19 **Abstract** The eruption of the Hunga Tonga-Hunga Ha'apai volcano on Jan 15th of 2022 provided a rare
20 opportunity to understand global tsunami impacts of explosive volcanism and to evaluate future hazards, including
21 dangers from "volcanic meteotsunamis" (VMTs) induced by the atmospheric shock waves which followed the
22 eruption. The propagation of the volcanic and marine tsunamis was analyzed using globally-distributed 1-min
23 measurements of air pressure and water level (from both tide gauges and deep-water buoys). The marine tsunami
24 propagated primarily throughout the Pacific, reaching nearly 2.0 m at some locations, though most Pacific
25 locations recorded maximums lower than 1.0 m. However, the VMT resulting from the atmospheric shock wave
26 arrived before the marine tsunami, and had a global signature, producing water-level perturbations in the Indian
27 Ocean, the Mediterranean, and the Caribbean. The resulting water level response of many Pacific Rim gauges was
28 amplified, likely related to bathymetric processes. The meteotsunami repeatedly boosted tsunami wave energy as
29 it circled the planet several times. In some locations, the VMT was amplified by as much as 35-fold relative to
30 inverse barometer, due to near-Proudman resonance and topographic effects. Thus, a meteotsunami from a larger
31 eruption (such as the Krakatoa eruption of 1883) could yield atmospheric pressure changes of 10mb to 30mb,
32 yielding a 3-10m near-field tsunami that would occur in advance of (usually) larger marine tsunami waves, posing
33 additional hazards to local populations. Present tsunami warning systems do not consider this threat.

34

35 1. Introduction

36 The immense energy of the **Hunga Tonga-Hunga Ha'apai** volcanic eruption (20.54°S, 175.38°W) at 0415
37 UTC on 15 January 2022 (hereafter the “Tonga Event”) was one of the strongest eruptions of the past 30 years
38 (Witze, 2022). It produced a variety of atmospheric waves at various levels that travelled the globe multiple times
39 (Adam, 2022; **Duncombe, 2022**). Lamb waves were produced first from the eruption (Lamb, 1911; Nishida et al.,
40 2014). These travel with a celerity $V \sim 310 \text{ ms}^{-1}$, which is faster than marine gravity longwaves, except in the
41 deepest parts of the ocean. **Lamb-wave generation is driven by a complex process involving eruption-generated**
42 **pulses of pressure, temperature, and density gradients in the atmosphere. The Tonga Event induced Lamb waves**
43 **and closely-following atmospheric gravity waves which were detectable up to the ionosphere (Lin et al., 2022;**
44 **Wright et al., 2022; Themmens et al., 2022; Kulichkov et al., 2022; Matoza et al., 2022; Kubota et al., 2022;**
45 **Nishida et al., 2014). Closer to the surface, the pressure pulse added momentum to the ocean surface through a**
46 **pressure-gradient forcing that pushed the ocean surface in the direction of the positive-pressure gradient (Lynett**
47 **et al., 2022). The subsequent and slower atmospheric gravity waves had phase speeds of 200-220 ms^{-1} , about the**
48 **speed of long waves in the deep ocean. Recent work has confirmed the presence of a slower internal Perkeris**
49 **wave (Perkeris, 1937; 1939) which has helped resolve long-standing issues about atmospheric resonance**
50 **(Watanabe et al., 2022).**

51 The Tonga Event differed from previously observed tsunamis, with unexpected dynamic atmospheric
52 variability in addition to the expected oceanic variability. The only documented historical corollary is the Krakatoa
53 Event of 1883, which had much stronger atmospheric shock waves and yielded global water level fluctuations,
54 due to a stronger volcanic meteotsunami (VMT) than occurred after the Tonga Event. Krakatoa also differed from
55 the Tonga Event, because the former event was land-based, while the latter was due to eruption of a submarine
56 volcano whose apex was between 500 and 1000m below the ocean surface. This layer of water likely shielded
57 and contained much of the explosive impact of the eruption; if the same event happened at sea level, it would
58 likely have been much more destructive. The Tonga Event is thought to have generated waves via multiple
59 mechanisms: air-sea coupling from the shockwave in the immediate vicinity, collapse of the underwater cavity
60 after the explosion (which controlled near-field impacts), and air-sea coupling with the pressure pulse that circled
61 the Earth and was responsible for the VMT (Lynett et al., 2022).

62 The unusual nature of the Tonga Event has inspired a plethora of publications. Several observation-based
63 studies documented and cataloged the initial dynamics of the eruption (Yuen et al., 2022; Poli and Shapiro, 2022),
64 the propagation of the atmospheric shock wave, its record-setting volcanic plume height (e.g., Carr et al., 2022),

65 the impacts of the marine tsunami in the Pacific, and the far-field water level fluctuations distant from the Pacific
66 that were due to the VMT (e.g., Carvajal et al., 2022).

67 Ocean-atmospheric interactions due to the Tonga Event produced far-field water-level perturbations
68 comparable to those from the 2004 Sumatra (Titov et al., 2005), the 2010 Chile (Rabinovich et al., 2013), and the
69 2011 Tohoku Events (Mori et al., 2011). It spread throughout the Pacific Ocean and was measured in all ocean
70 basins except the Arctic. Regional studies documented the VMT impacts to water level on the Russian coasts of
71 the Sea of Japan (Zaytsev et al., 2022), as well as along the coasts of Mexico. The Gulf Coast of Mexico only
72 affected by the VMT, while the Pacific coast was impacted by both the marine tsunami and the VMT (Ramírez-
73 Herrera et al., 2022). Tsunami signatures were also seen in parts of the South China Sea, such as Lingding Bay
74 near Hong Kong (Wang et al., 2023).

75 Tsunami characteristics around Japan were closely studied, due in part to an extensive array of ocean
76 bottom pressure instrumentation (S-net and DONET) established after the Tohoku megathrust earthquake of 2011
77 (Tanioka, 2020; Kubo et al., 2022; Kubota et al., 2021). The directionality, velocity, and intensity of the tsunami
78 were estimated through array analysis of this data network, finding that the amplitude of the first tsunami waves
79 diminished upon reaching shallow water regions, and that the wave split after passing the continental shelf
80 (Yamada et al., 2022). Different pressure sensors recorded different velocities, because they were located in
81 different water depths (Kubo et al., 2022).

82 Several studies have approached the Tonga Event through numerical modelling (e.g., Heidazadeh et al.,
83 2022; Kubo et al., 2022; Kubota et al., 2022; Tanioka et al., 2022; Sekizawa et al., 2022; Saito et al., 2022).
84 Typical tsunami models do not include pressure terms in the shallow-water equations, because atmospheric effects
85 are usually small for seismic tsunamis (Yeh et al., 2008), however, the pressure terms are vital for a meteotsunami.
86 Accordingly, Gusman et al. (2022) employed a simplified air wave model to generate oceanic waves in a tsunami
87 model. This model showed that ocean waves are excited by the passage of the air wave, and this generation is
88 more effective over oceanic trenches. Also, repeated passes of the air wave slowed the decay of the tsunami.

89 The global extent and unusual nature of the Tonga event provides a unique opportunity to investigate the
90 dynamics and impacts of a volcanic tsunami, especially the VMT component. The worldwide network of high-
91 frequency, real-time water level (WL) stations and other instrumentation improved significantly after the Sumatra
92 and Tohoku tsunamis, allowing for detailed study of how sensitive different locations and geometries are to
93 volcanically-induced atmospheric perturbations. Though severe devastation during the Tonga Event was confined

94 to the immediate vicinity (mainly at other Tongan islands; see e.g., Lynett et al, 2022), most Pacific observation
95 systems remained operational. Using these records, we assess the global spatial and temporal patterns of the
96 tsunami and show that significant WL variations were produced in distant locations, primarily due to Lamb waves.
97 Our investigation of 308 tide gauges where the tsunami could be detected (nearly 1000 locations were screened),
98 30 deep-water buoys, and 137 air pressure stations shows a patchwork of amplification, with some locations highly
99 susceptible to **meteotsunami** impacts and others relatively insensitive.

100 We document here how the **VMT** was induced after the passage of the atmospheric shockwave(s) before
101 the oceanic component, ahead of tsunami forecasts (where they were available) and occurred in areas where the
102 marine tsunami was absent. We will address the following questions in this work:

- 103 • What is the amplification potential of these waves, as observed by the unprecedented number of gauges
104 now available?
- 105 • Could a more significant volcanic event, such as a VEI 6 or 7 eruption, cause a **VMT** of dangerous
106 proportions ahead of forecasted arrival times, and in areas not reached by marine tsunami waves?
- 107 • **How does the persistence of a VMT under repeated passes of a planetary-scale shockwave over many**
108 **days contribute to overall water levels?**

109 **2. Meteotsunami background**

110 Tsunamis of volcanic origin are uncommon; less than 150 have been documented (Levin and Nosov,
111 2009), and aside from a few large events like Krakatoa (Wharton, 1888), most have had only local or regional
112 footprints. Volcanic tsunamis can occur when magma rapidly displaces water, and major eruptions such as the
113 Tonga Event can drive a planet-circling **atmospheric shockwave that induces water level fluctuations globally**.
114 Volcanic activity is not, however, the only source of atmospheric tsunamis – local atmospheric disturbances can
115 cause “meteotsunamis”, independent of seismic or volcanic activity (Šepić et al., 2014; Šepić et al, 2015;
116 Olabarrieta et al., 2017; **Monserrat et al., 2006; Ripepe et al., 2016; Vilibic et al., 2016**). Such meteotsunamis may
117 have amplitudes up to 3-5m and can cause significant coastal damage. **Some meteotsunami events can be deadly,**
118 **such as the 1954 meteotsunami of Lake Michigan which led to the drowning of seven fisherman in Chicago (Press,**
119 **1956). Meteotsunamis are a common occurrence in the Black and Mediterranean Seas (e.g., Vilibic and Sepic,**
120 **2009), Australia, the Persian Gulf (e.g., Heidarzadeh et al., 2020), the Great Lakes of North America, and perhaps**
121 **other, less documented locations. Meteotsunamis can even occur during good weather, as they can be forced by**

122 far-field atmospheric disturbances. A wealth of information about the history and dynamics of meteotsunamis can
123 be found in Rabinovich (2020).

124 The water level fluctuations induced worldwide by atmospheric waves after the Tonga Event are a form
125 of meteotsunami, using “meteo” in its larger context as referring to phenomena of the atmosphere in general, and
126 not just weather. VMTs and weather-driven meteotsunamis share similar physics, but with several important
127 distinctions. First, weather-related meteotsunamis move more slowly than VMTs, meaning that resonance with
128 ocean waves occurs at shallower depths. Second, since weather-related meteotsunamis have a purely atmospheric
129 origin, they may allow some predictability via observations of weather conditions which may be ideal for weather-
130 related meteotsunami generation, whereas meteotsunamis generated by an eruption such as the Tonga Event
131 happen with less warning. Third, weather-related meteotsunamis, while potentially destructive, are most often
132 singular events, and do not typically have multiple instances within a short period, such as what was seen with the
133 Tonga Event and the repeating “ringing” of water levels for each pass of the atmospheric shockwave. Fourth,
134 weather-related meteotsunamis will typically only impact discrete locations or regions, whereas the Tonga Event
135 had a worldwide impact. Finally, the periods or frequencies of the forcing events (weather-related vs volcanic)
136 are also likely distinct from one another, which may imply different responses at any particular harbor.

137 VMTs are generated by a combination of Lamb and Perkaris waves that result from atmospheric
138 explosions like Krakatoa or the Tonga Event which move, in this case, at $\sim 1115 \text{ km hr}^{-1}$ (see Methods and
139 Appendix A), while weather-related meteotsunamis are driven by strong, but slower weather disturbances (Šepić
140 et al, 2015). The importance of this difference can be explained in terms of Froude number, F_A :

141
$$F_A = \frac{V}{\sqrt{gH}}, \quad (1)$$

142 where: V is the atmospheric disturbance speed, H is water depth, and g is gravitational acceleration. For a VMT,
143 $F_A > 1$ for almost the entire ocean, while resonant, near-critical, conditions ($F_A \sim 1$) occur at moderate ocean
144 depths for meteo-tsunamis.

145 Atmospheric forcing of tsunamis has been analyzed in linear (Garret, 1976) and more realistic nonlinear
146 contexts (Pelinovsky et al., 2001). In either case, the solution consists of a forced ocean wave moving with the
147 atmospheric disturbance, plus forward and backward free waves. Shallow water, linear free waves of small
148 amplitude have celerity $c \approx \sqrt{gH}$, while nonlinear theory, relevant for $F_A \geq 1$, yields dispersive waves. The
149 forced wave has amplitude proportional to $\frac{V^2}{V^2 - c^2} \Delta P_A(I3)$, with a “nominal amplification” relative to an inverse

150 barometer effect of $a_n = \frac{v^2}{v^2 - c^2}$; ΔP_A is the P_A (air pressure) disturbance; $a_n > 1$ for most of the open ocean.
151 When $F_A \sim 1$, the forced and forward-moving free waves coalesce, and the atmosphere feeds energy into the ocean
152 (Proudman resonance), allowing waves to grow linearly with fetch (Williams et al., 2021). The actual forced wave
153 “amplification factor,” α , observed at an ocean bottom pressure gauge depends on many factors and may differ
154 from a_n .

155 For a subcritical wave, a *rise* in P_A of 1mb causes a *fall* in WL of 10mm via the inverse barometer effect.
156 However, VMT-forced waves are supercritical in ocean depths < 9.7 km, and the Bernoulli effect causes a *positive*
157 P_A spike to drive a forced ocean wave as a *rise* in WL (Garret, 1976) with Proudman resonance occurring only in
158 the deepest ocean waters. Amplification disappears ($a_n \cong 1$) in shallow water, but interaction of the forced wave
159 with the continental slope and shelf will energize the free waves, allowing shallow-water amplification (Garret,
160 1976). A VMT differs from a weather-related meteotsunami in that strong amplification is limited to deep ocean
161 trenches, where fetch is limited, compensated by a potential for ΔP_A to be larger in the VMT case than for the
162 weather-related case. We define the overall amplification of a tsunami at a tide gauge, encompassing Proudman
163 resonance and local effects, β .

164 What happens when a forced VMT wave encounters a sudden change in depth? A depth change, from
165 deep to shallow, requires the forced wave amplification, a_n , to decrease towards unity because $V^2 \gg c^2$ on the
166 shallow side, spawning transmitted and reflected waves. The transmission and reflection coefficients defined by
167 Garret (1976) suggest that the wave transmitted onshore as a VMT which approaches from the ocean side will be
168 considerably larger than the wave reflected back to the coast, as a VMT moves offshore. The offshore-directed
169 case is also different in that the forced wave must be small, because the shelf will typically be less than a
170 wavelength wide and the fetch for its development is limited. These factors suggest that coastal amplitudes may
171 be different for the direct and antipodal approaches of a VMT to any given location. While Garret’s formulae
172 strictly apply to transitions that are abrupt (i.e., occur over a distance small relative to a VMT wavelength of ~ 180
173 to 1100km). they still provide approximate guidance for VMT interactions with the continental shelf.

174 The dynamics at sharp, but more complex features, like deep ocean trenches, is presumably something
175 intermediate between the Proudman resonance case, where the forced wave amplification factor, a_n , adjusts as
176 the wave propagates, and the fission of the forced wave into transmitted and reflected components. Also, at a
177 trench near the coast, the depth difference will typically be larger on the landward side than on the seaward side
178 driving a larger transmitted wave. The transmitted wave may further grow over a continental shelf landward of

179 the trench as $h^{-\frac{1}{4}}$, per Green’s law (Green, 1838). Other resonance processes may occur in specific circumstances.
180 Pattiaratchi and Wijeratne (2015) cite quarterwave resonance and Greenspan resonance. Both of these processes
181 have specific geometric requirements, and the **large velocity of VMT waves** renders both of these mechanisms
182 less likely for a VMT than for weather-related events. Finally, the propagation of the **atmospheric shockwave**
183 may also be influenced by atmospheric temperature gradients (Amores et al., 2022), which may in turn modulate
184 the oceanic response to the shockwave.

185

186 **3. Methods**

187 **3.1 Data Inventory**

188 We employ high-frequency (1-min) water level (WL) data from multiple worldwide data sources,
189 including coastal tide gauges and deep-water pressure buoys (see Appendix A for detailed procedures and
190 uncertainty estimates). Air pressure (P_A) data at a variety of temporal resolutions (1, 6, and 10 min) were also
191 acquired. Some regions, such as the European Atlantic coast, the East China Sea, and the Arctic Ocean did not
192 show any tsunami-like WL fluctuations. In addition, some locations (e.g., Spain) that might have registered a
193 tsunami lacked data during the relevant period. The buoys provide 1-min data during “active” WL events and 15-
194 min data otherwise. However, many were not triggered until the **atmospheric shockwave** had passed; thus, the
195 resultant **VMT** was often not captured, though the oceanic signal was clearly observed. In total, data from 308
196 tide gauges (out of ~1000 investigated) and 30 (out of ~60) deep-water buoys are employed, with 210 locations
197 in the Pacific, and 98 in the rest of the world. Metadata for all tide gauges and deep-water buoys analyzed in this
198 study (latitude, longitude, data source, and distance from the Tonga volcano) are given in Table S1, and metadata
199 for air pressure stations are given in Table S2. We also list the tide gauges that were investigated but not analyzed
200 in Table S3, along with the reason for not using them, and show a color-coded map of the unanalyzed locations
201 in Figure S1. We use detrended residual WLs to quantify the amplitudes of the largest positive and negative
202 tsunami wave amplitudes at all stations from January 14 to 20, 2022. We also apply an EEMD analysis (Huang et
203 al., 1998) to all WL and P_A data to remove low frequency components and biases in mean water level to yield
204 data in which the tsunami-related signals are dominant.

205 **3.2 Water Level (WL) Analysis**

206 **VMT** magnitudes and arrival times, and the amplitudes of the largest positive and tsunami waves at each
207 location, were determined from the WL residuals via numerical and visual estimation of the residual time series
208 (see Appendix A for details of calculations and a discussion of inherent uncertainty in this study). We compare

209 the distances and “first arrival” times at all tide gauges stations via robust regression (Holland and Welsch, 1977)
210 to estimate **VMT celerity**. MATLAB continuous wavelet transform (CWT; Rioul and Vetterli, 1991; Torrence
211 and Compo, 1998; Lilly, 2017) routines are applied to the WL and P_A residuals to confirm approximate arrival
212 times (accurate within half a filter length) and to investigate the frequency response at each location. These are
213 discussed for selected locations. P_A data (onshore and offshore) and are compared with WL variability to
214 investigate the relative synchronization of the P_A -spikes and associated WL variability. This is performed at
215 certain Pacific locations, as well as in the Caribbean and Mediterranean Sea regions, where observed WL
216 variations are solely due to atmospheric effects.

217 **3.3 Energy Decay Analysis and β factor calculations**

218 We calculate the energy decay of the Tonga event and compare to other recent tsunamis. Following
219 Rabinovich, (1997) and Rabinovich et al (2013), we detide 1-min NOAA WL data, remove any residual trend,
220 and then produce power spectra for 4hr segments of the WL residual, with an overlap of 2 hours between
221 successive analyses. A multi-tapered method (McCoy et al., 1998) was applied, because it reduces noise and edge
222 effects, but still conserves energy. The energy within the tsunami band (between 10 minutes and 3 hours) was
223 then integrated for each 4hr period and an exponential decay model of form $E = E_o e^{\frac{-t}{t_d}}$ applied, where E_o is the
224 peak energy in the fit and t_d is the e-folding (decay) time scale.

225 We use the P_A -spike and **the related** WL fluctuation amplitudes to estimate β at locations where the **VMT**
226 was observed and where co-located or nearby P_A records were available. β is calculated as the ratio of the
227 maximum (positive) residual WL **at VMT arrival** divided by the maximum (positive) air pressure spike, with P_A
228 converted to a WL level fluctuation assuming the usual inverted barometer effect of 10mm WL change for 1mb
229 P_A change. In total, we are able to calculate β at 231 locations. For the “first arrival” of **the VMT, we only consider**
230 **waves arriving on 15 January**, but for the β calculations, we use the largest WL amplitude closely following a P_A -
231 spike visible in the record; for many locations in the Atlantic and Mediterranean, this occurred on the second or
232 third pass of the atmospheric disturbance (Jan 16th).

233 **4. Results**

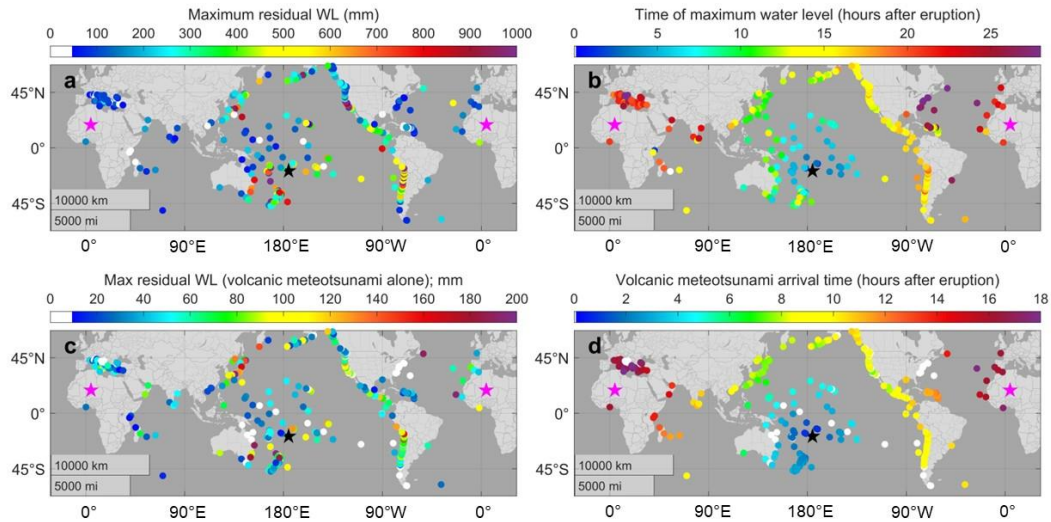

234 **4.1. Global tsunami impacts as determined from tide gauges**

235 The Tonga Event produced a **VMT** with a global footprint, along with a marine tsunami confined
236 primarily to the Pacific (Figure 1). VMT-related perturbations were recorded along the west coast of Africa, in

237 the Mediterranean and Caribbean Seas, in the Indian Ocean, and elsewhere (Fig. 1(a),(c)). Tsunami arrival times
238 at most places closely correlate with arrival of **atmospheric waves** (Fig. 1(b),(d)), which propagated concentrically
239 from the source around the planet, reconverging at the antipode. See also Tables S4-S6 and Figures S3-S12.

240 The largest amplitude far-field WLs from the marine tsunami occurred at dispersed Pacific Ocean
241 locations, without a clear spatial pattern (Fig. 1(a),(b)). Several gauges within 3000 km of the eruption registered
242 tsunamis >1m. Moderate tsunamis were measured at most island locations. In Hawaii, only Kahului measured
243 waves >0.5 m; several islands in French Polynesia also reached this level. Consistently stronger responses
244 occurred around the periphery of the Pacific, with wave heights of >1m at Kushimoto, Japan, four locations in
245 Chile, four locations in California, and one in Alaska. Away from Tonga, the largest maximum and minimum
246 measured WLs in the Pacific occurred at Chañaral, Chile (+1.73m and -1.95m); the largest in the US was Port
247 San Luis, CA, at +1.34m. A ~2m tsunami was reported, but not measured, near Lima ([https://www.nytimes.com/
248 2022/01/21/world/americas/peru-oil-spill-tonga-tsunami.html](https://www.nytimes.com/2022/01/21/world/americas/peru-oil-spill-tonga-tsunami.html)). **VMT amplitudes** are small (<0.1m) in most
249 locations (Fig. 1(d)), moderate (up to 0.15m) at certain locations in Chile, the Northeastern Pacific, Russia, and
250 Hawai'i, and up to 0.22 m at some locations in Japan, Australia, and New Zealand (Table S5).

251 The “first arrival” map (Fig. 1(c)) shows a circular pattern emanating outwards from Tonga. Robust
252 regression between the **VMT** first-arrival times and the distances from Tonga yield a slope of $1115 \pm 3 \text{ km hr}^{-1}$
253 (Figure S2), about 90% of the sound speed at sea-level (1225 km hr^{-1}), and similar to the estimate of 1080-1170
254 km hr^{-1} for the Krakatoa tsunami (Garret, 1976). Estimates from tide-gauge arrivals yield a smaller **VMT celerity**
255 estimate ($1054 \pm 7 \text{ km hr}^{-1}$; Figure S2(b)), because the waves observed at tide gauges are subcritical, free waves that
256 fall behind the Lamb waves in coastal waters. A similar regression analysis gives a celerity estimate of $708 \pm 8 \text{ km}$
257 hr^{-1} for the oceanic wave, consistent with a mean ocean depth of about 5km. In the Pacific, the **fairly regular VMT**
258 arrival pattern can be contrasted with the less regular arrival times of the largest maximum/minimum amplitude
259 marine tsunami (Fig. 1(b)) and the time difference between “first arrival” and highest water level (Figure S9 and
260 S10). The latter emphasizes that **the VMT** can occur some hours before the marine tsunami, where both were
261 observed.

262

263 **Figure 1.** Tonga tsunami global manifestations: (a) maximum amplitude of combined volcanic (VMT) and marine
 264 tsunamis; (b) time of maximum amplitude; (c) first arrival VMT amplitude; and (d) VMT arrival time. White
 265 markers in (c) and (d) indicate locations where meteotsunami properties could not be determined. The location of
 266 the eruption and its antipode are shown by black and magenta stars, respectively.

267

268 Several Indian Ocean tide gauges (East Africa, Oman, Sri Lanka, and India) show WL changes shortly
269 after the **atmospheric** waves arrived, but little evidence of a marine tsunami. In the Atlantic Ocean there was a
270 strong signal in Senegal, Ghana, and in the Cabo Verde, Canary, and Azores Islands. **The Azores** showed a large
271 WL amplitude (~0.6m), but this area is undergoing volcanic activity with frequent seismicity. While no nearby
272 air pressure record is available to confirm a relationship to the **meteotsunami wave** here, no strong seismic activity
273 was recorded either, so the causality of this result is uncertain. All of these gauges are located within ~3000 km
274 of the antipode of the Tonga Event (20.54° N, 4.62° E in the Sahara Desert), where the concentric shock waves
275 re-converge. The resulting interference pattern may have increased the magnitude **of atmospheric waves and the**
276 **subsequent VMT.**

277 In the Eastern North Atlantic, small tsunamis occurred after the second pass of the **VMT wave** on 16
278 January, e.g., at St. Johns, Canada (~0.2m). Storminess after 16 January precluded further detection there and in
279 the Baltic Sea; and little or no signal was seen on the European Atlantic Coast at any time. Wide-spread **VMTs**
280 occurred in the Caribbean and Mediterranean Seas, the latter being close to the antipodal point of the shockwave.
281 In both regions, successive occurrences of the **VMT** wave have different impacts on WL variability.

282 **These results** suggest that **VMT** characteristics vary between closely spaced stations, because of local
283 bathymetry, ambient currents, and the orientation relative to the source (Šepić et al., 2015; Garrett, 1976; Williams
284 et al., 2021). **VMT** properties also change with atmospheric stratification and due to dispersion as the shockwave
285 propagates; the directionality of the **VMT** (towards or from land) also matters (Garrett, 1976). Thus, the level of
286 threat from a **VMT** event is locally variable, despite its global reach.

287 ***4.2. Tsunami propagation in the Pacific as determined from deep water buoys***

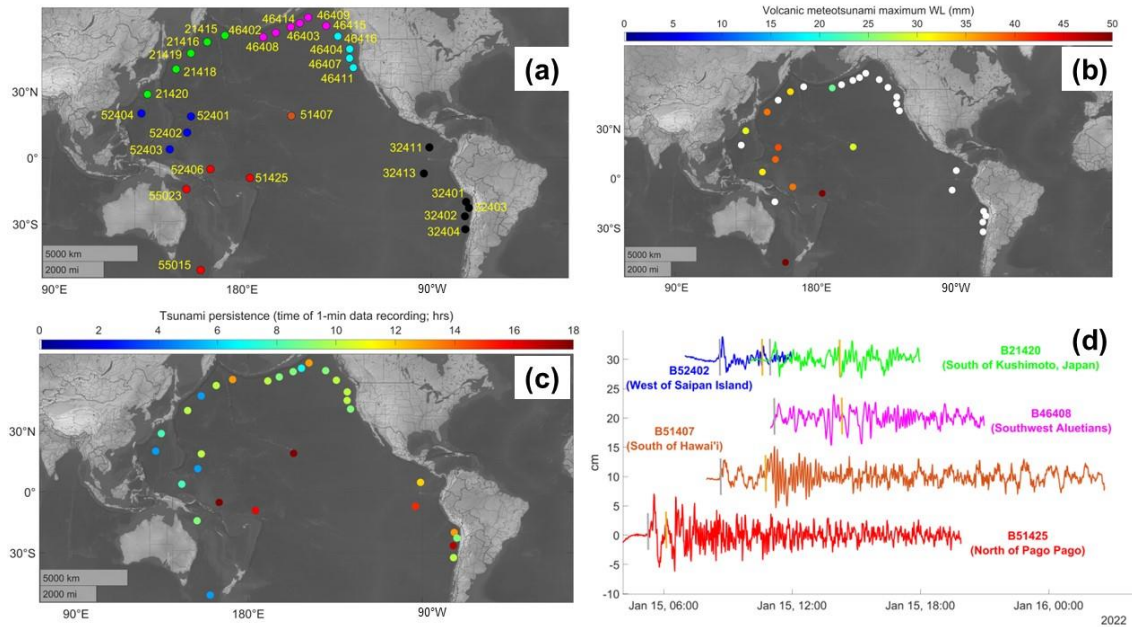

288 The network of **the** National Data Buoy Center (NDBC) deep-water tsunami warning buoys provides
289 significant spatial coverage of the Pacific and can reveal the offshore characteristics of strong oceanic signals like
290 tsunamis (e.g., surface amplitude) without contamination by surface swell. These buoys generally provide a 15-
291 min temporal resolution but, when “triggered” by large signals, record 1-min data. We examined all available
292 buoys but found that many buoys did not record any data at all during the Tonga event. Thirty NDBC buoys in
293 the Pacific recorded at least part of the **marine** tsunami; however, only a subset caught the **VMT** (12 buoys).
294 Locations are given in Figure 2(a) and details of the buoys are given in Table S1. Ten locations measured the
295 **VMT** in the Western Pacific, one in Alaska, one in Hawaii, and none in the Eastern Pacific. The Western Pacific

296 data reveals a similar spike-like waveform, with a steep rise followed by a rapid decrease. The magnitude of the
297 **VMT-induced** WL response is nearly consistent across the basin, except at two of the nearest buoys to Tonga
298 (55015 and 51425), where amplitudes were larger, 70 and 58mm, respectively. All other **VMT** magnitudes were
299 between 25 and 40mm, independent of distance from Tonga (Figure 2(b)).

300 The energy generated by the Tonga tsunami may have been sustained by repeated returns of the
301 atmospheric wave at many locations. Can the spatial characteristics of energy decay be suggested from the limited
302 buoy data? We next make an estimate of the “persistence” of the tsunami in the Pacific by determining the length
303 of time (in hours) that the buoys were “triggered” in each region of the Pacific for one-minute resolution
304 observations. This metric, possibly influenced by instrumental problems at some locations, allows a simple, if
305 imperfect, estimate of tsunami energy decay for individual buoys and for regional averages. **We omit buoy 52406**
306 **(which recorded at high resolution for > 30 hr, for reasons unclear) and determine a median regional "persistence"**
307 **in the southwest Pacific (i.e., the buoys nearest to Tonga) of 9hr, while the buoys immediately west of Tonga had**
308 **a median regional persistence of 6.5 hr. At the periphery of the Pacific, the median regional persistence was 610**
309 **hours in the Northwestern Pacific (Japan and surrounding areas), 9 hours in the Northern Pacific (Alaska), 10**
310 **hours in the Northeastern Pacific (California-Canada), and 13 hours around South America.** Thus, we generally
311 see a longer persistence in far-field Pacific regions than in near-field regions (Figure 2(c)). The maximum **VMT**
312 magnitude (where detected) and the persistence times at all buoys are given in Table S7.

313 A subset of five buoys provides an effective summary of the **VMT** behavior in deep water (Figure 2(d)).
314 Two buoys (52402 and 21420) are close to being a great circle with each other and the Tonga eruption; buoy
315 52402 is ~ 5000 km from Tonga, while 21420 is ~2700 km further towards the southern coast of Japan. The **VMT**
316 maximum WL at the first buoy is about 38mm versus 30mm at the second; the subsequent WL oscillations at both
317 buoys are similar in form. This suggests that the **VMT** response of the oceanic WL decayed very slowly, at least
318 across the Pacific basin. The full set of WL responses at all buoys are given in the Supplement and compared by
319 region (Figures S13-S18).

320

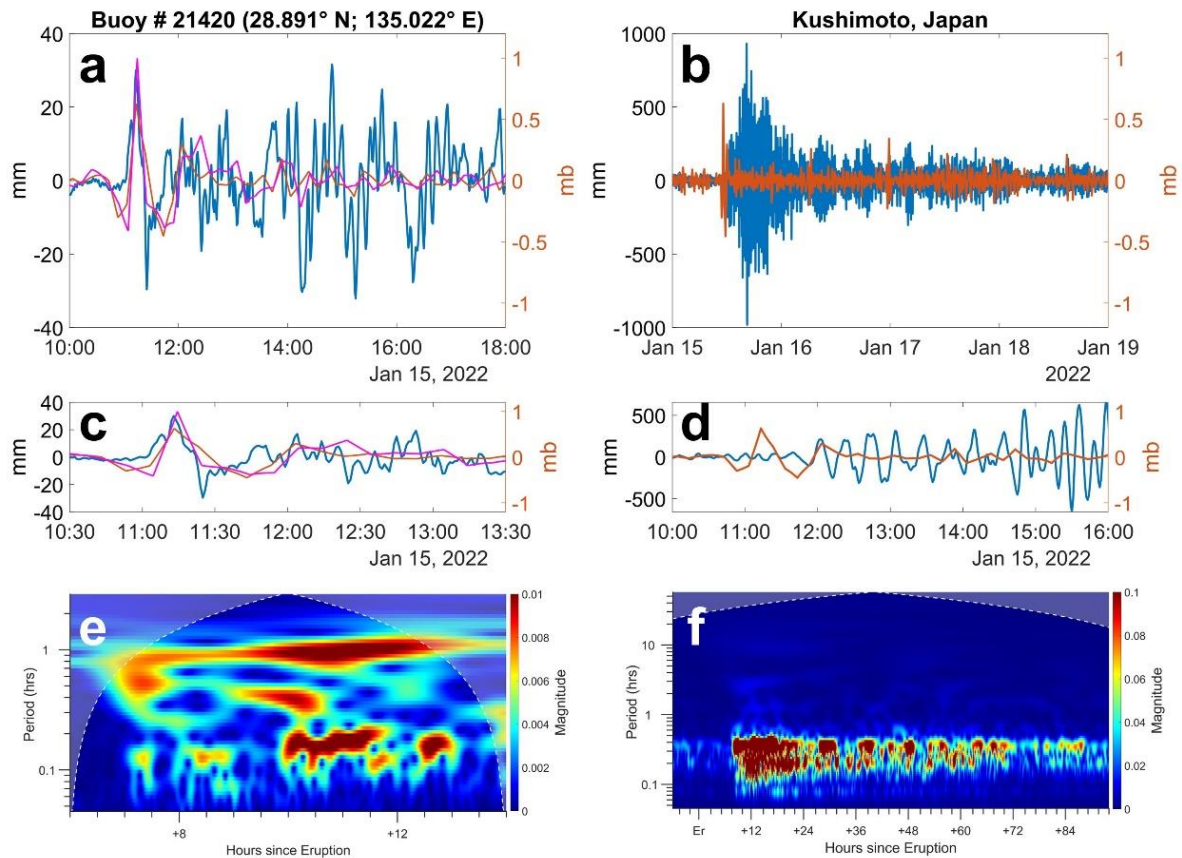

321 **Figure 2** Pacific deep-water NDBC buoys used to detect the VMT and marine tsunami of the Tonga event. (a)
 322 Buoy locations and NDBC buoy designation numbers (Table S1), with colors used to show Pacific regional
 323 delineation (red: Southwest; orange: Central; dark blue: West; green: Northwest; magenta: North; cyan: Northeast;
 324 black: Southeast). (b) Maximum VMT-induced WL (mm) detected at each buoy according to color scale at top of
 325 map. White markers indicated that the VMT was not detected at the buoy. (c) Persistence time of the tsunami
 326 signal at each buoy, representing the length of time that each buoy recorded at 1-minute resolution (hr). (d) WL
 327 response to the VMT and marine tsunami at five deep-water buoys in the Pacific using same color scheme as (a).
 328 Two buoys are given on the same line (B52402 and B21420) since their physical locations were on nearly the
 329 same great circle path from Tonga; other buoys are offset 10 cm vertically from each other. VMT arrivals based
 330 on a theoretical travel time of 1115 km/hr⁻¹ are indicated by grey vertical lines, and marine tsunami arrivals based
 331 on an average travel time of 700 km/hr⁻¹ are indicated by orange vertical lines.

332

333 **4.3 Coastal characteristics of VMTs**

334 As the **VMTs** propagated from deep water to the coast, we observed several cases in which an abrupt
335 change in geometry produced a large amplification. We return to the example of buoys 52402 and 21420
336 discussed above, and now compare data from the buoy closer to Japan (21420) with the nearest coastal tidal
337 gauge that also has P_A data, Kushimoto, Japan (Figure 3). The first **Lamb wave with a pressure change of** ~ 0.6
338 mb occurred at ~ 1130 UT, 15 January at Kushimoto (Fig. 3(a),(c)). The WL response in the P_B record (a positive
339 ~ 30 mm spike then a ~ 30 mm negative one) is direct and presumably represents the forced wave. We compare
340 the two closest P_A records to the P_B data (Aburatsu and Kushimoto; see **Appendix A** for details). Longwave
341 celerity at buoy depth (5700m) is 850 km hr^{-1} ; $a_n = \frac{v^2}{v^2 - c^2} \sim 2.4$, relative to the observed amplification of $\alpha \cong 4$.
342 The CWT scaleogram in Fig. 3(e) shows the WL response to the **shockwave** at ~ 10 hr post-eruption as two
343 relatively distinct bands of energy with periods of ~ 1 hr and 5-10min; these fade within ~ 1.5 hr.

344 Kushimoto WLs effectively illustrate the potential for amplification of **VMTs**. **The first (VMT) waves**
345 arrived between 1200 and 1450UT (Figs. 3(b),(d)), prior to the marine tsunami at about 1450UT; their period is
346 ~ 0.3 hr (Fig. 3(f)); shorter-period energy is seen only after the arrival of the oceanic wave. The initial positive
347 **VMT amplitude** of ~ 210 mm is a response to the atmospheric shockwave and represents an amplification of $\sim 7X$
348 relative to the forced wave, and $\beta \sim 35X$ relative to the **VMT magnitude**, for which the inverse barometer response
349 would be only 6mm. Apparently, the Japan trench with depths to 8km ($a_n \approx 5.5$) and continental shelf between
350 buoy 21420 and Kushimoto allowed considerable growth of the forced wave relative to Fig. 3(a),(c). A large
351 volcanic explosion (**such as Krakatoa**) could yield a shockwave with a magnitude of 30-60mb (Schufelt, 1885),
352 which could potentially drive a **disastrous VMT at this location before the arrival of the oceanic waves**.

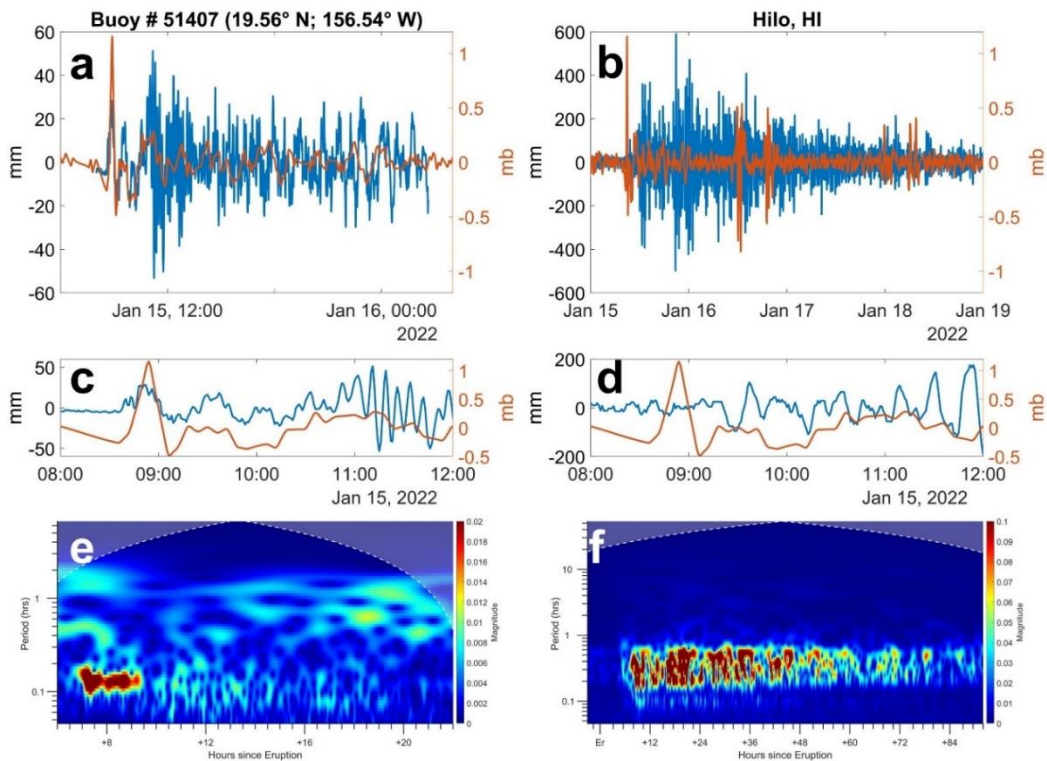

353

354 **Figure 3.** Tsunami response at NOAA P_B buoy 21420 and a coastal tide gauge (Kushimoto, Japan): (a) Residual
 355 P_A at Kushimoto (orange) and Aburatsu (magenta), and detided residual buoy WL (blue) with P_A records shifted
 356 plot 26 and 16min to account for distance from the buoy (see Appendix A for details); (b) P_A (orange) and detided
 357 residual WL (blue) at Kushimoto; (c) expanded view of (a) showing arrival of a **VMT** as a supercritical forced
 358 wave at 1150UT, ahead of the **oceanic** wave at 1450UT (c); (d) expanded view of (b) showing the arrival at
 359 Kushimoto of the **VMT** as a subcritical free wave at 1200UT; (e) buoy residual WL CWT scalogram, 6-14hr post-
 360 eruption; (f) Kushimoto WL CWT scalogram for 92hr post-eruption.

361

362 Observations near Hilo show similar phenomena to those observed at Kushimoto (Figure 4). We use
363 NOAA tsunami bottom-pressure (P_B) buoy 51407 in 4.7 km water depth south of Hilo combined with
364 atmospheric-pressure (P_A) and WL data from Hilo (NOAA station 1617760). Fig. 4(a),(c) show P_A and P_B data
365 (converted to WL). Despite the distance (~ 100 km) between the two records, the WL and P_B responses are almost
366 simultaneous, at 0854 UT. The first P_A pulse of ~ 1.5 mb elicits an oceanic response of ~ 30 mm ($\alpha \sim 2$) of the same
367 sign, as expected for a super-critical wave and similar to the response at Kushimoto. This modest amplification is
368 still slightly larger than expected for $\alpha_n \sim 1.2$. Smaller positive WL pulses follow the first; after the third, these
369 pulses are overlain by the beginnings of the ocean tsunami signal at ~ 1030 UT. These may be a soliton train, as
370 predicted by the nonlinear theory (Pelinovsky et al., 2001). The CWT scalogram in Fig. 4(e) shows that ocean
371 waves with periods of 0.15-0.2hr arrived at buoy 51407 before 1100 UT; shorter waves (periods < 0.1 hr) arrived
372 later, confirming the weakly dispersive character of the ocean waves. The **VMT** is also clearly visible. It appears
373 just before 0900 as a broadband signal with periods of 0.4-1.1 hr. Over time, the pulse shifts to higher frequencies
374 and then disappears by ~ 1200 UT.

375 The Hilo detided residual WL data present quite a different appearance from the offshore P_B data (Fig.
376 4(b),(d)). The first wave arrival (~ 120 mm) occurs at 0928 UT (~ 1 hr after the P_A -spike) with a *negative* excursion
377 rather than a *positive* one. This is followed by a series of smaller oscillations leading up to the arrival of the marine
378 tsunami at about 1137 UT. The forced wave is not evident, and the early arriving **VMT** waves at Hilo are likely
379 free waves that have propagated around the island on which Hilo sits and then amplified, having been generated
380 at the abrupt rise of the island platform; the total amplification is $\beta = 9X$. The waves from the ocean tsunami wave
381 reach ~ 400 mm, which represents an amplification of about $5X$ relative to the same P_B waves at the buoy. Records
382 from nearby Hawaiian gauges show similar features. The CWT scalogram for Hilo WL in Fig. 4(f) emphasizes
383 the absence of longer period tsunami waves with periods around 1 hr. Instead, the **weak VMT WL** response is
384 followed by waves with similar periods, ~ 0.15 to 0.7 hrs. Over the next several days, the oscillations weaken, with
385 the shortest period waves disappearing first. Hilo is well known to be resonant to tsunamis, and our observations
386 may be related to quarterwave resonance (Pattiaratchi and Wijeratne, 2015; Tang et al., 2017). However, other
387 Hawai'ian tide gauges shows behaved similarly to Hilo.

389

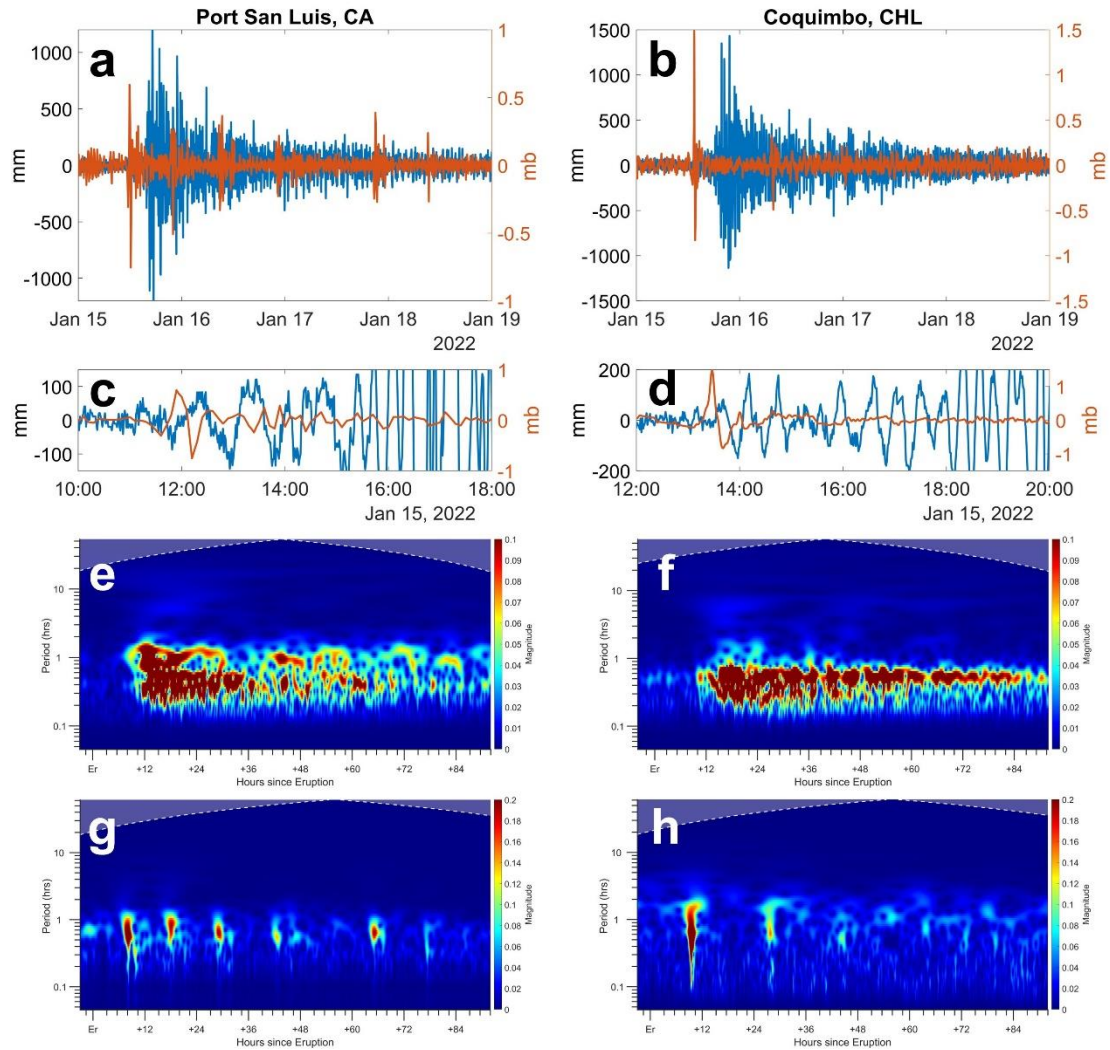

390 **Figure 4.** Comparison of WL (blue, mm) and P_A (orange, mb) at offshore buoy 51407 and Hilo, HI. (a) P_A at
 391 NOAA tide gauge 1617760 Hilo, HI and detided WL residual from NOAA P_B Buoy 51407 south of Hawai'i
 392 following the Tonga Event; (b) P_A and detided residual WL (blue) at Hilo; (c) expanded view of (a) showing the
 393 arrival of the **VMT** at Buoy 51407 in the form of a supercritical forced wave at 0854 UT, ahead of the **oceanic**
 394 wave arrival at ~1054 UT (c); (d) expanded view of (b) showing the arrival at Hilo of the **VMT** in the form of a
 395 subcritical free wave at 0928 UT; (e) a CWT scalogram of buoy heights from P_B for hr 6-24 post-eruption; (f) a
 396 CWT scalogram of WL measured at Hilo for 92hr post-eruption.

397

398 Kushimoto and Hilo are only two examples of **VMT effects in the Pacific**. **VMT-induced WL** magnitudes
399 were similar to Kushimoto at other Japanese locations and were 50-210mm in New Zealand and Eastern Australia.
400 Much smaller (~20mm) **VMTs** were seen in the South China Sea, though 1-min data were available at only two
401 locations (Hong Kong and Shenzhen; **Wang et al., 2022**). In the Eastern Pacific, distant from Tonga, **VMT waves**
402 arrived 3.5 (California) to 5hr (Chile) before the marine tsunami, allowing their WL effects to be easily
403 distinguished (Fig. 1(a),(c), Table S3), and both regions had particularly large maximum tsunami magnitudes
404 (positive and negative swings). Air pressure (P_A) spikes of ± 0.6 - 0.7 mb and $+1.5$ and -0.8 mb at Port San Luis, CA,
405 and Coquimbo, Chile (Figure 5) led to **wave excursions** of $+110$ and -150 mm, respectively, with total
406 amplifications of $\beta \sim 15$ - $25X$ at Port San Luis (Fig. 5(c), and $\sim 6X$ (positive wave) and 30 - $40X$ (negative wave) at
407 Coquimbo (Fig. 5(d)). There were at least six arrivals of the **shockwave** over 3d. This recurrence, coupled with
408 very long decay times (below) caused WL disturbances to continue for >90 hr, emphasizing the role of the **VMT**
409 in recharging **the combined marine and volcanic tsunami** (Fig. 5 (e-h)).

410 **These Pacific examples demonstrate combined marine and VMT impacts; in other regions, the VMT**
411 **occurs in isolation**. At Charlotte Amalie in the Caribbean (Figure 6), the P_A -spikes and resulting **VMTs** are well
412 correlated (Fig. 6(a)). The first P_A -spike of ~ 1.2 mb led to waves of 80mm about an hour later, apparently from
413 the free wave (Fig. 6(b)). In contrast, the third P_A -spike of ~ 0.5 mb apparently excites a forced wave with amplitude
414 of about 50mm, simultaneous with and of the same sign as the P_A -fluctuations (Fig. 6(c)). Waves arriving an hour
415 later and presumably representing the free wave were larger, ~ 80 mm, giving $\alpha \sim 16$. The fourth P_A -spike $\sim \pm 0.2$ mb
416 again excited a forced plus free wave response, with the later waves being as large at ± 100 mm (Fig. 6(d)). This
417 corresponds to an impressively large $\beta = \sim 30$. The CWT scalogram shows that water level in this harbor responds
418 most strongly at periods of ~ 0.5 to 0.9 hr (Fig. 6(e)). The CWT of P_A shows eight spikes at ~ 12 hr intervals,
419 suggesting that the **shockwave** circled the planet at least four times (Fig. 6(f)). The largest WL response occurred
420 from the fourth **VMT** (Fig 6(e), (f)) for yet unknown reasons. Other gauges in the Caribbean showed significant
421 **VMT effects** (Figure S11) that were strongest on the second or third pass of the atmospheric disturbance. While
422 β varies with the event, there are numerous volcanoes in the Caribbean, and severe tsunamis (**both VMT and**
423 **marine**) could be a very real threat in locations where amplification occurs.

424

426

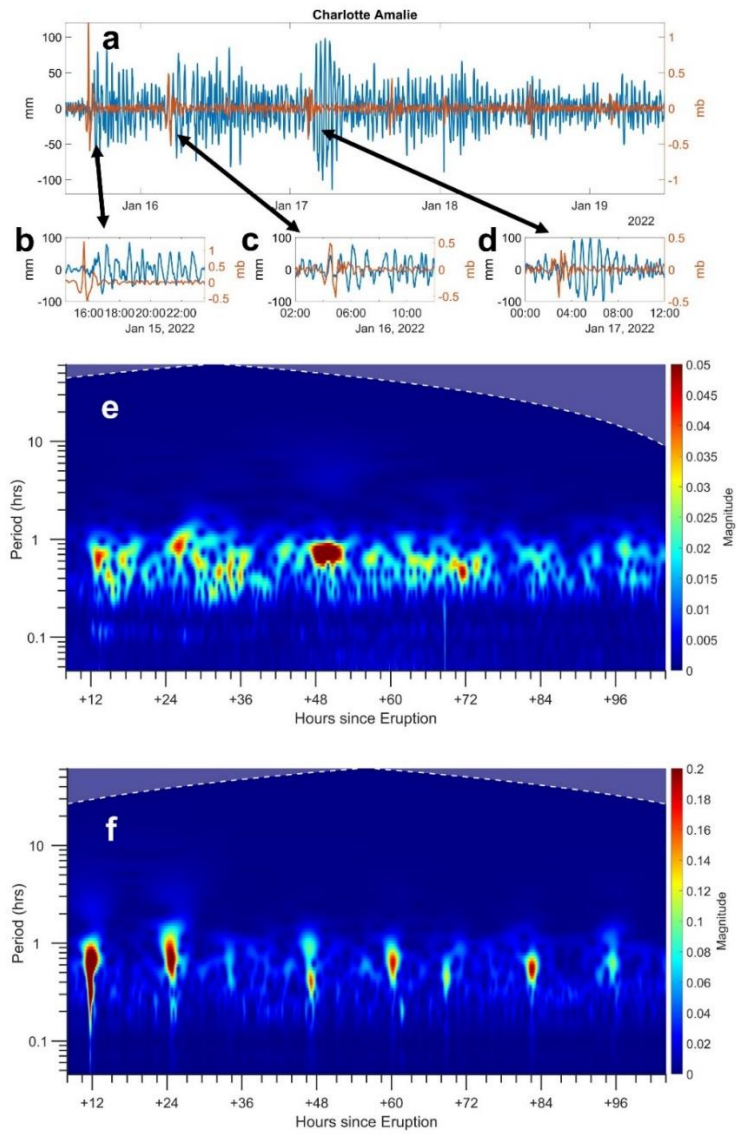

427 **Figure 5.** Residual WL (blue, mm) and detrended air pressure (orange, mb) at: (a) Port San Luis, California
 428 (NOAA Station 9412110) and (b) Coquimbo, Chile; (c) and (d) expanded views of (a) and (b) of the WL and P_A
 429 records **showing the initial arrivals of the VMT and marine tsunami**); and scalograms from CWT analyses of WL
 430 in (e) and (f) for P_A in (g) and (h). Vertical scales in (c) and (d) are set to a small range to highlight the **VMT**
 431 impacts.

432 The shockwave magnitudes were generally smaller in the Mediterranean than in the Caribbean, perhaps
433 because of the greater distance from Tonga and the complex land topography in the region. Still, **VMT-induced**
434 **meteotsunamis** were measured at many locations; they were largest in Sicily, Sardinia, and the “boot” of Italy.
435 Because this region is close to the antipode, the first P_A waves arriving from opposite directions were only a few
436 hours apart, occurring at ~2000 and 2330 UTC on 15 January, and producing a wave packet rather than a clear
437 P_A -spike that swept across the region. A weaker second packet occurs 38hr later at ~1200 UTC on 16 January,
438 followed by a third packet at ~0000 UT on 19 January, not seen at all stations. WL records usually show a single,
439 long-lasting event following the first P_A -packet arrival, with muted responses for the second and third packet. The
440 largest tsunami amplitude, ~300mm (Figure S12), occurred at Crotona, Italy after a steady build-up from the **VMT**
441 **arrival**. At a small number of stations, e.g., Cagliari, Italy, there were multiple **VMTs**, as in the Caribbean (Figure
442 S11). Finally, a few locations in the Adriatic Sea had no response to the first wave packet but responded strongly
443 to the **second VMT**, with $\beta \approx 8 - 13$. Thus, the discrete response of WLs to individual shockwaves is not as clear
444 in the Mediterranean as in the Caribbean, though **repeated passes of the shockwave lead to sustained WL**
445 **variability**.

446 **4.4. Energy decay**

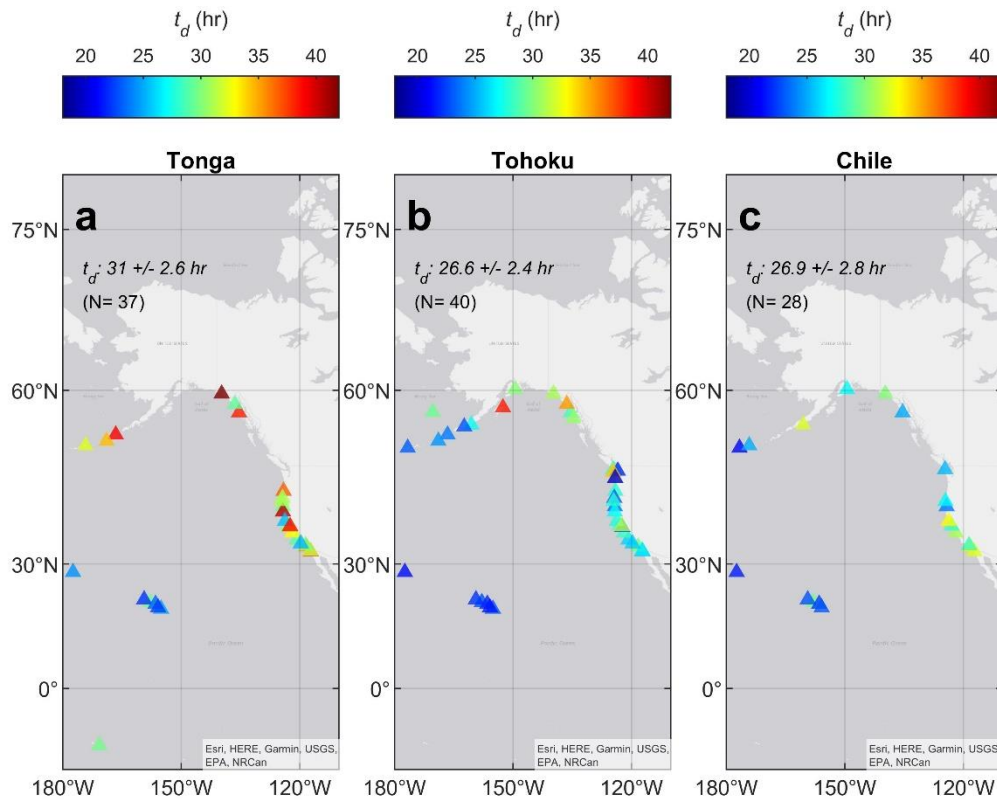

447 The Tonga event released significant energy and its tsunami persisted longer in the Pacific than other
448 recent tsunamis. Our estimate of energy E_o for the Tonga Event (0.0096m^2 , $N=37$) is comparable to the Chilean
449 event (0.01m^2 ; $N=28$) and about 3.8x less than the Tohoku Event (0.036m^2 ; $N=40$). Previous estimates for the
450 Chilean and Tohoku Events were 0.009m^2 and 0.032m^2 , respectively (Rabinovich et al., 2013). Decay time scales
451 for the Tonga Event varied from 29-44hr in Alaska, 25.4hr (Santa Barbara) to 37hr (San Diego) on the US West
452 Coast, and 22.2hr (Nawiliwili, Hawaii) to 29.3hr (Pago Pago, Samoa) for island stations (Figure S19). The Tonga
453 decays are notably longer than other events, especially in Alaska and (most) California locations. The differing
454 timescales depend on distance from the event, frequency content (high frequency decays more quickly), and
455 shallow water processes (Rabinovich et al., 2013). Our estimated median t_d values for the Tohoku, Chile and
456 Tonga events are $26.6 \pm 2.4\text{hr}$ ($N=40$), $27.6 \pm 2.8\text{hr}$ ($N=27$) and $31.0 \pm 2.6\text{hr}$ ($N=37$), respectively (Figure 7). Previous
457 estimates for the Tohoku and Chilean Events were 24.6 and 24.7hr. The longer decay time of the Tonga Event
458 emphasizes the importance of the **VMT**. Though the **VMT was smaller than the marine tsunami**, it was refreshed
459 by the Lamb waves that repeatedly circled the planet. The long energy decay scales calculated for the Northern
460 Pacific are in line with our simple estimates of decay taken from the buoys; longest in the Northern/Northeast
461 Pacific and near Tonga (e.g., Hawai'i and Pago Pago).

462

463

464 **Figure 6.** VMTs at Charlotte Amalie (NOAA gauge 9751639) in the Caribbean: (a) Residual WL variability
 465 (blue) and P_A (orange) from UT 15 to 19 January 2022; (b)-(d) expanded views of (a) at the times of the 1st, 2nd,
 466 and 4th P_A -spikes; (e) and (f) CWT scalograms of the WL and P_A records in (a).

467

468 **Figure 7.** Decay timescales (hours) of recent tsunami events at NOAA gauges in the Northern Pacific; showing
 469 (a) Tonga; (b) Tohoku; and (c) Chile. Median t_d , errors, and number of stations used are given in each panel.

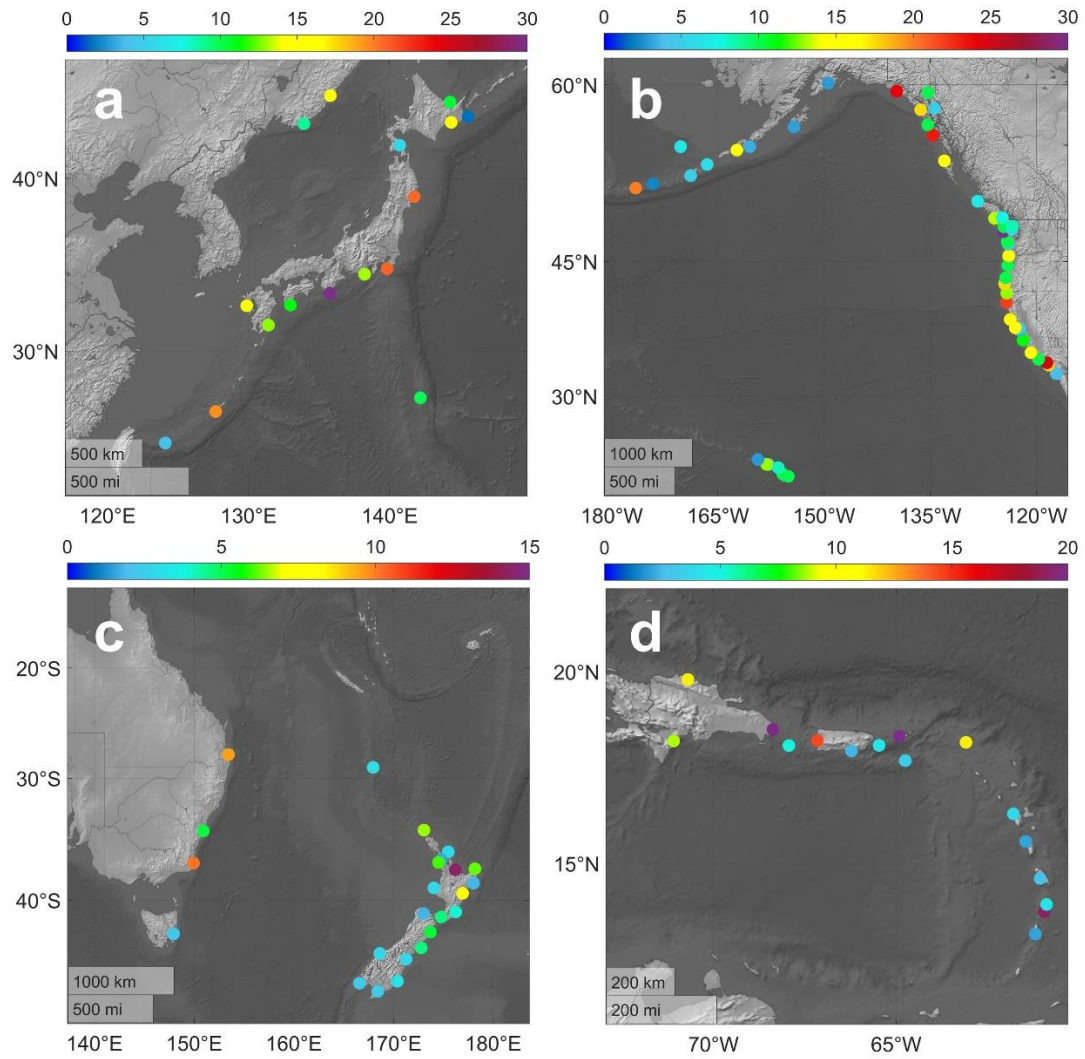

470

4.5. Amplification, β

471

Amplification, β , is a vital indicator of **future VMT hazards**. It was calculated for ~75% of all tide gauge
 472 locations where the **shockwave** was detected in a nearby P_A record (Tables S5 and S6). Clearly, β is highly local,
 473 with values of 15-35 at 26 stations in all regions where **the VMT** was observed; over 40 locations had $\beta > 10$
 474 (Figure 8 (a-d)). The largest values of β are seen in Japan, the Northeast Pacific, New Zealand and Australia, and
 475 the Caribbean. Wherever high β values are observed near an active volcano, there is the potential for a **large VMT**.
 476 Note that β values are uncertain by ~30% (see Appendix A), mainly due to the uncertainty of P_A observations
 477 which have low amplitudes and coarse temporal resolution.

478

479

480 **Figure 8.** Amplification, β in: (a) Japan; (b) the Northeast Pacific; (c) New Zealand and Australia; and (d) the
 481 Caribbean. Note diverse color scales.

482

483 5. Discussion

484 Analyses of high-resolution WL data from tide gauges (with local P_A , where possible) provides an
485 unprecedented global view of a volcanic meteotsunami (VMT) acting together with a marine tsunami. A moderate
486 marine tsunami was measurable at nearly all Pacific Ocean tide gauges and deep-water buoys, but at only a few
487 stations elsewhere. In addition, most tide gauges and about half of the deep-water buoys also observed the VMT.
488 In the North Pacific, wave amplitudes and energy were comparable to the Chilean Event. Out of 308 tide
489 gauges, 10 showed a total VMT amplification (β) of > 20 , 54 were >10 , 113 were >5 , 204 were 2 or more, and
490 230 were 2 or less; the remainder did not register any detectable VMT signal. Hence, significant amplification is
491 a localized, but still potentially important, process. We note that much of the world's coastline is still not gauged,
492 and there are many locations in which the VMT was amplified, but not measured, e.g., Lima. Thus, the Tonga
493 Event tsunami was “global” because of the reach of the VMT and its impacts on WLs.

494 In the Pacific, the VMT preceded the marine tsunamis by up to five hours and the two together produced
495 observable perturbations in water levels for more than three days after the eruption. The effects of atmospheric
496 gravity waves were observed in ocean bottom pressure data after the arrival of the lamb waves and before the
497 oceanic component arrived. However, we observed a delay (~1-2 hours) of the water level response to the
498 shockwave at coastal tide gauges. This delay may be related to the “sequencing” of tsunami waves and
499 observations that the first wave of a tsunami is not always the largest (Okal and Synlokas, 2016). However, this
500 suggestion is based on “traditional” seismic tsunamis; it is not clear if VMTs follow exactly the same physics.

501 How can we place the Tonga event in a larger context? This Event drove VMTs no larger than ~210mm
502 in the far field due to shockwave magnitudes of ~0.5 to 5 mb. However, the total amplification, β , varied from ~1
503 to 35 \times . Values at the larger end of this range were mainly seen at coastal locations; island locations typically had
504 $\beta < 5$, with only a few exceptions (e.g., Hawai’i and Naha). The reasons why certain regions exhibited a larger
505 amplification (e.g., β) than others, and the possible role of bathymetry, remain to be understood, e.g., through
506 model studies like Denamiel et al. (2022). It seems likely, however, that locations with an ocean trench between
507 the source and the coastal station are at particular risk; this is typical for much of the Pacific “Ring-of-Fire”, as
508 conceptualized in Figure 9. We assume a 5mb Lamb wave travelling over deep water which initially induces a
509 forced wave WL fluctuation of 60mm. After travelling some distance, the forced wave grows four-fold. The
510 trench, with F_a near unity, increases VMT amplitude even if the trench is narrow relative to the wavelength of the
511 longer-period tsunami components. Coastal and harbor processes, which can vary substantially along a coast,
512 provide a further boost. Taken together, these processes can an amplification of up to $\beta = 36$ (as suggested in

513 Figure 9), in which case an initially modest (5mb) P_A -spike and corresponding WL fluctuation of 6cm can become
514 a ~1.8m tsunami.

515 The **VMT** from the Tonga event was small, but β was >10 in many parts of the world with active
516 volcanoes, including Italy, Alaska, Japan, and New Zealand. A much larger **VMT** can occur close to a VEI 6-7
517 volcanic explosion. For example, in 1883, ship barometers measured fluctuations of 1-2 inches of mercury (30-
518 60mb) near Krakatoa (Symons, 1888). Taking 30mb as a conservative upper limit for a VEI 6 event and $\beta = 10$ to
519 35, a **VMT** of 3.5 to ~10m is possible. In most cases, this would be later followed by larger water waves, but the
520 rapid arrival of **VMT waves** of this size could be catastrophic and might occur in some locations without being
521 followed by a marine tsunami. Moreover, Krakatoa is not the largest historical event by any means—the **Santorini**
522 (**~1800YBP**) and **Tambora (1817)** events were much larger (Newhall and Self, 1982), but these events lack data
523 regarding **VMT impacts**.

524 Present-day warning systems are designed for marine tsunamis, and do not generate timely warnings for
525 **meteotsunamis of any origin**, as noted by Vilibić et al. (2016). **Future warning systems should consider both**
526 **marine and VMT threats**, but this is not straightforward, because of differences in the causation and warning times
527 **between weather and volcanic meteotsunamis**. **Weather conditions for meteotsunami genesis**, which evolve over
528 **days**, may be able to be at least partially predicted, and this threat is confined to specific regions. **Volcanic**
529 **eruptions are a different problem**. The **VMT threat is global**, **VMTs can cross an ocean basin in a matter of hours**,
530 **given the rapid shock wave celerity (~1100 km hr⁻¹)**, and their magnitude can be larger. **This possibility deserves**
531 **further consideration**.

532 **6. Conclusions**

533 **In summary**, there are several conclusions regarding the **VMT from the Tonga Event**:

- 534 • It arrived before the oceanic wave at all stations where both were observed, though the oceanic wave
535 was larger at stations where both occurred.
- 536 • **The atmospheric shockwave transited the globe multiple times; on every pass it imparted additional**
537 **energy to WL fluctuations which sustained or re-excited the VMT**, leading to a ~25% longer decay
538 timescale than for recent marine tsunamis generated by earthquakes.
- 539 • The re-focusing of the **shockwave in the atmosphere** near the antipode of the eruption may have
540 increased nearby tsunami amplitudes in Africa and the Mediterranean. The reasons for the strong
541 Caribbean response are yet unclear.

547
548
549

- The first wave observed at deep-water pressure gauges was the super-critical **VMT-forced wave** predicted by theory, but at most tide gauges only the sub-critical free wave response was observed.
- The nominal amplification, a_n , shows that deep water allows strong growth of the forced wave beneath a **VMT** (Proudman resonance). The large total amplification, β , at Japanese coastal stations suggest that deep water trenches around the Pacific “Ring-of-Fire” (with its many volcanoes) and elsewhere may increase the potential for **large, even catastrophic, VMTs**.

551

552 **Figure 9.** Conceptual view of amplification of a **VMT**, based on Tonga-Event observations. **An initial shockwave**
 553 **amplitude of 5mb** is amplified by Proudman resonance in the trench, and again by shallow water processes, after
 554 reflection of a free wave by the steep topography landward of the trench. With $\beta = 36$, a 1.8m tsunami occurs at
 555 the tide gauge. A larger **VMT** would lead to a proportionally larger response.

556

557 **Appendix A: Extended Details of Materials and Methods**

558 ***A1. Data Inventory***

559 We acquired one-minute resolution data from the following sources: the European Commission (EC)
560 World Sea Levels Database (<https://webcritech.jrc.ec.europa.eu/SeaLevelsDb/Home>), the Intergovernmental
561 Oceanographic Commission (IOC) sea level station monitoring facility (<https://www.ioc-sealevelmonitoring.org/>;
562 VLIZ, 2022), the National Oceanic and Atmospheric Administration (NOAA) CO-OPS Tides and Currents
563 tsunami warning network (<https://tidesandcurrents.noaa.gov/tsunami/>), and Land Information New Zealand
564 (<https://www.linz.govt.nz/sea/tides/sea-level-data/sea-level-data-downloads>), plus data obtained by direct
565 communication from the National Institute of Water and Atmospheric Research (NIWA) of New Zealand
566 (<https://niwa.co.nz/our-services/online-services/sea-levels>). Other stations from these networks with less frequent
567 data were used when 1-min data were not available. Tidal predictions and residuals are provided in the EC and
568 NOAA databases, however, a tidal signature or a slope sometimes remains in the provided residuals, and the IOC
569 and NIWA data does not provide any predictions. Therefore, we apply an EEMD analysis (Huang et al., 1998) to
570 all WL data to remove low frequency components and biases in mean water level to yield data in which the
571 tsunami signal is dominant.

572 Air pressure (P_A) records at 1-minute resolution is downloaded from the Chilean Meteorological
573 Directorate (CMD; <https://climatologia.meteochile.gob.cl/>), the Australia Bureau of Meteorology (BOM;
574 <http://www.bom.gov.au/climate/data/>), and the Istituto Superiore per la Protezione e la Ricerca Ambientale
575 (ISPRA; <https://www.mareografico.it/>) network for Mediterranean locations, 6min P_A data is downloaded from
576 NOAA at tide gauges and P_B data from offshore buoys in the Pacific and Caribbean
577 (<https://tidesandcurrents.noaa.gov/stations.html?type=Meteorological+Observations>;
578 <https://www.ndbc.noaa.gov/obs.shtml>), and 10-min P_A data is acquired from the Japan Meteorological Agency
579 (JMA; <https://www.data.jma.go.jp/obd/stats/etrn/index.php>) and the National Institute of Water and Atmospheric
580 Research National Climate Database (NIWA/NCD; <https://cliflo.niwa.co.nz/>). A total of 137 air pressure locations
581 were used, listed in Table S5.

582 Finally, we download data from 30 Pacific deep-water buoys (see Table S1) from the National Data Buoy
583 Center (NDBC; <https://www.ndbc.noaa.gov/obs.shtml>) tsunami warning center operated by NOAA; these provide
584 1-min data during “active” WL events and 15-min data otherwise. Other buoys were investigated, but because the

585 buoys only sometimes operated at 1-min resolution, many were not triggered until the **VMT wave had passed;**
586 **thus, it was most** often not captured. All buoy data and air pressure data were conditioned using EEMD as
587 described above.

588 *A2. Water Level (WL) Analysis*

589 **VMT** magnitudes and arrival times, and the amplitudes of the largest positive and negative tsunami
590 waves at each location are determined from the WL residuals via numerical and visual estimation of the residual
591 time series. The “first arrival” times and amplitudes represent the effects of the **VMT**, which travels faster than
592 the marine tsunami; times are determined by finding the rising edge of the first obvious anomalous wave in the
593 residual WL time series, and the **VMT** amplitude is defined as the maximum WL immediately after the first arrival
594 (Table S3). At a small number of locations, the **VMT** wave could not be clearly observed, as noted in Table S3,
595 and in Figs. 1(c),(d). We compare the distances and first arrival times at all tide gauges stations via robust
596 regression (Holland and Welsch, 1977) and find an estimate of the **VMT** velocity from the slope of the regression
597 as $1054 \pm 7 \text{ km hr}^{-1}$ (Figure S11(b)), slightly less than that estimated from the air pressure gauges ($1115 \pm 3 \text{ km hr}^{-1}$;
598 Figure S11(a)). These estimates can be compared to the much slower celerity estimate for the water wave
599 component of the tsunami ($708 \pm 8 \text{ km hr}^{-1}$; Figure S11(c)), clearly demonstrating that the “first arrival” WLs are
600 due to the **VMT**. Note that the water-wave celerity corresponds to an average water depth of about 5km.

601 The timings and amplitudes of the largest positive (negative) waves due to the marine tsunami are
602 determined by when the first local maximum (minimum) occurs after the first arrival of the tsunami. **At some**
603 **locations, slightly larger amplitudes are seen many hours later, usually on the following tidal cycle (i.e., “tidal**
604 **pulsing”), while other locations have the largest wave arriving a few oscillations after the arrival; the latter may**
605 **be due to the issue of “sequencing” as described by Okal and Synolakis (2016).** WLs and times for maximum
606 WLs, as well as the differences between extreme levels and the **VMT** arrival are given in Table S2 and Fig. 1(a),(c)
607 and Figure S5 and S6, and the same parameters for minimum WL are provided in Table S4 and Figures S7 and
608 S8. The time differences between “first arrival” and max/min WLs are shown in Figures S9 and S10.
609 Determination of **VMT** (“ P_A -spike”) amplitudes was carried out in the same manner as for the tsunami amplitudes.

610

611 ***A3. Air-pressure gauge choices for Kushimoto***

612 Comparison of the Kushimoto tide gauge WLs to offshore buoy #21420 and air pressure (Figure 3) raises
613 the difficulty that there is no P_A station within more than 300km of the buoy; we use, therefore, the two nearest.
614 Aburatsu (~465 km) is on a direct line from Tonga and the buoy, while Kushimoto is 305 km from the circle
615 centered on Tonga through the buoy. Accounting for the distance between the coastal gauges and the buoy using
616 a shockwave velocity of 1092 km hr⁻¹ (Table S3), we shift the time index of the P_A records by 16 and 26 minutes,
617 respectively. Both P_A records are used, because the sparse, 10 min, resolution of the P_A records precludes either
618 from completely capturing the **VMT**.

619 ***A4. Energy Decay Analysis***

620 Following (Rabinovich, 1997), we detide 1-min NOAA WL data, remove any residual trend, and then
621 produce power spectra for 4hr segments of the WL residual, with an overlap of 2 hours between successive
622 analyses. A multi-tapered method (McCoy et al., 1998) was applied, because it reduces noise and edge effects,
623 but still conserves energy. The energy within the tsunami band (between 10 minutes and 3 hours) was then
624 integrated for each 4hr period and an exponential decay model of form $E = E_o e^{\frac{-t}{t_d}}$ applied, where E_o is the peak
625 energy in the fit and t_d is the e-folding (decay) time scale. To account for the initial “diffusion period” (Van Dorn,
626 1984; 1987), the two initial, largest energy values were removed; hence, E_o represents the energy at the
627 commencement of exponential decay. The exponential decay was fit to all tsunami-band energy values until
628 measurements dipped below the noise floor. The noise floor was defined as the 80% percentile energy in the
629 tsunami band from 7-12 days after the event. Each fit was examined for validity, and the range of points in the
630 fit was manually adjusted in five cases. For fits for which the standard error in the coefficients was more than
631 20%, the coefficient value was removed. The analysis was applied to four events: The 2009 Samoa tsunami, the
632 2010 Chilean tsunami, the 2011 Tohoku tsunami, and the 2022 Tonga tsunami. However, due to the low energy
633 of the Samoa event, we focus primarily on the other three. In our analyses, we also distinguish between coastal
634 and island stations. Unfortunately, high resolution DART data are not presently available over a sufficiently long
635 time scale to repeat the analysis of (Rabinovich et al., 2013) exactly.

636 ***A5. Uncertainty and Errors***

637 The possible sources of uncertainty in this study arise from:

638 1) Instrumental accuracy: Measurements of WL at most locations considered report values to an accuracy of 1mm,
639 and US locations from the NOAA tsunami network are only reported to an accuracy of 10mm. Values are reported
640 to this accuracy in figures and tables. However, due to oceanographic noise from coastal waves and other
641 processes, a “noise floor” of at least 10 mm is likely at all locations. Thus, we assume all locations have an
642 uncertainty of ± 10 mm in the calculations of β below. This noise level represents a small uncertainty in the
643 determination of maximum and minimum tsunami heights, e.g., a 1000mm tsunami wave would have a relative
644 error of 1%. However, there will be a larger relative error in the estimation of the **VMT** WL amplitude, e.g., a 20-
645 200mm **VMT** WL would have a relative error of 5 to 50%. All P_A readings are reported to an accuracy of 0.1mb.
646 Since the P_A fluctuations are mainly in a range of 0.5 to 2.0mb, the instrumental error may be up to 20%.

647 2) Mean offset/bias in residuals: Common estimates for tidal prediction, such as those performed in the
648 downloaded residual products here, subtract tidal components from water levels using harmonic analysis methods,
649 which are typically based on past epochs and may not always remove all tide-related fluctuations or may include
650 a bias due to sea-level rise or other oceanographic processes (Jay, 2009; Zaron and Jay, 2014; Devlin et al., 2014;
651 Devlin et al., 2017; Devlin et al., 2021; Fang et al., 1999). These artifacts may give erroneous estimates of tsunami-
652 related WLs. Our application of EEMD to further separate and remove leftover tidal components in the lower
653 modes of the decomposition largely alleviates this issue. Analyses of the mean values of residuals WLs after the
654 EEMD conditioning show that almost all residual time series have a mean value $\ll 10$ mm, a problem no larger
655 than the instrumental accuracy issue. However, we still subtract the mean bias from our reported results of WL
656 (max/min tsunami waves and **VMT** amplitudes). Similarly, the EEMD process also removes diurnal and low-
657 frequency variability in P_A , and analyses of the residuals show that all locations have mean values less than
658 0.001mb. Thus, the offset or bias in P_A values is insignificant in relation to the instrumental accuracy.

659 3) Coarse temporal resolution: Nearly all WL data used here are 1-min resolution. This is sufficient in the
660 estimation of the oceanic and **VMT** related waves, which have frequencies of ~ 5 min to a few hours. However,
661 only some of our P_A data is at 1-min resolution (Italy, Chile, and Australia), the remainder is 6-min resolution
662 (US) or 10-min resolution (NZ and Japan). The pressure wave is a rapidly changing phenomenon which shifts
663 from strongly positive to strongly negative over a short time (20-60 min) Therefore, it is possible that the P_A spikes
664 may not be fully captured in the coarser resolution data and may misrepresent the actual intensity of the **VMT**
665 wave. This unavoidable problem is the largest source of uncertainty in our study. We account for this by
666 qualitatively increasing the uncertainty values of the instrumental accuracy for P_A (± 0.1 mb) to ± 0.15 mb for the 6-
667 min data and ± 0.2 mb for the 10-min data.

668 The calculation of β divides the **VMT** WL by the P_A spike; i.e., $\beta = \frac{WL_{airshock}}{P_A}$. We determine the relative
669 error in β by propagating the uncertainties detailed above as: $\frac{\delta\beta}{\beta} = \sqrt{\left(\frac{\delta WL}{WL}\right)^2 + \left(\frac{\delta P_A}{P_A}\right)^2}$; δWL is 10 mm, δP_A is
670 0.1mb at 1-min stations, 0.15mb at 6-min stations, and 0.2mb at 10-min stations. Using these error estimates, 21
671 locations have relative uncertainties in β which are greater than 50%, four of which are greater than 100%
672 (statistically insignificant). The overall average uncertainty is 30.8%. Best results were found for 1-min pressure
673 data (e.g., Chile had an average of 16% and Australia had an average of 13%), and somewhat less accurate results
674 for 10-min pressure data (e.g., Japan and New Zealand both have averages of 27%). However, the largest
675 uncertainties occurred in places where **VMT** amplitudes were very small, regardless of air pressure data resolution.
676

677 **Code and Data Availability** All data used in this study are deposited in an online repository of the Harvard
678 Dataverse at: <https://doi.org/10.7910/DVN/F0G63H>. Datasets included are original 1-min water levels, post-
679 EEMD water level residuals, original air pressure data (1-minute, 6-minute, and 10-minute resolution), and post-
680 EEMD air pressure residuals. All code was performed in MATLAB and can be shared via direct communication
681 with the authors.

682

683 **Author Contributions:** All authors contributed to conceptualization, validation, visualization, and
684 reviewing/editing. A.T.D. contributed data curation, formal analysis, investigation, methodology, software, and
685 text writing. D.A.J. contributed formal analysis, investigation, methodology, and writing and editing. S.A.T.
686 contributed formal analysis, investigation, software, and methodology. J.P contributed funding acquisition and
687 supervision.

688

689 **Competing Interest Statement:** The authors have no competing interests.

690

691 **Acknowledgments** The authors wish to thank Wong Wai-chung (Alvin) for his helpful discussion and insights
692 on submarine volcanic eruptions.
