m),
127 the negative resistivity variations are found from the surface to the bottom of the section until t_4 (Fig.3B-3F), highlighting a
128 main initial vertical infiltration of the injected water. In the following time steps the negative values develop mainly at few
129 meters of depth (Figs. 3F-3L), indicating a possible anomalous upslope subsurface flow (south-west direction). These negative
130 variations, upslope of the injection area, are still present after 24 hours (t_{10} , Fig. 3M). but, at the same time, the water still
131 flows downslope in the north-east direction. On the other hand, inside the defined frozen layer negative resistivity variations
132 are practically null, suggesting that the injected water did not propagate through it.

133 **4 Discussion and conclusions**

134 High negative resistivity variations ($>20\%$) observed for t_1 close to the injection area indicate a rapid vertical infiltration of
135 the water due to the presence of boulders, fractures and coarse sediments with high vertical permeability. The large amount of
136 injected water has probably saturated this area, which has become the source of the subsurface flow. Although we do not have
137 any measurements of saturated hydraulic conductivity, we can speculate that hydraulic conductivities may be much higher (in
138 the order of 10^{-2} m/s) than the ones observed in shallow soil layers of young moraines, as found in the Swiss Alps by Maier et
139 al. (2021). Subsurface flow, moving downslope along the north-east direction, is likely originated at the boundaries between
140 large boulders and a finer sediment. This layer is in fact characterized by lower resistivities (in t_0 $\rho < 10$ $k\Omega m$) compared to the
141 shallower depths, and has likely lower permeability. Nevertheless, the presence of large boulders at various depths can lead to
142 funnel flow, and/or splitting of flow paths (Hartmann et al., 2020), which may have determined the infiltration of some injected
143 water upslope (south-west direction) the injection point. From t_1 to t_5 the negative resistivity variations suggest almost a
144 continuous subsurface flow in the north-east direction along the maximum slope gradient, whereas from t_6 to t_{10} local negative
145 resistivity variations indicate the accumulation of injected water in areas where there is a likely local decrease in permeability,
146 and water may reside there for a longer period.

147 The experiment confirms the assumption that a continuous permafrost layer can act as an aquiclude (Giardino et al., 1992;
148 Krainer et al., 2007) or, if it discontinuous as in the Sadole rock glacier, as an aquitard (Harrington et al., 2018). Furthermore,
149 the survey confirms the reliability of the steepest gradient method to define the boundary of the frozen layer, and the high
150 heterogeneities (vertical and lateral) in mountain permafrost subsurface, as recently highlighted from continuous core drilling
151 by Phillips et al. (2023). Due to these high heterogeneities, a quantitative analysis regarding hydraulic conductivity just via
152 time-lapse ERT monitoring is very challenging. As highlighted by Mewes et al. (2017) with synthetic analysis and seasonal
153 field measurements, it is unrealistic to define the flow paths of water in mountain permafrost subsurface just via resistivity
154 changes in tomograms. Moreover, the sampling step of the ERT datasets is forced by the necessary acquisition time and may
155 be too large, especially in the initial phases. In our case, due to logistical problems (adverse weather), it was not possible to
156 extend the survey measurements for the time necessary to return completely to the pre-injection conditions.

157 Future development of the current work is to perform the experiment in an active rock glacier during late summer, in order to
158 test the flow paths with a fully developed active layer, collecting datasets with a shorter sampling step and for a longer period,
159 until the subsurface system returns completely to the pre-injection conditions. In this way, a possible estimation of the active
160 layer average hydraulic conductivity could be achieved.
