**Abstract.** Anthropogenic emissions of methane (CH<sub>4</sub>) have made a considerable contribution towards the Earth's changing radiative budget since pre-industrial times. This is because large amounts of methane are emitted from human activities and the global warming potential of methane is high. The majority of anthropogenic fossil methane emissions to the atmosphere originate from a large number of small (point) sources. Thus, detection and accurate, rapid quantification of such emissions is vital to enable the reduction of emissions to help mitigate future climate change. There exist a number of instruments on satellites that measure radiation at methane-absorbing wavelengths, which have sufficiently high spatial resolution that can be used for detecting plumes of highly spatially localised methane 'point sources' (areas on the order of m<sup>2</sup> to km<sup>2</sup>). Searching for methane plumes in methane-sensitive satellite images using classical methods, such as thresholding and clustering, can be useful but

27 are time-consuming and often involve empirical decisions. Here, we develop a deep neural network to identify  
28 and quantify methane point source emissions from hyperspectral imagery from the PRekursore IperSpettrale della  
29 Missione Applicativa (PRISMA) satellite with 30-m spatial resolution. The moderately high spectral and spatial  
30 resolution, as well as considerable global coverage and free access to data, make PRISMA a good candidate for  
31 methane plume detection. The neural network was trained with simulated synthetic methane plumes generated  
32 with the Large Eddy Simulation extension of the Weather Research and Forecasting model (WRF-LES), which  
33 we embedded into PRISMA images. The deep neural network was successful at locating plumes with F1-score,  
34 precision and recall of 0.95, 0.96 and 0.92, respectively, and was able to quantify emission rates with a mean error  
35 of 24%. The neural network was furthermore able to locate several plumes in real-world images. We have thus  
36 demonstrated that our method can be effective in locating and quantifying methane point source emissions in near  
37 real time from 30-m resolution satellite data which can aid us in mitigating future climate change.

## 38 **1 Introduction**

39 Methane (CH<sub>4</sub>) is a powerful greenhouse gas with a warming potential which per unit mass emitted is 84 times  
40 larger than for carbon dioxide over a 20-year period (Stocker et al., 2013). Emissions of methane as a result of  
41 human activities have contributed one quarter of climate warming since preindustrial times (Etminan et al., 2016).  
42 A large proportion of anthropogenic methane from industrial sources originates from point sources such as coal  
43 mines and oil and gas production facilities (Saunio et al., 2020). Furthermore, these emissions are generally  
44 underestimated by inventory-based approaches (Alvarez et al., 2018; Karion et al., 2013; Zavala-Araiza et al.,  
45 2015). A large proportion of these anthropogenic emissions originates from a small number of strong point sources  
46 due to oil and gas production equipment malfunction (Brandt et al., 2016; Duren et al., 2019; Zavala-Araiza et al.,  
47 2017). Consequently, much of the methane emitted from such sources could be reduced at no net cost (IEA, 2017;  
48 Ocko et al., 2021). Acting to reduce methane emissions in this sector can be one of the most cost-effective methods  
49 of mitigating against further climate change.

50  
51 Methane point sources from oil and gas production are typically small in extent and emissions difficult to quantify  
52 and variable in time (Allen et al., 2013; Frankenberg et al., 2016; Cusworth et al., 2021). The primary challenge  
53 faced when estimating methane emissions from point sources from satellite data comes from the relatively low  
54 spatial resolution (in the order of kilometres) of satellite imagery from dedicated sensors such as the Greenhouse  
55 Gases Observing SATellite (GOSAT) (Kuze et al., 2009) and the TROPOspheric Monitoring Instrument  
56 (TROPOMI) (Levelt et al., 2006). These sensors typically have high spectral resolution of methane absorption  
57 bands in the shortwave infrared (SWIR) range of the electromagnetic spectrum to provide accurate measurements  
58 with high precisions of around 10-20 parts per billion (ppb) (Lorente et al., 2021; Parker et al., 2020). SWIR bands  
59 can also be effectively utilised to detect and quantify point sources from lower spectral-resolution sensors (Jacob  
60 et al., 2016; Duren et al., 2019). Recent hyperspectral spaceborne imaging spectrometers contain hundreds of  
61 spectral channels in the visible-shortwave-infrared range with spectral resolution typically around 10 nm and  
62 spatial resolutions of tens of m. Due to their spatial and spectral resolution, they have been identified as useful  
63 new tools for identifying and quantifying methane point source emissions. PRekursore IperSpettrale della  
64 Missione Applicativa (PRISMA), developed and operated by the Italian Space Agency (ISA) since 2019, is the

65 first hyperspectral mission where the satellite imagery has been openly released to the scientific community. The  
66 satellite consists of a panchromatic camera and an advanced hyperspectral instrument that measures radiances in  
67 approximately 250 bands between 400 and 2500 nm. The instrument has a spatial resolution of 30 m, a swath of  
68 30 km, and a 12-nm spectral resolution (Galeazzi et al., 2008). PRISMA has been successful in quantifying CO<sub>2</sub>  
69 emissions from coal and gas-fired power plants (Cusworth et al., 2021a). However, how to best extract information  
70 on the location and extent of methane plumes is not yet fully established. Successful detection of methane point  
71 sources from PRISMA using a matched-filter retrieval technique has been reported by Guanter et al. (2021), albeit  
72 with a strong dependence of detection accuracy on surface type. In particular, brightness and homogeneity of the  
73 satellite images were identified to significantly influence the accuracy of methane detection techniques.

74

75 Current approaches for detecting methane point sources and quantifying emission rates are time-intensive,  
76 laborious, and can be prone to errors without sufficient training. They typically involve a spectral analysis of  
77 satellite data to infer methane column mean mixing ratios (Thorpe et al., 2014) followed by a methane plume  
78 detection method (often based on thresholding and clustering) and finally the integrated mass enhancement (IME)  
79 method to estimate the emission (Varon et al., 2018). Previous efforts utilising spaceborne imaging spectrometers  
80 to quantify methane point source emission rates have proved successful, but often with large errors of source  
81 detection and emissions estimates. The IME method yielded errors between 5-12% using 50-m resolution  
82 Greenhouse Gas Satellite - Demonstrator (GHGSat-D) imagery (Varon et al., 2018). However, this uncertainty  
83 estimate does not include errors from unknown wind speed and direction, which are both highly uncertain, where  
84 uncertainties are estimated to be 15-65% larger. The multi-band multi-pass (MBMP) method was successful in  
85 quantifying methane point source emissions from Sentinel-2 multispectral instrument (MSI) imagery with  
86 precision between 30% and 90% (Varon et al., 2021). The primary limitation of this approach is surface  
87 interference (Cusworth et al., 2019) which leads to artefacts and false anomalies, which can be mistakenly  
88 attributed to emission plumes. This is a major disadvantage for multi and hyperspectral missions because the  
89 better the resolution (and the greater the number of channels), the better the discrimination between the surface  
90 and methane absorption. Sherwin et al., (2023) found comparatively lower errors, but required considerable  
91 human intervention. Thus, producing a model that minimises errors and can automatically locate methane sources  
92 would make emission monitoring from space faster, more reliable, and more scalable, thus providing an invaluable  
93 tool to aid mitigation. A first effort has also been made to estimate emission rates from AVIRIS-NG data using a  
94 neural network and without utilising wind speed and direction data. These estimates were subject to an error of  
95 roughly 30% of the emission rates (Jongaramrungruang et al., 2019). It is apparent that the noise in the satellite  
96 data, the lack of accurate wind data, and the complex structures of methane plumes make it difficult to model  
97 emission rates accurately via traditional approaches.

98

99 In recent years, deep neural network methods have improved rapidly. LeNet (Lecun et al., 1989) was one of the  
100 earliest convolutional neural networks (CNNs) and was used successfully to identify handwritten digits. This work  
101 laid the foundations for using artificial intelligence to obtain meaningful information from image data (known as  
102 *computer vision*). Deep learning models entered the mainstream following considerable reductions in model  
103 training time through the utilisation of graphics processing units (GPUs) (Oh and Jung, 2004). Deep learning was  
104 then revolutionised for image classification with the introduction of AlexNet (Krizhevsky et al., 2012). CNNs

105 have since been applied to self-driving cars (e.g., Nugraha and Su, 2017), discovering new drug treatments (e.g.  
106 Wallach et al., 2015), facial recognition (e.g. Matsugu et al., 2003), and many other applications. The ease with  
107 which deep neural networks can be trained and deployed has also improved considerably in recent years, partially  
108 due to the development of application programming interfaces (APIs) such as Keras (Chollet, 2015). This has  
109 been supplemented by the increasing ubiquity and decreasing costs of GPUs and cloud computing servers, which  
110 together have enabled deep learning models to be trained rapidly and at a relatively low cost. Currently, work  
111 utilising deep neural networks has already proven to be considerably more effective than classical methods to  
112 detect point source emissions of nitrogen dioxide (NO<sub>2</sub>) (Finch et al., 2021).

113

114 More recently, a deep neural network has been used to quantify methane point source emissions using the airborne  
115 AVIRIS-NG instrument (Jongaramrungruang et al., 2022). In this study, a CNN was trained on synthetic plumes  
116 inserted into real images to extract features present in plumes of varying intensities and with differing wind speeds  
117 to locate and quantify the emission rates of the point sources. Jongaramrungruang et al. (2022) estimated emission  
118 rates of plumes with a mean absolute error of 17% for emissions larger than 40 kg hr<sup>-1</sup>. The classification accuracy  
119 (determining whether a plume is present in an image) was 90% when testing plumes with emission rates above  
120 100 kg hr<sup>-1</sup>, however, the accuracy dropped to 50% for emission rates around 50-60 kg hr<sup>-1</sup>. The spatial and spectral  
121 resolution of the aircraft data used in this study (AVIRIS-NG) has far higher spatial and spectral resolution than  
122 PRISMA, thus making methane detection prone to lower errors. However, PRISMA data is publicly available and  
123 covers a far larger spatial range with regular repeat measurements, thus making it a superior resource for rapid  
124 detection of methane point source emissions across many regions on earth. Thus, a deep neural network that is  
125 capable of utilising PRISMA data to detect methane emissions could be very effective in our efforts to mitigate  
126 future climate change.

127

128 In this study, we produced pseudo-observations of simulated synthetic methane plumes generated with the Large  
129 Eddy Simulation extension of the Weather Research and Forecasting model (WRF-LES). These simulated plumes  
130 were then embedded into an array of PRISMA images and used as training data for a novel neural network  
131 architecture that aimed to produce masks of the locations of methane plumes and estimate their emission rates  
132 from PRISMA satellite imagery. The effectiveness of this model was then tested on images of real-world plumes.  
133 The results from the neural network were then compared with a classical technique that combined PCA-based  
134 retrievals with clustering using DBSCAN. The techniques utilised here can be adapted to locate and quantify  
135 emission rates using any satellite imagery with suitable shortwave-infrared bands, or applied to detecting other  
136 greenhouse gases, such as carbon dioxide (CO<sub>2</sub>).

## 137 **2 Methods**

### 138 **2.1 Simulating methane plumes with WRF-LES**

139 The Weather Research and Forecasting (WRF) model system has comprehensive and multiple capabilities for  
140 studying atmospheric phenomena from global down to large eddy scales. The default large eddy simulation case  
141 (LES) of the WRF V4.2.2 was used and modified to simulate methane plumes for a single point source with a  
142 releasing rate of 1000 kg hr<sup>-1</sup>. The default LES case does not consider clouds, radiation, or topography, but

143 includes surface physics and 1.5-order TKE (Turbulent Kinetic Energy) prediction scheme (WRF model User's  
144 Guide: <https://www2.mmm.ucar.edu/wrf/users/>). A constant thermal flux of  $100 \text{ W m}^{-2}$  was applied at the surface  
145 to drive the turbulence. Two nested domains with one-way nesting were deployed in the simulations. The outer  
146 domain had a size of  $5.4 \text{ km} \times 6.3 \text{ km}$  with  $90 \text{ m}$  horizontal resolution and periodic boundary conditions. The  
147 inner domain had a size of  $3.6 \text{ km} \times 4.5 \text{ km}$  with  $30 \text{ m}$  horizontal grid spacing and  $30 \text{ m}$  vertical resolution, and  
148 flow-dependent boundary conditions for scalars. The plume was only released in the inner domain after a 3-hour  
149 spin-up run. The total running time is 5 hours, and the final 2-hour run was considered for the training, test, and  
150 validation data.

151

152 We designed 15 scenarios consisting of 5 different southerly wind speeds ranging from  $1 \text{ m s}^{-1}$  to  $9 \text{ m s}^{-1}$ , each of  
153 which was uniformly applied from the surface to the model top, and 3 different patterns of potential temperature  
154 vertical profiles (Figure S1). The potential temperature in the scenarios is specified as  $290 \text{ K}$  from the surface to  
155 one of the 3 different mixing depths of  $500 \text{ m}$ ,  $800 \text{ m}$ , and  $1100 \text{ m}$  (Figure S2). Above the mixing depth, there is  
156 an inversion layer of  $700 \text{ m}$  with a vertical gradient of potential temperature of  $0.009 \text{ K m}^{-1}$  applied from the top  
157 of the mixing layer to the model top. For each simulation, the  $\text{CH}_4$  distribution is saved once every minute and  
158 thus there are 120 different scenes for a two hour simulation. Altogether there are 1800 scenes for the 15  
159 simulations in the data, where the plume was integrated over vertical columns. Figure 1 shows one snapshot of a  
160 plume with initial conditions of  $3 \text{ m s}^{-1}$  southerly wind and  $800 \text{ m}$  mixing depth 30 minutes after release.

161

162 **Figure 1: Snapshot of a simulated plume 30 minutes after release for initial conditions of  $3 \text{ m s}^{-1}$  southerly wind and**  
163  **$800 \text{ m}$  mixing depths. Red arrows indicate wind direction at the moment of the snapshot.**

## 164 2.2 Satellite data retrieval

165 Methane absorbs solar radiation at a set of shortwave-infrared wavelengths that are well known and documented  
166 in spectroscopic databases. The absorption of light by methane in the atmosphere therefore alters the reflected  
167 sunlight measured by the satellite in a very predictable way that allows us to quantify the amount of methane  
168 along the light path. Here we use a data-driven retrieval algorithm to estimate the methane enhancements from  
169 reflected sunlight using statistical methods based on the work by Thorpe et al. (2014). This type of simple and  
170 fast retrieval method is commonly used for instruments with comparably low spectral resolutions, for which a  
171 more sophisticated, so-called full-physics approach provides no extra benefit.

172  
173 The relationship between the spectral intensity at each point in the satellite spectra and the column enhancement  
174 of methane in the scene is represented by a methane Jacobian vector, which describes the change in the logarithm  
175 of the intensity  $I_k$  in band  $k$  with respect to the column enhancement of methane  $C_{CH_4}$ . The spectral variation of  
176 the background of the scene (i.e. outside of the plume) is approximated by a number of Principal Components of  
177 all measured spectra combined derived using the Principal Component Analysis (PCA) method. We perform the  
178 PCA on the logarithm of measured spectra of the scene and select the singular vectors (principal components) that  
179 best describe the spectral variability of the scene. The optimal number of singular vectors was determined by trial  
180 and error, and was found to be the first three. We then concatenate these vectors with the methane Jacobian to  
181 construct the matrix  $J$  with dimension  $4 \times$  number of PRISMA bands, which we use along with the logarithm of  
182 the measured radiances,  $y$ , to find a vector  $W$  that minimises the cost function in a linear least squares fit for each  
183 pixel:

$$184 \|y - JW\|^2, \quad (1)$$

185

186 The modelled radiance  $F$  is calculated from  $J$  and  $W$  as follows:

$$187 F = JW, \quad (2)$$

188

189 We can then rewrite Eq. (2) as the sum of the background ( $k$ ) and  $CH_4$  ( $c+1$ ) components of the radiance:

$$190 F(W, J) = \sum_{k=1}^c J_k \cdot W_k + J_{c+1} \cdot W_{c+1}, \quad (3)$$

191

192 where  $c$  is the number of singular vectors used. Thus, the modelled logarithmic radiance  $F(W, J)$  is a linear  
193 combination of the singular vectors,  $J_k$ , the  $CH_4$  Jacobian,  $J_{c+1}$ , and their weights,  $W_k$  and  $W_{c+1}$ , respectively. This  
194 method is described in more detail in Thorpe et al. (2014). In order to avoid column-wise changes in the  
195 instrument's radiometric response, and since the wavelengths scale for each across-track pixel of a PRISMA  
196 image is different, it is necessary to infer the Principal Components for each column in the across-track direction  
197 separately.

## 198 2.3 Training data generation

199 We generated synthetic datasets to train the machine-learning model by combining PRISMA images with the  
200 synthetic plumes simulated with WRF-LES (described in section 2.1). We use the SWIR spectral radiance from  
201 PRISMA Level-1b data as well as the RGB bands. These datasets come with pixel quality and cloud mask

202 information, which we apply in our data preparation process. We selected 36 different PRISMA background  
203 images to cover a wide range of scenes representative of places where methane plumes might be expected (Table  
204 S1). These images also cover a range of different dates throughout the ~3 years of PRISMA data available in the  
205 archive, to account for different illumination conditions. All the selected scenes have less than 1% cloud cover,  
206 and any pixels flagged as cloudy in the PRISMA product were excluded from the analysis.

207

208 A total of 9700 image tiles were generated for training, each tile with a size of  $256 \times 256$  pixels. The tile size was  
209 deliberately selected as a power of two to optimise the model performance. Each tile was selected at random from  
210 one of the 36  $1000 \times 1000$ -pixel PRISMA background scenes, and a synthetic methane plume subsequently  
211 embedded in it. The synthetic plume was also selected randomly from the WRF-LES simulations, with the  
212 following parameters also randomised following a uniform distribution:

- 213 - **Time step:** between 1 and 120 seconds (Figure S3).
- 214 - **Plume origin:** any point within the background scene tile, excluding the areas near the edges to avoid  
215 missing parts of the plume.
- 216 - **Emission rate:** all simulated plumes have a  $1000 \text{ kg hr}^{-1}$  emission rate, so we applied a scaling factor  
217 between 0.1 and 10 to have a range of emissions between 100 and  $10,000 \text{ kg hr}^{-1}$  (Figure S4).

218

219 The synthetic plumes from WRF-LES are first converted into maps of methane vertical column densities in  
220 molecules  $\text{cm}^{-2}$ . The original plume simulations are all carried out for an emission of  $1000 \text{ kg hr}^{-1}$  and the scenarios  
221 for different emission rates are obtained by scaling the simulated concentrations. Each plume is inserted into the  
222 background PRISMA image tile by modifying the PRISMA SWIR radiances according to the Beer-Lambert law  
223 for absorption. Methane columns are converted into optical depth for each band using a representative methane  
224 absorption cross-section for each band computed from the HITRAN database (Gordon et al., 2022) for a  
225 temperature of 293 K and pressure of 1 atmosphere. The use of a single temperature and pressure value is a  
226 simplification that could introduce small uncertainties for vertically extended plumes. Each of the 9700 training  
227 datasets contain: 38 PRISMA radiance bands (3 RGB, and 35 SWIR (2100 - 2365 nm) channels) and the synthetic  
228 plume (i.e., the “true” methane enhancements to be used as labels in the model).

## 229 **2.4 Training data processing**

230 Each PRISMA sub-image ( $256 \times 256$ -pixel tile) was normalised by subtracting the mean and dividing by the  
231 standard deviation (std) of the whole collection of training images such that the mean of all the images was 0 and  
232 the std was 1 for each band. This data normalisation step is standard when using deep neural networks as it is  
233 understood to optimise the training time. Following on from this, the undefined (NaN) values present in the images  
234 were changed to equal the mean value of each band in the respective image. These NaN values correspond to  
235 either invalid (e.g., saturated) or cloudy pixels.

236

237 Every time an image was retrieved during the training process, data augmentations were randomly applied. The  
238 augmentations were as follows: rotation by a multiple of  $90^\circ$ , and horizontal and vertical flipping. No brightness  
239 and contrast augmentations were made because the quantification of methane plumes relies on the specific band  
240 information inside the plume region. The purpose of data augmentation was to increase the data volume, to reduce

241 overfitting, and improve the ability of the model to produce accurate results with data that is different to the  
242 training data.

243

244 To predict the methane concentration, it was first necessary to model the methane plume mask (binary  
245 classification of plume/non-plume per pixel) because the vast majority of pixels in the training images did not  
246 contain a plume (zero-inflated data). To create the ground truth masks for binary segmentation, an initial methane  
247 concentration threshold of  $8 \times 10^{18}$  molecules  $\text{cm}^{-2}$  was chosen as it was the cut-off point where the plumes were  
248 no longer visible. Furthermore, training the model with a lower threshold resulted in non-convergence. After the  
249 model was trained at the  $8 \times 10^{18}$  molecules  $\text{cm}^{-2}$  threshold, it was possible to continue training the model at a lower  
250 threshold. Thus, we tested training the model at  $5 \times 10^{17}$  molecules  $\text{cm}^{-2}$  increments until the validation loss dropped  
251 substantially. The lowest threshold where this was the case was  $4 \times 10^{18}$  molecules  $\text{cm}^{-2}$ . This final step is important  
252 because it increases the range for which the model can locate and quantify methane emissions.

## 253 **2.5 Deep neural network architecture and training process**

254 The training of the neural network was split into 4 steps. First, the model was trained to locate the regions of the  
255 image containing a plume via per pixel binary semantic segmentation. Next, the column enhancements of methane  
256 were predicted inside the region of the estimated plume mask from the first stage. Following on from this, the  
257 emission rate of the plume in the image was estimated. To ensure that the emission rate estimates would equal  
258 zero when no plume was present, an intermediate prediction layer was included where a whole image binary  
259 classification was made regarding whether a plume was present in the image or not. At each stage of the model,  
260 the input was a concatenation of the input satellite image and all the previous outputs (Figure 2). To optimise the  
261 training of the model weights, each portion of the model was trained alone such that the weights in all the other  
262 parts were not being updated. The parts of the model were trained in order moving downwards across the models  
263 depicted in Figure 2. The loss function to predict the plume mask was as follows:

$$264 \text{Loss}_{\text{mask}} = 1 + BC - SDC, \quad (4)$$

265

266 Where  $BC$  is binary cross entropy,  $SDC$  is the Sørensen-dice coefficient defined as follows:

$$267 SDC = \frac{2TP}{2TP + FP + FN}, \quad (5)$$

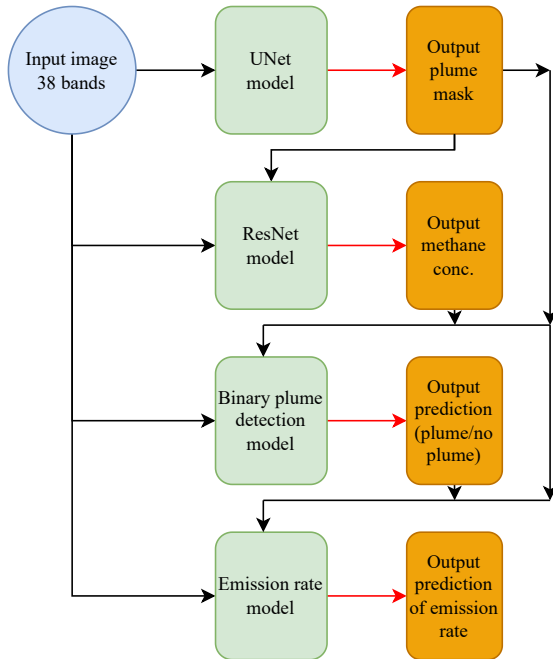

268

269 where TP is true positive, FN is false negative, and FP is false positive. This loss function was chosen because of  
270 the large number of non-plume pixels present in the image. The loss function for the mask concentration was  
271 mean squared error (MSE), a standard choice for regression modelling. For the whole image binary classification  
272 part of the model, binary cross-entropy was chosen, which is common for solving 1-dimensional binary problems.  
273 Finally, for the emission rate part of the model, MSE was chosen as the loss function until the validation error  
274 started to plateau, after which, the model was only trained on images containing plumes and mean absolute  
275 percentage error was given as the loss function. This was done to ensure that the proportion error was minimised  
276 rather than the absolute error. Mean absolute percentage error was not used throughout the whole training process  
277 because it was important that the model was trained on some images with no plumes (so an emission rate of zero  
278 could be possible) and mean absolute percentage error produced very high loss values when false positives were  
279 made by the model.

280

281 For plume mask detection, a UNet model was used and for methane concentration, a ResNet model was used. For  
282 the whole image binary plume detection and emission rate estimation, however, CNNs with only an encoder  
283 branch were used. The two encoder CNNs have identical architectures except the activation function at the end of  
284 the whole image binary classification model has sigmoid activation because the predictions are constrained  
285 between 0 and 1, and the emission rate estimator has a ReLU activation function.

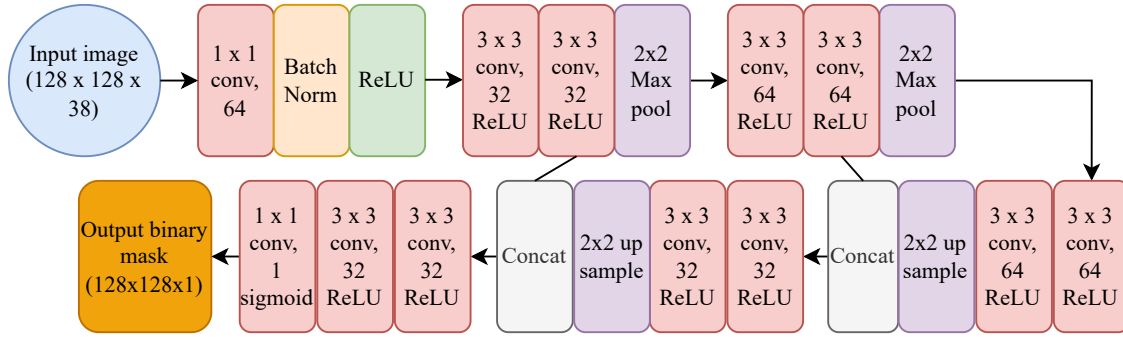

286

287 **Figure 2: Structure of the neural networks used in this study. Green boxes indicate portions of the neural network,**  
288 **orange boxes indicate predictions made by each stage of the neural network. Black lines indicate flow of data into**  
289 **models, and red lines indicate predictions resulting from a model.**

### 290 2.5.1 Estimating plume masks

291 Estimating the mask of a methane plume involved using a similar architecture to a UNet model (Ronneberger et  
292 al., 2015) (Figure 3). UNet models consist of two paths; the first is the encoder, which captures the context in the  
293 image and is composed of convolutional and max pooling layers. The second path is the decoder, which enables  
294 localisation of the features captured by the encoder and consists of convolutional and upsampling layers  
295 (Ronneberger et al., 2015). In our model architecture, there is an additional  $1 \times 1$  convolutional layer with 64 filters  
296 at the beginning because methane plumes are associated with anomalies in certain SWIR bands of the PRISMA  
297 imagery. This additional convolution makes the network pay closer attention to individual pixel values in the  
298 satellite data rather than focussing more on the shapes present in the image. Methane does not absorb in the visible  
299 bands; thus, the inclusion of the visible bands helps the neural network to distinguish between plume and non-  
300 plume by providing information on the background of the image. Methane plumes can be identified based on the  
301 typical spatial structures that form as a result of turbulence and advection in the atmosphere, as well as the  
302 variations in methane-absorbing bands compared with the background landscape. It is the latter reason why an  
303 additional  $1 \times 1$  convolutional layer was deemed to be helpful in improving the accuracy of the model.

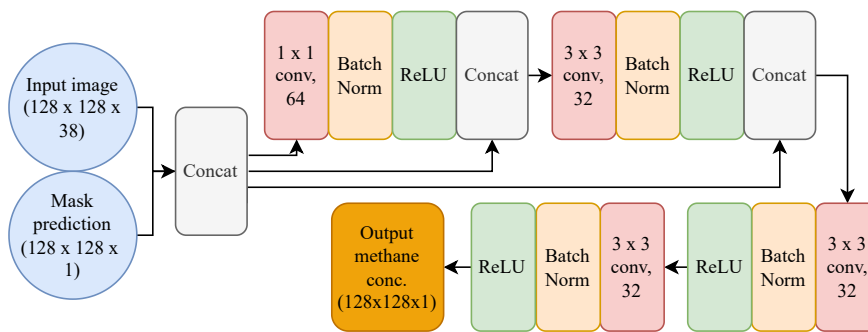

304

305  
 306 **Figure 3: Architecture of the deep neural network for the UNet portion of the model.**  $1 \times 1$  conv, 64 refers to a  
 307 convolutional filter with kernel size  $1 \times 1$  and 64 filters. Batch Norm refers to a batch normalisation layer, Concat  
 308 refers to a concatenation between the inputs to that layer,  $2 \times 2$  Max pool refers to a max pooling layer with pool size  
 309 2, and  $2 \times 2$  up sample refers to upsampling layer with size 2. ReLU and sigmoid refer to the Rectified Linear Unit and  
 310 sigmoid activation functions respectively.

### 311 2.5.2 Estimating methane column enhancements inside plumes

312 Estimating the methane column enhancement within the plumes predicted in section 2.4.1 uses a concatenation  
 313 of the input image and the mask predictions. This step to aid the estimation of methane concentrations is necessary  
 314 because the vast majority of pixels do not contain a plume (a zero-inflated regression problem). Such problems  
 315 often have the issue that the model will converge at predicting zeros everywhere. Thus, the inclusion of the mask  
 316 prediction helps to prevent this. The ensuing model is composed initially of a  $1 \times 1$  convolutional layer for a similar  
 317 reason as its inclusion in the UNet model (see section 2.5.1). Following on from this are 2 ResNet layers (He et  
 318 al., 2016), which are characterised by double-layer skip connections, ReLU activation functions, and batch  
 319 normalisation (Figure 4). A ResNet architecture was selected for this portion of the model as it is known to be  
 320 lightweight and powerful at regression predictions in computer vision.

321  
 322 **Figure 4: Architecture of the deep neural network for the ResNet portion of the model.**  $1 \times 1$  conv, 64 refers to a  
 323 convolutional filter with kernel size  $1 \times 1$  and 64 filters. Batch Norm refers to a batch normalisation layer and Concat  
 324 refers to a concatenation between the inputs to that layer. ReLU refers to the Rectified Linear Unit activation function.

### 325 2.5.3 Estimating emission rate of plumes

326 The prediction of the whole image binary classification of plume/not plume involved an architecture identical to  
 327 the one presented in this section (except the final activation layer was sigmoid, not ReLU). The inputs to the

328 emission rate portion of the model are the outputs from all the previous stages of the model concatenated with the  
 329 input image. The outputs of the mask prediction and whole image binary segmentation are continuous between 0  
 330 and 1. The majority of the methane concentration output is also in this range because the methane concentration  
 331 ground truth was pre-processed via min-max normalisation (to optimise training time). This is to ensure that more  
 332 information is available to the model to accurately estimate emission rates. Following on from this is the  $1 \times 1$   
 333 convolutional layer, which was included for the same reason as in the previous stages of the model (see section  
 334 2.5.1). This is followed by the encoder part of the model, in which a convolutional layer is followed by batch  
 335 normalisation, ReLU activation, and max pooling, which is done 7 times with increasing filters every 2<sup>nd</sup> loop.  
 336 These layers encode features about the methane plumes and reduce the dimensionality of the tensors. Finally,  
 337 there is a dense layer and ReLU activation to collect all information obtained and output a single floating-point  
 338 number as the predicted emission rate (Figure 5).

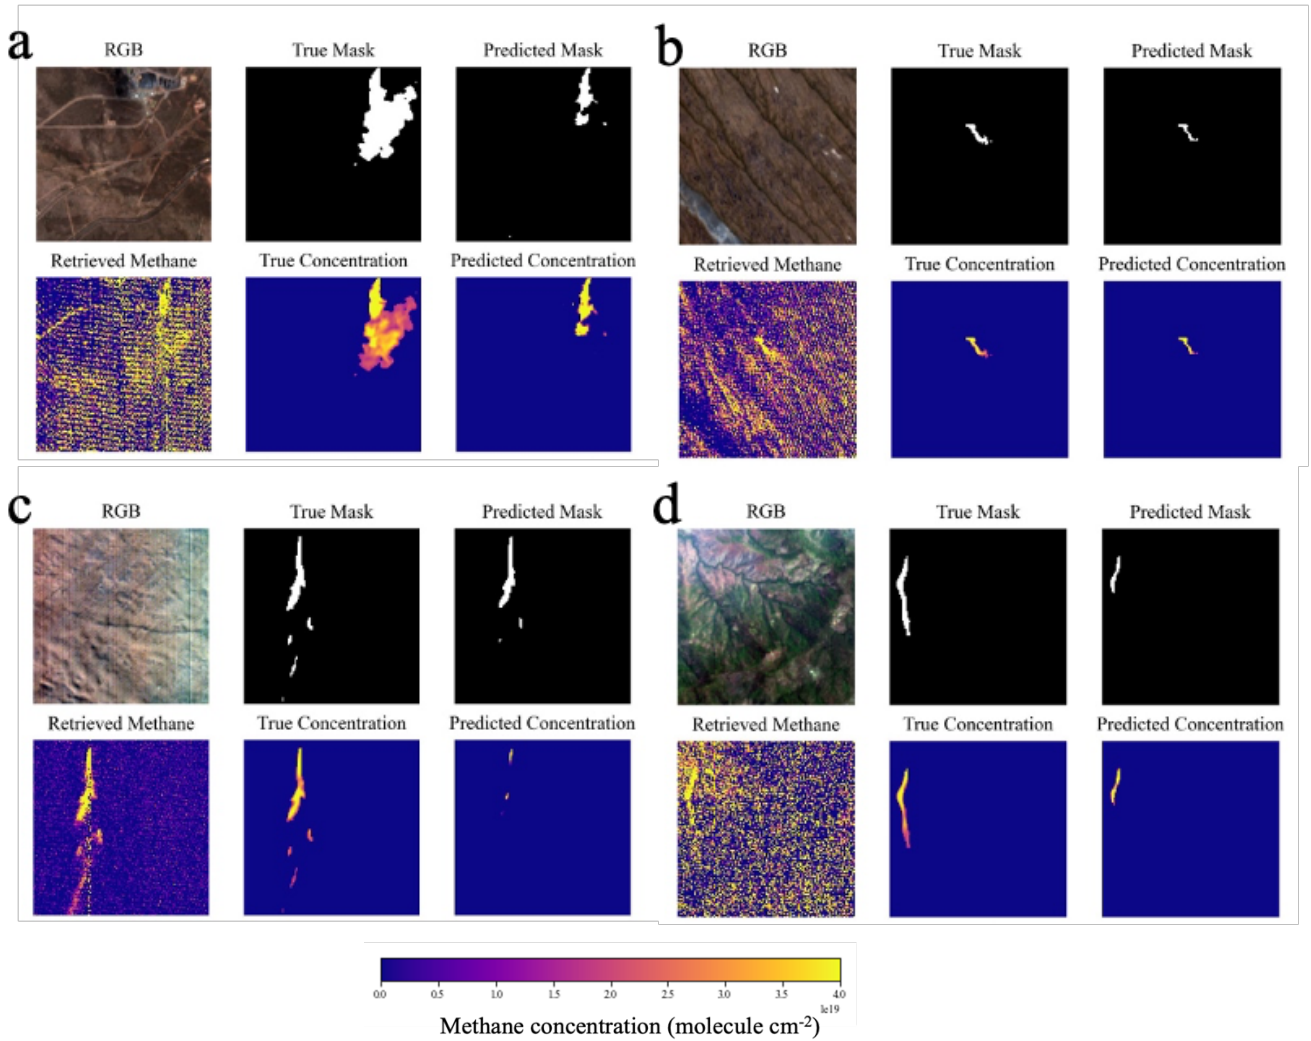

339  
 340 **Figure 5: Architecture of the deep neural network for the emission rate prediction of the model.  $1 \times 1$  conv, 64 refers**  
 341 **to a convolutional filter with kernel size  $1 \times 1$  and 64 filters. Batch Norm refers to a batch normalisation layer, Concat**  
 342 **refers to a concatenation between the inputs to that layer, and  $2 \times 2$  Max pool refers to a max pooling layer with pool**  
 343 **size 2. ReLU refers to the Rectified Linear Unit activation function.**

### 344 3 Results

#### 345 3.1 Application of neural network to simulated plumes

346 The total training/validation dataset consisted of 9700 images, 80% of which were reserved for training and the  
 347 remaining 20% for validation. After each iteration of the model through the training dataset (known as an *epoch*),  
 348 the model was tested on the validation dataset. If the loss of the model when tested on the validation dataset was  
 349 lower than the lowest loss previously recorded, the weights of the model were updated. Thus, at the end of the  
 350 training procedure, the best model was saved. Each of the stages of the model depicted in Figure 2 were trained  
 351 separately in descending order, where the weights of the other stages did not vary. This was done so that the most  
 352 accurate predictions were being produced from the earlier layers so that no errors from insufficient training would  
 353 propagate through the model because the outputs are concatenated with the satellite data in later parts of the model.  
 354

355 Once training was complete, the model was tested on an additional 2000 images not seen during training sampled  
356 randomly from a uniform distribution of emission rates from 500 to 10 000 kg hr<sup>-1</sup>. 36 out of the 2000 images had  
357 a maximum methane concentration under the  $4 \times 10^{18}$  molecules cm<sup>-2</sup> threshold imposed during training, however  
358 they were still included in the testing to determine if they could still be detected by the model. The model is able  
359 to accurately locate and identify the shape of methane plumes in the test dataset (Figure 6).  
360

361

362

363 **Figure 6: Example images and predictions taken from the test dataset. Images are  $3840 \times 3840$ m composed of  $128 \times$**   
 364  **$128$ -pixel tiles. True emission rates and initial wind speeds are (a)  $8068 \text{ kg hr}^{-1}$ ,  $1 \text{ ms}^{-1}$ , (b)  $1484 \text{ kg hr}^{-1}$ ,  $1 \text{ ms}^{-1}$ , (c)  $7673$**   
 365  **$\text{kg hr}^{-1}$ ,  $5 \text{ ms}^{-1}$ , (d)  $6270 \text{ kg hr}^{-1}$ ,  $4 \text{ ms}^{-1}$ . Retrieved methane comes from the retrieval described in section 2.2. RGB**  
 366 **image courtesy of PRISMA © (Italian Space Agency).**

367 The average methane column enhancement in the images was well estimated, where average estimated methane  
 368 was closely correlated with the ground truth (Figure 7) with a tendency to slightly overestimate column values.  
 369 This is possibly because predicted methane masks were generally smaller than the true masks, so during training,  
 370 the methane concentration model overpredicted the centre of the plumes to compensate.

371

372 **Figure 7: Scatter Plot of mean methane concentration predicted vs true. The true (predicted) average methane**  
 373 **concentration was calculated from the average inside the true (predicted) plume.**

374  
 375 In the whole image binary classification part of the model, we assess its success using the F1-score, precision and  
 376 recall, which are defined as follows:

377  $F1 = TP / (TP + 0.5 * (FP + FN)),$  (6)

378  $Precision = TP / (TP + FN),$  (7)

379  $Recall = TP / (TP + FP),$  (8)

380  
 381 In the whole image binary classification part of the model, the F1-score, precision, and recall were 0.95, 0.96 and  
 382 0.92, respectively (Table 1). These statistics come from predictions made on the 2000 images with plumes in, as  
 383 well as an additional 1533 images with no plumes.

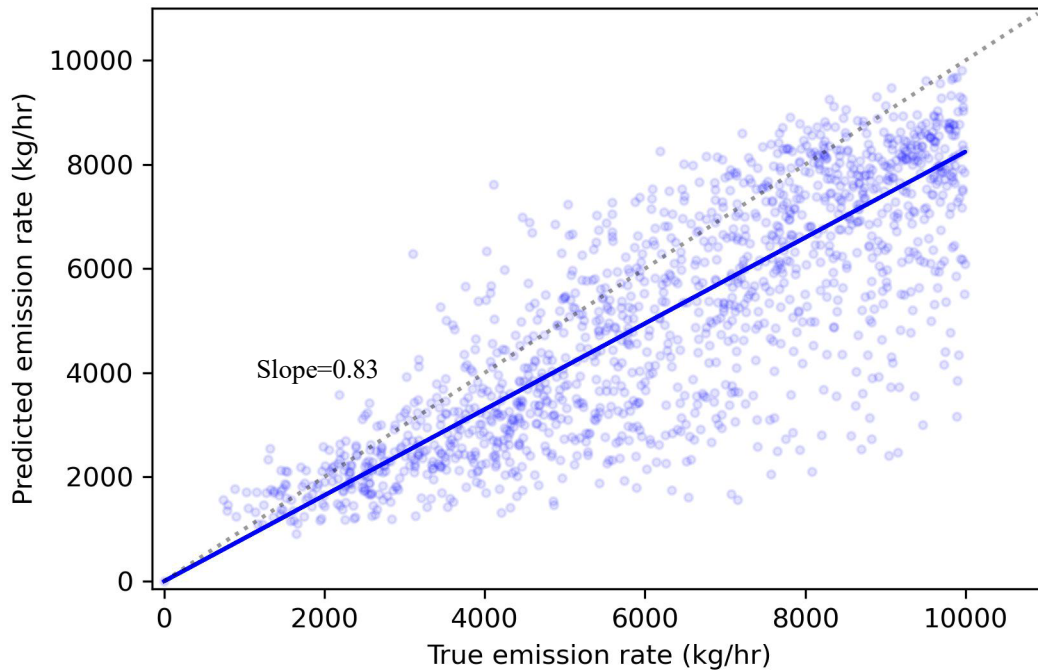

384  
 385 **Table 1: Confusion matrix of whole image binary classification portion of the model broken down per image.**

	<b>Plume present</b>	<b>No plume present</b>
<b>Predicted plume</b>	1846	51
<b>Predicted no plume</b>	154	1482

386 The distributions of the scene noise and methane concentrations in the cases where no plume was predicted but a  
 387 plume was present (false negative) reveal slightly lower than average scene noise and much lower than average  
 388 maximum methane concentration (Table S2). However, in the cases where a plume was predicted but no plume  
 389 was present (false positive), scene noise is not noticeably different (Table S2).

390

391 The actual vs predicted emission rate has a slope of 0.83 with a relatively small spread about the line of best fit  
392 (std = 1447 kg hr<sup>-1</sup>). This means that there is a tendency for underestimating emissions with a mean absolute  
393 percentage error in emission rate of 23.7% (Figure 8). Underpredictions are common in regression models  
394 especially when data points with zeros are included such as in this case because the model was trained on images  
395 without plumes as well as those containing plumes. This was a necessary step, however, because the model did  
396 not converge so well without these images and predictions were far worse at lower emission rate ranges.

397  
398 **Figure 8: Actual vs predicted emission rate using the deep learning model. Line of best fit calculated using Huber loss**  
399 **so outliers do not have an inordinate influence on the slope.**

400 The absolute emission rate error increased in magnitude as the emission rate increased (Figure 8), as one might  
401 expect. The percentage error was largest in magnitude for the smallest emission rates (500-999 kg hr<sup>-1</sup>), but the  
402 distribution remained relatively consistent above 2000 kg hr<sup>-1</sup>, with a median error of 25% and interquartile range  
403 of 40% error (Figure 9). The error in percentage emission rate had a positive bias for emission rates under 1000  
404 kg hr<sup>-1</sup> and a negative bias for emission rates over 2000 kg hr<sup>-1</sup> (Figure 9).  
405

406

407 **Figure 9: Error in emission rate predictions from the deep learning model as a function of true emission rate. Positive**  
 408 **values indicate predicted emission rates being larger than true emission rates. Top panel shows absolute emission rate**  
 409 **error and bottom panel shows percentage emission rate error.**

410 **3.2 Application to real-world images**

411 The model was then tested on 40 PRISMA scenes obtained during 2020-2022 in the Korpeje oil field,  
 412 Turkmenistan (37.9°N, 53.2°E - 39.4°N, 55.2°E), a well-studied area with frequent methane point source emissions  
 413 plumes (Irakulis-Loitxate et al., 2022). The images were normalised in the same way that the training, test, and  
 414 validation images were. 21 plumes were identified using the neural network from 15 different scenes with  
 415 predicted emission rates ranging from 1112-7615 kg hr<sup>-1</sup> (Figure 10; Table S3).

416

417  
 418 **Figure 10: Images of plumes detected by the neural network in the Korpeje oil field, Turkmenistan. Left panels depict**  
 419 **physics-based methane retrievals, middle panels depict the RGB of the image, and the right panel depicts the mask**  
 420 **prediction by the neural network. The predicted emission rates are (top) 7615 and (bottom) 2370 kg hr<sup>-1</sup>. RGB image**  
 421 **courtesy of PRISMA © (Italian Space Agency).**

422  
 423 Methane plume detection capability using the neural network was compared with using clustering and  
 424 thresholding techniques. The DBSCAN clustering technique was used to estimate clusters based on the output  
 425 from the PCA retrieval method (see section 2.2). Out of the 21 plumes, 14 were found using the clustering and  
 426 thresholding approach. The neural network model took roughly 1 minute to make predictions of plume masks,  
 427 methane concentrations, and emission rates of located plumes in an image of 1000 × 1000 pixels (900 km<sup>2</sup> area)  
 428 without the need for time-consuming human inspection typically needed for classical clustering approaches.

#### 429 **4 Discussion**

430 Reduction of methane emissions and hence identification of high emitters can have a considerable influence over  
 431 the Earth's surface radiation budget and hence our efforts to mitigate climate change. Methods utilising classical  
 432 approaches have had some success in detecting fossil fuel methane point sources and estimating their emissions,  
 433 but the errors are high (roughly 50% mean absolute error for emission rate predictions) if no accurate local wind  
 434 speed information is available and often time-consuming human judgement is necessary to separate plumes from  
 435 surface effects. Within the pseudo-observation dataset produced in this study, only one quarter of the images were  
 436 deemed suitable to be analysed via visual inspection after using clustering algorithms. This was due to interference  
 437 effects from surface features and demonstrates the limitation of this approach for detecting methane point source  
 438 emissions. In comparison, only 7.7% of the pseudo-observations were undetected by the neural network (Table  
 439 1). The binary prediction neural network presented in this study was able to accurately locate simulated methane  
 440 point source plumes. From testing the neural network on a variety of images with and without simulated plumes,  
 441 it achieved a precision and recall of 0.96 and 0.92, respectively. The estimates of emission rate did not require  
 442 wind speed information, which is a major source for uncertainty in emission estimates in conventional approaches

443 such as the IME method, and had an average error of 23.7%, which is considerably lower than that obtained from  
444 our classical method. The emission rate prediction error could possibly be further reduced with training on a larger  
445 dataset.

446

447 The approach used in this study differs from the approach by Jongaramrungruang et al. (2022), who directly  
448 predicted the emission rate from the satellite data without first estimating the plume mask. However, we found  
449 that excluding these stages dramatically worsened the model prediction, where the error in emission rate was  
450 greater than 50%. The model architecture presented here utilises the maximum amount of information available  
451 from the training data. Possible explanations for why the model from Jongaramrungruang et al. (2022) was  
452 nevertheless successful could include the large training data volume available in their study (in the order of  
453 hundreds of thousands of images), which is an order of magnitude larger than that available in this study. This  
454 larger training volume may have enabled the neural network to make the link between plume shapes and emission  
455 rates. In addition, the spectral and spatial resolution of the aircraft imagery used in their study (AVIRIS-NG) is  
456 substantially higher than that of PRISMA. Finally, the input bands for this study totalled 38, whereas in the study  
457 of Jongaramrungruang et al., (2022), only 1 band was sufficient due to the low noise in the signal in the AVIRIS-  
458 NG data and high methane absorption in that band. Thus, it may have been easier for their neural network to learn  
459 features in the image due to lower noise present.

460

461 When producing the training data labels for plume masks, a constant threshold was chosen for what methane  
462 concentration constitutes a plume. However, the minimum methane concentration that is detectable likely varies  
463 depending on scene noise and brightness. Thus, more work is necessary to quantify the most appropriate threshold.  
464 However, precise estimates of the edges of a plume are of lesser importance than the initial identification of a  
465 plume and its corresponding emission rate. Additional improvements could be made with a larger volume, and  
466 greater variety of scenes used in training. This would greatly improve the performance of the model in different  
467 surface types and atmospheric conditions.

468

469 There is a noticeable bias present in the emission rate prediction errors (Figure 8; Figure 9) which was also evident  
470 in the study by Jongaramrungruang et al. (2022). This bias should be rectified, and future work is needed in fine  
471 tuning the neural network training procedure to do so. Such adjustments could include modifying the emission  
472 rate loss function or the model architecture. The model was trained only on images with a single methane point  
473 source; thus, the model is not able to discriminate between emissions from different sources within a single  $128$   
474  $\times$   $128$ -pixel image. The solution to this would be to add in training data with multiple sources and solve the  
475 instance segmentation problem using an appropriate architecture, such as Mask-RCNN (He et al., 2020). It is  
476 likely that the errors would be larger in general when using this approach owing to the increased noise present.  
477 Nevertheless, the key advantage of this approach is the speed with which methane plumes can be identified with  
478 little specialist training necessary.

## 479 **5 Conclusions**

480 In this study, we present a novel deep neural network model for identifying and quantifying methane point source  
481 emissions from PRISMA satellite data. PRISMA data has sufficient spectral and spatial resolution to identify  
482 methane plumes, while still having considerable spatial coverage and is still in operation today. These factors  
483 make PRISMA an ideal tool for methane detection and the deep neural network developed here has great potential  
484 to impact climate mitigation efforts. The model proved successful with both identification and quantification but  
485 biases were present in the predictions. Rapid identification and quantification of methane point sources is a vital  
486 contribution to climate change mitigation, and the approach outlined here opens the door to the capability to  
487 automate methane plume detection. Our model was able to produce predictions on an area of 900 km<sup>2</sup> over real  
488 PRISMA images in less than a minute. Such a capability would vastly reduce the time and costs associated with  
489 reducing anthropogenic methane emissions.
