Abstract.

The main drivers of the continental Northern Hemisphere snow cover are investigated in the 1979-2014 period. Four observational datasets are used and two large multi-model ensembles of atmosphere-only simulations with prescribed sea surface temperature (SST) and sea ice concentration (SIC). A first ensemble uses observed interannually varying SST and SIC conditions for 1979-2014, while a second ensemble is identical except for SIC where a repeated climatological cycle is used. SST and external forcing typically explain 10 to 25% of the snow cover variance in model simulations, with a dominant forcing from the tropical and North Pacific SST during this period. In terms of the climate influence of the snow cover anomalies, both observations and models show no robust links between the November and April snow cover variability and the atmospheric circulation one month later. On the other hand, the
first mode of Eurasian snow cover variability in January, with more extended snow over western Eurasia, is found to precede by one month an atmospheric circulation pattern similar to a negative Arctic Oscillation (AO). A decomposition of the variability in the model simulations shows that this relationship is mainly due to internal climate variability. Detailed outputs from one of the models indicate that the Western Eurasia snow cover anomalies are preceded by a negative AO phase accompanied by a Ural blocking pattern and a stratospheric polar vortex weakening. The link between the AO and the snow cover variability is strongly related to the concomitant role of the stratospheric polar vortex, with the Eurasian snow cover acting as a positive feedback for the AO variability in winter. No robust influence of the SIC variability is found, as the sea ice loss in these simulations only drives an insignificant fraction of the snow cover anomalies, with few agreements among models.

1 Introduction

Understanding the origin and impact of snow variability is important for many activities such as agriculture, tourism, management of freshwater resources, or road maintenance. It is also essential for the evolution and understanding of midlatitude and subarctic ecosystems. Snow is an important element for the climate as the high albedo of snow leads to increased reflected shortwave radiation at the surface with a direct influence on the earth’s radiative budget. The small thermal conductivity of the snow pack also insulates the soil from the cold winter atmosphere and plays an important role in the stability of the permafrost (Pulliainen et al., 2017).

Snow over land accumulates from snowfall events and is melted by surface air temperatures above the freezing point. The variability of snow cover and snow depth is therefore modulated by the midlatitude and polar atmospheric variability. Winter atmospheric variability is large and is mostly unpredictable beyond a week or two as it owes its existence to internally-driven atmospheric processes (Feldstein, 2000; Deser et al., 2012). However, other processes influence the atmospheric variability at low frequency, which leads to the potential predictability of winter climate at the seasonal time scale (Scaife et al., 2014). Tropical surface anomalies can strongly alter the large-scale atmospheric circulation and influence the
extra-tropical regions through atmospheric teleconnections. In particular, the El Niño-Southern Oscillation (ENSO) has a large influence over North America through the Pacific-North American (PNA) pattern (Wallace and Gutzel, 1981; Lau 1997), and also over Europe (Mathieu et al. 2004; Lopez-Parages et al. 2016). The PNA can in turn modify the snow depth, as found in observations (Ge and Gong, 2009). Extra-tropical surface anomalies may also drive the winter atmosphere, through the influence of extra-tropical sea surface temperature (SST; see the review of Kushnir et al. 2002; Gastineau and Frankignoul, 2015), sea-ice (Deser et al., 2007; Honda et al., 2009; Garcia-Serrano et al., 2015; King et al., 2016), and snow cover (Cohen and Entekhabi, 1997; Gastineau et al., 2017; see the review of Henderson et al., 2018). Lastly, troposphere-stratosphere coupling in winter can also enhance and increase the persistence of atmospheric modes (Perlwitz and Graf; 1995; Baldwin and Dunkerton, 1999; Scaife et al., 2014).

The land snow cover is also affected by external forcings such as the increasing concentration of greenhouse gases, the evolution of aerosol or ozone concentration, and land use change. The snow cover extent was found to decrease over the last decades (Déry and Brown, 2007; Gulev et al., 2021), although observational data shows a large spread in fall and early winter (Brown and Derksen, 2013; Mudryck et al., 2017). Mudryk et al. (2020) reported negative trends below \(-50 \times 10^3\) km\(^2\) per year over 1981-2018 in November, December, March and May. Recent observational estimates also found a decreasing trend of the snow mass over North America but an insignificant decrease over Eurasia (Pulliainen et al., 2020). Detection-attribution studies have attributed the decrease of snow cover to human activities (Paik and Min, 2020; Guo et al., 2021), but the specific role of the different drivers is unknown. Furthermore, the atmosphere-ocean general circulation models (AOGCM) from CMIP5 (Coupled Model Intercomparison Project phase 5) underestimate the land snow extent, while they overestimate the snow mass (Derksen and Brown, 2012; Mudryk et al., 2020). Even if the snow cover extent is better simulated in CMIP6 (Coupled model Intercomparison Project phase 6) models (Mudryk et al., 2020), global climate models mostly use highly simplified snow physics (Krinner et al. 2018). The simulation of snow cover anomalies over land, therefore, remains a challenge as it involves the large-scale circulation together with the parametrized atmospheric and land surface processes. In the present study, we will further assess the influence of external forcing, SST and sea ice concentration (SIC) anomalies on the snow cover.
Land snow variability also influences the climate. Cohen and Entekhabi, (1997) found that when the snow cover over eastern Siberia is anomalously large in October, negative phases of the Arctic Oscillation (AO) are more frequent during the following months. This was confirmed by Saito and Cohen (2003) and Cohen et al. (2014). Using an extended observational record, Gastineau et al. (2017) found a similar relationship, albeit between November snow cover and the subsequent December and January AO. They also found that concomitant sea ice anomalies reinforced the atmospheric response to snow cover anomalies. These relationships suggest that snow cover anomalies can influence the mid-latitude atmospheric circulation in the same way as SST or SIC anomalies. The pathway of the snow influence involves an amplification of the climatological tropospheric stationary wave associated to a lower-troposphere cooling as the snow cover increases (Cohen et al., 2014), as found for the 2017/2018 winter (Lü et al., 2020). Such amplification was suggested to lead to stratospheric warming which can result in more frequent negative AO events through downward propagation (Baldwin and Dukerton, 1999). Sensitivity simulations using models with prescribed snow cover also revealed a consistent AO-like atmospheric response to more extensive Eurasian snow cover (Gong et al., 2003; Fletcher et al., 2009). Such influence is consistent with changes in subseasonal forecast skill when modifying the initialization of the snow cover in 2004-2009 (Orsolini et al., 2013) or in 2009-2010 (Orsolini et al. 2016), even if this influence is not found systematically from other periods and different models (Garfinkel et al., 2020). The statistical relationships found in observations are stronger than, but consistent with those in some of the AOGCM simulations from CMIP5 climate models (Gastineau et al., 2017). Liang et al. (2021) proposed that the apparent underestimation of the atmospheric response to sea-ice anomalies in the Barents-Kara Seas in CMIP6 atmosphere-only simulations was in part due to the lack of consistency between sea ice and snow cover anomalies when the former was prescribed. Indeed, Ural blocking increases the eastern Siberian snow cover while it decreases the Barents-Kara SIC (Gastineau et al., 2017; Peings 2019). Both the increased Siberian snow cover and Barents-Kara sea ice loss are found to lead to negative AO-like anomalies in the following months (Gastineau et al., 2017; Simon et al. 2020). This may result in a larger AO response than expected from the sea ice alone, as proposed by Cohen et al. (2014). Hence, atmosphere-only simulations using prescribed sea-ice anomalies but with prognostic snow cover cannot
simulate the synchronization of sea ice and snow, and the atmospheric response to SIC anomalies could not be reinforced by the snow cover anomalies, unlike in observations.

In the present study, we will further assess the drivers and impacts of snow cover anomalies, focusing on early winter, winter and early spring. We use a large ensemble of atmosphere-only simulations to characterize the snow cover variability in the Northern Hemisphere. To sample the uncertainties of the observations, we analyze four observational products. Section 2 presents the data and methods. Section 3 discusses the influence of the observed SST and SIC anomalies on continental snow. In Section 4, we investigate the internal variability of the snow cover and its influence on the atmosphere. Discussion and conclusions are given in the last section.

2. Data and methods

2.1 Observations

Several snow datasets are used to sample the observational uncertainty. We use the monthly snow water equivalent (SWE) and snow cover of ERA5-land in 1981-2014 (Muñoz-Sabater, 2019; Muñoz-Sabater et al., 2021), resulting from the ECMWF land-surface H-TESSEL model forced with ERA5 atmospheric reanalysis (Hersbach et al., 2020). We also use the monthly snow diagnostics from MERRA2 (GMAO, 2015; Gelaro et al., 2017) for the same period. The NOAA climate data record (CDR) of Northern Hemisphere weekly snow cover extent dataset (Robinson et al., 2021) is retrieved from the National Center for Environmental Information and aggregated into monthly time series for the 1981-2014 period. The monthly SWE from GlobSnow v3 (Pulliainen et al., 2020) is used in 1980-2014, where the missing data in December 1981 was interpolated linearly between November 1981 and January 1982. Lastly, we use the daily CanSISE SWE in 1981-2010 (Mudryk et al., 2015; Mudryk and Derksen, 2017), which is based on five products: GlobSnow v2, ERA-Interim/Land reanalysis, MERRA reanalysis, Crocus (Brun et al., 2011) and GLDAS version 2 (Rodell et al., 2004). The CanSISE product also provides a spread based on the range (maximum minus minimum) of these five products. A snow cover from CanSICE is then estimated from the SWE using a threshold of 7 mm. If the daily SWE depth is lower (larger) than 7
mm, then it is assumed that the snow cover is zero (1). A minimum and maximum snow cover is also estimated with the same procedure using the SWE and its spreads, assuming the spread is centered on the mean SWE. The SWE and snow cover from CanSISE are then aggregated into monthly means.

The atmospheric 2m air temperature and sea level pressure (SLP) fields are retrieved from ERA5 reanalysis (Hersbach et al., 2019; Hersbach et al., 2020).

All data is regridded with bilinear interpolation into a 1.26°x2.5° regular grid before analysis. Coastal regions are masked if the fraction of land is below 50%. Some products, such as GlobSnow, have missing data over mountain regions. Therefore, mountain and ice cap regions are masked in all data.

2.2 Model simulations

We use the outputs of the two multi-model land-atmosphere simulation ensembles discussed in Liang et al. (2020, 2021). These simulations used as boundary conditions the SST and SIC provided by the HighResMIP panel of CMIP6 (Haarsma et al., 2016) and atmospheric concentration of aerosol, greenhouse gases, and ozone from CMIP6 (Eyring et al., 2016) in the 1979-2014 period. We use the outputs of eight models where the snow depth was saved and distributed (Table 1). The ensemble ALL uses interannually-varying daily SST and SIC. The other ensemble, called NoSICvar, is identical but uses a repeated 1979-2014 climatological SIC in the Arctic, with adjustment of the associated local SST (Hurrell et al., 2008). The climate sensitivity to SIC anomalies is provided by the difference ALL minus NoSICvar. As noted in Liang et al. (2020) and Table 1, the experimental protocol has some small differences for each model, but these deviations are unlikely to affect the results substantially. The number of members varies among models from 10 to 30, while the horizontal resolution varies from about 60 km to 150 km. The large diversity of models allows us to study the model dependence. However, for comparison with observations, these ensembles of atmosphere-only models have limitations associated with the lack of active two-way coupling with sea ice and SST, uncertainties in the SST and SIC forcing, and simplified sea ice physics, as discussed in Liang et al. (2021).
We use the monthly SLP, 2m air temperature, and snow depth in all models. For LMDZOR6 and CMCC, the snow depth was converted into snow water equivalent (SWE) depth, assuming a constant snow density of 240 kg m$^{-3}$, as found in observations (Sturm et al. 2010). The snow cover is a diagnostic variable in many models and was not available for four models (see Table 1): EC-Earth3, ECHAM6, HadGEM3 and IAP4. Lacking a better formulation, we calculate the snow cover from the SWE using a threshold of 7.5 mm. If the monthly SWE depth is lower (larger) than 7.5 mm, then it is assumed that the snow cover is zero (1). This estimation is based on LMDZOR6, where we found that a reasonable snow cover extent is obtained with the 7.5 mm threshold when using monthly outputs. This procedure is similar to that of Krinner et al (2018), except they used a threshold of 5 mm.

The detailed outputs from LMDZOR6 are also used with the monthly geopotential height at 500-hPa and 50-hPa, and the daily air temperature. For this model, the wave activity flux from Plumb (1985) is also calculated from daily geopotential height, zonal wind and meridional wind at 500-hPa and 250-hPa.

All data sets were regridded with bilinear interpolation into the regular grid 1.26°x2.5° (~150 km) before analysis. Coastal regions and grid points with complex orography were masked consistently in all models using the observational mask. Multi-model ensemble means (MMM) are constructed by giving the same weight to each ensemble member, which largely removes the influence of internal atmospheric variability.

2.3 Methods

We study the effects of SST, SIC and external forcing in driving snow cover anomalies with an analysis of variance (ANOVA) with two factors, also known as two-way ANOVA. The ANOVA is a statistical analysis method for comparing the means of various samples and investigating the influence of one or several categorical independent variables, called factors, on one continuous variable (Von Storch and Zwier, 1999). Here the ANOVA is applied in a balanced design to the land snow from the ALL and NoSICvar ensembles, separately for each individual model and for each calendar month. The first factor is the simulated year, called \( t \), which varies from 1979 to 2014. The second factor is the ensemble, called
and represents the ALL versus NoSICvar ensembles. The interaction between the year and the ensemble is called $t:e$. In the analysis, the sum of squares quantifies the variance associated with each factor. The ANOVA then compares such variance to the residual variance to test the effect of the factors. The corresponding p-value indicates if the effect of the factors ($t$, $e$ and $t:e$) is statistically significant. Hereafter, we show such p-values, together with the ratio of the sum of squares over the total variance to quantify the variance explained by each factor.

The statistical model of the ANOVA decomposes the snow cover anomalies of a calendar month in each year and ensemble, called $X$, by:

$$ X(t, e) = \mu + \beta_t(t) + \beta_e(e) + \beta_{t,e}(t, e) + \varepsilon, $$

where $\mu$, the theoretical mean of $X$, corresponds to the seasonal mean of the calendar month. $\beta_t$ is a different constant for each year, $\beta_e$ is a constant for each ensemble, $\beta_{t,e}$ is an interaction term different for each year and ensemble, and $\varepsilon$ is a gaussian noise. If the ANOVA is significant for the factor $t$, then at least one of the $\beta_t$ is significantly different from zero. It implies that the time-varying prescribed boundary conditions have an influence on the snow cover in both ALL and NoSICvar, which should result from time-varying SST or external forcings, as they both can influence the atmosphere and land. Similarly, the effect of time-varying SIC is accounted for by the second factor $e$. If the second factor is significant, with at least one of the $\beta_e$ different from zero, it demonstrates an influence of varying sea-ice concentrations on the mean land snow. Lastly, if at least one of the interaction terms, $\beta_{t,e}$, is significant, it suggests that the influence of SIC is time-dependent. The ANOVA is repeated for each calendar month.

The main drivers of snow cover are characterized using Empirical Orthogonal Functions (EOFs). The EOFs of the Northern Hemisphere snow cover are calculated north of 30°N, while the domain for Eurasian snow cover EOFs is (0°E-180°E, 30°N-90°N). Three EOF analyses are performed using the year-to-year time series corresponding to each calendar month separately. The first EOF analysis performed is based on the MMM calculated from the ALL experiments. The EOF pattern is denoted as $\text{EOF}_{BC}$, where BC stands for boundary conditions and indicates the driving effect of the prescribed SST, SIC and external forcings (concentration of greenhouse gases, aerosol and ozone). As the forcing from sea ice
concentration is weak (Liang et al., 2021), the EOFs are almost identical when using NoSICvar instead of ALL. For instance, the pattern correlation between the first EOF$_{BC}$ (EOF$_{1BC}$) of ALL and that of NoSICvar is 0.95, 0.93 and 0.98 for November, January and April, respectively. EOF$_{1BC}$ therefore mainly quantifies the main pattern of variability induced by the SST and external forcing. The corresponding principal components (PCs) are denoted PC$_{BC}$. A second EOF analysis, called EOF$_{SIC}$, is identical but performed on the difference between the MMM of ALL and NoSICvar, to highlight the effect of the SIC variability. The corresponding principal components (PCs) are denoted PC$_{SIC}$.

Hereafter, all principal components are standardized, and the EOFs are illustrated using their regression onto the standardized PC. The sign convention is that a positive PC corresponds to an EOF with positive loading over eastern Europe (20°E-70°E 55°N-70°N).

Lastly, the internal land-atmosphere variability is investigated in the model simulations with a third EOF analysis. The internal variability is investigated after removing the ensemble mean of the snow evolution that mostly reflects the effect of SST, SIC, and external forcing. We conduct an EOF analysis separately for each model using all the members of ALL and NoSICvar concatenated after the removal of their respective ensemble means. This third analysis provides EOF$_{Int}$, and PC$_{Int}$ as spatial patterns and time series, respectively. The relevance of this analysis might be limited when the ensemble size is small (only 10 members for some models), as the ensemble means are more affected by internal variability.

In addition, various fields, such as the surface air temperature, SLP, geopotential height, and zonal wind, are regressed onto PC$_{BC}$, PC$_{SIC}$ and PC$_{Int}$. The p-values of the univariate regression slopes are given by a Student’s $t$-test. The year-to-year autocorrelations for separate calendar months are typically insignificant between 0 and 0.05 (not shown). The only exception is for April, where such autocorrelation is significant over Scandinavia and the East European Plain, but it remains modest with maximum values at 0.08. Hence, we did not account for a reduction in the degree of freedom due to year-to-year correlation.
The ANOVA, the retrieval of $\text{EOF}_{\text{Int}}$ and the regression analyses using $\text{PC}_{\text{Int}}$ are performed separately for each model, but the figures provide the mean for the eight models using a weight proportional to the ensemble size of each model ensemble, referred to as the multi-model mean (MMM). This avoids giving too much weight to models with only 10 ensemble members. We indicate grid points where the sign of anomalies is the same in seven models out of eight. This corresponds to a probability of 6.2% when considering that the sign of the anomaly has a probability of 50% in the models, as deduced for the Binomial probability distribution. We also indicate the grid points where the p-value is below 5% in at least five models out of eight.

3. Simulated Northern Hemisphere snow cover and depth

3.1 Climatology

First, we briefly assess the Northern Hemisphere land snow simulated in the eight models. The mean seasonal cycle of land snow extent and snow mass is first calculated over North America and Eurasia in 1979-2014. The snow extent over North America (0°N-90°N 180°W 0°E) and Eurasia (0°N-90°N 0°E 180°E) has a maximum in January-February (Fig. 1a-b, black lines). November and April are associated with the start and the end of the season with extensive land snow coverage, respectively. The seasonal cycle of the Eurasian snow area is well represented by all the models (Fig. 1b, color lines). The differences between the models are within the range of uncertainty between the observational data sets, except for EC-Earth3 that simulates a slower snow cover decrease in spring. The snow cover area over North America (Fig. 1a) is also well captured by models, but it is overestimated in EC-Earth3 and underestimated by ECHAM6. We also calculate the standard deviation obtained from year-to-year time series for each month. The interannual variability in models also agrees with that found in observations (Fig. S1).

There is less agreement on the snow mass (Fig. 1c-d). First, the snow mass estimations from observations show a large spread that is maximum from February to May. Then, LMDZOR6 and CMCC both overestimate the snow mass in Eurasia and North America from December to March. NorESM and
CESM2 only overestimate the snow mass over North America, especially from February to March. Other models simulate snow masses within the spread of observational products. In conclusion, the models reproduce the observed snow cover seasonality, but tend to overestimate the snow mass. These conclusions are in agreement with the similar analysis of CMIP6 AOGCMs from Mudryk et al. (2020) or Zhong et al. (2022). Therefore, the use of atmosphere-only simulations does not significantly reduce the land snow biases compared to AOGCM simulations.

The location of the snow cover biases of each model compared to CanSISE is illustrated for January in Fig. 2. We chose here CanSISE as a reference as it is based on an ensemble of observations. Most models simulate more snow cover than observational products from the Tibetan plateau to Eastern Siberia and too little snow cover over southwestern Eurasia. No apparent snow biases are found over the fully snow-covered domain between Eastern Europe and Central Asia. Over North America, there is generally more snow in models than in observations over the Rocky Mountains, and a few models also underestimate the snow cover over Northeastern Canada. Given the large uncertainty of the observational products over Mountain regions, more observations would be needed to fully confirm the biases over these regions. The snow water equivalent in models (Fig. 3) shows a generally positive bias over land with no consistent large-scale pattern in LMDZOR6, CMCC, NorESM, and CESM2. The bias is negative in ECHAM6 and IAP4.1, with an underestimation of the SWE over the East European Plain and North-Eastern Siberia, respectively. EC-Earth3 and HadGEM3 agree with the observations.

Hereafter, we focus on the land snow variability in November, January, and April, which represent the start, the maximum, and the end of the period with large snow coverage in the Northern Hemisphere (Fig. 1).

3.2 Assessment of snow cover anomalies

Figure 4a-b shows the time series of the anomalous snow cover area in winter, defined by the average from November to March, in the MMM of ALL. The anomalies are defined with respect to the 1979-2014 climatology. The observational values are also shown but using a different scale to facilitate the comparison. Indeed, the decreasing trend of the MMM snow cover area is roughly half of that observed
over Eurasia and North America (see also red and grey symbols in Fig. 5b). In addition, the year-to-year variability of ALL is much smaller than that observed. This presumably reflects that the observations correspond to one realization while the model ensemble means are averaged over 10 to 30 members, depending on the model, which strongly reduces the impact of internal variability. This suggests either that half of the observed trends is due to internal variability, or that the influence of SST or external forcing is underestimated by half in the models. Similar results are found for the snow mass, but the decreasing trend over Eurasia is much weaker in models than in observations (Fig. 4c-d and Fig. 5a). The timing of some of the minima and maxima are consistent, as in 2007/2008 for the snow extent over Eurasia (Fig. 4a), in 1993 and 1999-2000 for the snow extent over North America (Fig. 4b), or in 1987, 1998 and 2010 for the North American snow mass (Fig. 4d). This is consistent with the strong relationship between El Niño events and positive phases Pacific North American (PNA) pattern, which are associated with warm anomalies and decreasing snow depth over western North America (Ge and Gong, 2009).

The correlation between the ALL MMM and ERA5-Land snow cover area is 0.66 (0.59) over Eurasia (North America), while it is 0.69 (0.60) over Eurasia (North America) for snow mass, which demonstrates a dominant influence of the boundary conditions. After removing the linear trend from every time series, the correlations are smaller, but they remain significant, except for snow mass over Eurasia (compare red and yellow symbols in Fig. 5d).

The overall impact of the sea-ice variations on the snow cover area and snow mass is limited, as shown by the differences between the MMM of ALL and NoSICvar over North America (Fig. 4f-h). The time series in Fig. 4f-h show no clear trend and are not significantly related to observations at the 5% level (Fig. 5d), except for the Eurasian snow extent (Fig. 4e), which is significantly correlated with observations (R=0.43) even for detrended time series (R=0.38).

The correlations of land snow area and mass between observation and models remain significant over Eurasia and North America separately for November, January and April in Fig. 5c-d for ALL (red and orange symbols), which confirms the robust influence of boundary conditions. The 1980-2014 linear
trends of snow cover and snow depth are also assessed in Fig. 5a-b, using the MMMs, and calculating their statistical significance with a Student’s $t$-test, as detailed in Liang et al. (2021).

Over Eurasia and North America, the trends in ALL for November and January (Figs. 5a-b, red circle and plus) are consistent with that of the whole winter (NDJFM). However, in April, the snow depth trend over Eurasia in ALL is more negative, while the snow extent trend over North America is smaller and insignificant. The comparison between the observed CanSISE (Figs. 5a-b, grey circle and plus) and simulated trend reveals important differences, as a dominant negative trend is observed in November and January for snow extent and mass, respectively. A comparison of the trends obtained in other observational datasets (Figs. S2 and S3) shows a large spread in trend estimates, with increasing snow extent in fall and early winter in the NOAA-CDR observations, while ERA5-Land, MERRA2 and CanSISE show a decreasing snow extent, as found previously (Brown and Derksen, 2013; Mudryck et al., 2017). The reason for this difference between the NOAA-CDR and multi-observation products is unknown (Mudryck et al., 2017). This suggests that observational uncertainties are important, especially in fall, as reported by Fox-Kemper et al. (2021). The trend maps obtained from ALL MMM in November, January, or April (Figs. 5e-g) reveal an important large-scale decrease in snow cover, maximum at the edges of the snow-covered domain.

The influence of sea-ice is investigated with the trends of the MMM of ALL minus NoSICvar, and the correlation between observations and the MMM of ALL minus NoSICvar in Fig. 5a-d (blue and sky-blue symbols). The trends of ALL minus NoSICvar are negative and significant for snow mass only, which may reflect an influence of the sea-ice loss reducing the snow mass. For the snow cover, the correlation and trend are mainly small and insignificant. The trend maps (Fig. 5h-j) show a weak but significant decreasing trend for January, or April in Southern Scandinavia extending eastward into Eurasia. In November, a decreasing trend is located east of Scandinavia, downstream of the Barents Sea. Such a location is in agreement with the large oceanic heat release expected from the observed Barents-Kara sea ice loss (Deser et al., 2015). Another decreasing snow cover trend is also simulated over north-eastern Canada in November.
3.3 Role of the boundary conditions in driving snow cover

The influence of boundary conditions is quantified using an ANOVA (see section 2.3). We first applied the ANOVA separately at each grid point. The effect of SST and external forcing represented by the factor $t$ is found to be dominant. The snow cover variance fraction associated with this factor is significant in all models in November, January, or April (Figs. 6a-c). It is largest over the mid-latitude edges of the snow-cover in Eurasia or North America, and may reach 15% over the Tibetan plateau, although models and observations have large uncertainties there (Mudryk et al., 2020). A large variance fraction (>5%) is also simulated over the Rockies and Scandinavia. In November, the variance fraction is ~4 to 5% over Northern Canada and a latitudinal band from Scandinavia to Eastern Siberia. By January, the variance fraction at the edge of the snow cover domain increases on average to ~6% and shifts toward eastern Europe and from the Caspian Sea to eastern China. In April, the large variance fraction is more important (~6-10%) but more localized from the East European Plain to southern Siberia and over Northern Canada.

The results are summarized by an ANOVA using the Eurasia or North America snow area instead of grid point values in Fig. 6d-f. Models show a significant influence of SST and external forcing (indicated by SST/ext in Fig. 6d-f) with 10% to 25% of the variance explained over both domains, despite important differences between models.

The snow cover variance associated with the varying sea ice concentration is given by the factors $e$ and $t:e$ (see section 2.3 for details) representing the influence of the SIC on the time-mean and time-varying snow, respectively. The variance fractions show no clear agreement between models and are largely insignificant at most grid points (not shown). The results are summarized in Fig. 6d-f for the snow cover area over Eurasia and Northern America. The sea ice only explains 1% to 5% of the variance, as found in the interaction $t:e$ and the impact on the time mean snow cover is below 0.3% in most models. In most models, the ANOVA test is not significant for these two factors. We conclude that sea ice does not have a robust influence on the snow cover in our simulations. Using SWE instead of snow cover yields similar results (not shown).
3.4 Assessment of the role of the boundary conditions for snow cover

To assess the main patterns of simulated year-to-year snow cover variability, we first investigate observations, with separate EOFs (north of 30°N) for each calendar month. Figure 7 shows the first two snow cover EOFs in ERA5-Land in, from top to bottom, November, January, and April, as well as their pattern correlation with the corresponding EOFs obtained from the three other observational data sets (right). In November, the first EOF (EOF1) shows anomalies of the same sign with large loading over the East European Plain, eastern Eurasia, and central North America, near the edges of the mean snow-covered area. The second EOF (EOF2) is a dipolar pattern with large loading over eastern Europe and small loading with the opposite sign between the Aral Sea and the Baikal Lake and in western North America. In January, EOF1 is dominated by a large loading over Europe, while EOF2 is dominated by strong anomalies over North America. In addition, EOF1 and EOF2 display small anomalies near the edge of the Eurasian snow-covered domain. In April, EOF1 is a dipole with large loading over North America, and anomalies with an opposite sign between the Caspian Sea and the Baikal Lake. EOF2 only shows large loading over the East European Plain. CanSISE provides very similar snow cover EOFs to ERA5-Land in all months. The EOF1 patterns in MERRA-2 and NOAA-CDR are also similar in January and April, but they are different in November. The EOF2 patterns in MERRA-2 and NOAA-CDR mainly disagree with ERA5-Land. This suggests that the observational uncertainty is large in November but that the EOF1 pattern is otherwise rather robust.

To emphasize the role of external forcing, SST and SIC for the simulated snow cover changes, the first EOF of the Northern Hemisphere snow cover in the MMM of ALL, called EOF1\textsubscript{BC} is shown in Figs. 8a, 8d and 8g. The corresponding principal components, hereafter PC1\textsubscript{BC}, all show a positive trend (not shown), so that the EOF1\textsubscript{BC} resembles the maps of the land snow trend from ALL in 1981-2014 (compare Fig. 5e-g and Fig. 8a,d,g). November EOF1\textsubscript{BC} (Fig. 8a) also shows anomalies of the same sign over North America and from Scandinavia to eastern Siberia, at the edges of the mean snow-covered region, and near the Tibetan plateau. In January (Fig. 8d), the pattern is again a monopole, but it is centered over a band from Europe to East Asia as the snow-covered domain is broader than in November. In April (Fig. 8g),
the loading over Eurasia is similar to that found in November, but the anomalies over North America are opposite. EOF1_{BC} explains 36% to 48% of the variance in November, January, and April.

The EOF associated with the boundary conditions and external forcings can be compared with the observed snow cover EOF. The first two EOFs in ERA5-Land (Fig. 7, left) have some similarities with the EOF1_{BC} patterns in Figs. 8a,d,g. However, the loading is more localized in ERA5-Land, without a clear location at the edge of the snow-covered domain. Moreover, in ERA5-Land EOF1 (EOF2) only explains 15% to 21% (12% to 13%) of the variance. The somewhat different patterns and the smaller explained variance may reflect in part the large influence of internal atmospheric variability in observations. To reveal the links between the observed snow cover variability and the influence of SST and external forcing, PC1_{BC} is compared to the observed snow cover PC1 and PC2. The correlation between PC1_{BC} and the observed PC1 (Fig. 8c,f,i, left, blue bars) is only significant when using ERA5-Land and CanSISE in November and when using ERA-Land and NOAA-CDR in April, and it is not significant at all in January. Moreover, the correlation between PC1_{BC} and the observed PC2 (orange bars) is only 5% significant in November for NOAA-CDR. After removing a linear trend from all the time series (not shown), the correlations with PC1_{BC} that largely stem from SST forcing are smaller, and they only remain significant with ERA5-Land PC1 in November (R=0.36), and with ERA5-Land (R=0.47) and NOAA-CDR (R=0.48) PC1 in April. This confirms the larger effect of changing SST and external forcing in November and April, although the EOF analysis is not robust among the observational dataset. There is no significant correlation in January, presumably because the internal variability is larger.

The snow cover EOFs solely related to the sea ice are calculated from the MMM difference of ALL minus NoSICvar (Figs. 8b,e,h). The variance fraction explained by the first EOF_{SIC} is between 10% and 13%. The absolute variance explained by EOF_{SIC} (not shown) is 6 to 13 times smaller than the one explained by EOF1_{BC}, which confirms that sea ice has a much smaller influence than SST or external forcing. In November, EOF1_{SIC} is a dipole with the same sign between the East European Plain and North America, and an opposite sign over eastern Siberia. In January, EOF1_{SIC} is a dipole with the opposite signs between North America and Eurasia. The pattern in April is reminiscent of EOF1_{BC}, but with smaller anomalies.
EOF1_{SIC} can hardly be related to the observed snow cover variability, as the correlations between PC1_{SIC} and the observed PCs are weak. This confirms that the sea ice cover has little or no impact.

The SSTs related to the snow cover changes are given by the regression of the SST anomalies from ALL onto PC1_{BC}. The regressions can be interpreted as the SST patterns contributing to the snow cover anomalies of EOF1_{BC}, or the SST pattern responding to the external forcing that affected the snow cover changes. We note warm SST anomalies in the western equatorial Pacific and the central midlatitude North Pacific in all months (Fig. 9a-c), consistent with the extended negative snow cover anomalies of EOF1_{BC} (Fig. 8a,d,g). This might reflect the SST trends observed during that period, which were found to result from the combination of external forcing superimposed on the changes of the Pacific decadal variability (Dai and Bloëcker, 2018; Gastineau et al. 2019). In April, there is a cold anomaly in the Central and Eastern equatorial Pacific, with an extension toward the eastern North Pacific. This horseshoe pattern resembles a La Niña pattern and its extension toward mid-latitudes, called the Interdecadal Pacific Oscillation (Newman et al., 2016). We also note warm SST anomalies over the North Atlantic in November, which remain similar, but with smaller amplitude, when removing the linear trends (not shown), suggesting a role of interannual or decadal North Atlantic variability.

To understand these links, the SLP anomalies in ALL MMM associated to PC1_{BC} are shown in Fig. 9d-f. In April, the SST is associated with a weakened Aleutian Low in the North Pacific and a PNA pattern, which are consistent with the expected pattern associated with cold equatorial Pacific SST anomalies. The weakened Aleutian Low leads to cold air advection over western North America, which explains the positive snow cover anomalies in that region (Fig. 8g). Therefore, the SST over the Pacific Ocean plays a significant role in the April snow cover over North America. The SLP anomalies are otherwise not significant for November and January. We also note positive SST anomalies in the Atlantic and Pacific oceans, which might reflect the positive SST trend observed during that period at those locations.

To investigate the role of sea-ice driven variability, we calculated the regression onto the PC1_{SIC} index, using the prescribed SIC in ALL, and the MMM difference of SLP from ALL minus NoSICvar. PC1_{SIC}
has a decreasing trend in November (not shown) and it reflects small but significant negative SIC anomalies in the Barents, Labrador, and Bering Seas (Fig. 9g). In November, the SLP anomaly is negative over the negative sea ice anomalies, as expected from the warming in the atmospheric planetary boundary layer, as shown in previous studies (Peings and Magnusdottir, 2014; Liang et al. 2021). The November SLP pattern (Fig. 9g) is different from a negative North Atlantic Oscillation (NAO) or a Ural blocking pattern as previously found as a response to sea ice loss (Mori et al., 2014; Kug et al., 2015; Nakamura et al., 2015; King et al., 2016; Smith et al., 2022), but it is consistent with previous studies using atmosphere-only experiments (Ogawa et al., 2018; Liang et al. 2021). In January and April, the sea ice anomalies are very small. In January, the SLP pattern is insignificant, but in April, there is a cyclonic anomaly around 50°N over the Atlantic Ocean, a small cyclonic anomaly over the Mongolian Plateau, and a weakening of the Aleutian Low. Positive SLP anomalies are also located over the Kara Sea, but these anomalies cannot be linked to the snow cover anomaly in a simple way. In all cases, removing the linear trends lead to different results (not shown), so the relationships shown in Fig. 9g-i mostly reflect the impact of the sea ice declining trend.

4. Internal variability and climate impacts of snow cover anomalies

4.1 Internal variability of snow cover

The impact of internal atmospheric variability on snow cover anomalies is investigated over Eurasia. We focus on Eurasia as it is the largest continent, and snow cover was previously suggested to influence the Northern Hemisphere atmospheric circulation (Cohen and Entekhabi, 1999; Cohen et al. 2014; Gastineau et al. 2017). In the observational datasets, we remove a quadratic trend from all variables, which should remove a large part of the changes linked to the long-term evolution of external forcing, and then quantifies the internal variability, which is largely due to atmosphere-land processes, in addition to a residual influence of SST and SIC. The first EOF of the detrended snow cover in ERA5-Land is shown in Figs. 10a, 10e and 10i. The patterns are somewhat similar to those obtained over the Northern Hemisphere before detrending (Fig. 7), but the EOF1 over Eurasia in November and April corresponds to the EOF2 of the Northern Hemisphere before detrending. The similarity in the EOF1 pattern obtained
in January in models and observations (Figs. 7d and 10e) suggests that internal variability is dominant during that month, as opposed to November and April where forcings are important. The regressions of the SLP and surface air temperature (Figs. 10b,f,j) onto the PC1 at no lag illustrate in January the influence of the NAO on the snow cover with cold air advection increasing the European snow cover. In November and April, the snow cover is linked to a trough over the Ural region, with cold (warm) air advection over its western (eastern) flank. The trough over Central Eurasia is part of a wave-like perturbation between the Atlantic Ocean and Eurasia. In November, the trough extends to eastern Siberia and is associated with a warming and a snow cover decrease in Central Siberia. These patterns are similar in January when using the other three snow cover datasets (see Figs. 10d and 10h). In November, the patterns remain similar except for MERRA-2. In April, the patterns are different (Fig. 10i) and the SLP anomalies are smaller (Fig. 10j).

To investigate the internal atmospheric-land variability in the model simulations, we repeat the same analysis except that we remove from snow cover, SLP, and surface air temperature the effect of boundary conditions by removing for each model the model ensemble mean of the ALL and NoSICvar simulations from the individual members. This removes most of the variability driven by external forcing, SST and SIC. EOF$_{\text{Int}}$ is calculated for each model separately and then, as it is found to be similar among models, averaged among the eight models using the ensemble size as a weight (Fig. 11a-f). This robustness is shown by the large pattern correlation of EOF1$_{\text{Int}}$ (blue bars) and EOF2$_{\text{Int}}$ (orange bars) of each model and those of the multi-model average, with a pattern correlation largest when the model has a large ensemble of 30 members (indicated by black stars in the x-axis numbers of Fig. 11g-i). In November, January, and April, a large monopole with positive snow cover anomalies over the edge of the snow-covered domain appears as the first mode (Fig. 11a-c), with between 9% and 30% of the variance explained. The maximum loading of the monopole is located in Western Eurasia in November. It shifts to Eastern Europe in January, and moves eastward toward Central Siberia in April. The second mode is a dipole, with anomalies positioned on the northwestern and southeastern ends of the EOF1 patterns; its explained variance ranges between 6% and 18%.
The SLP and surface air temperature associated with the first mode are calculated by a regression onto the PC1_{int} of the snow cover in each model, which is then averaged similarly among all models. The snow EOF1_{int} in November, January, and April is always associated at no lag with an anticyclone located at the north or the north-west of the positive snow cover anomalies (Fig. 12a-c), as expected from cold air advection which increases snow cover. However, the location and amplitude of the cold surface air temperature anomalies are not always matching the snow cover anomalies. For instance, the cold anomalies are strongest in January with a widespread cooling extending from western Europe to far eastern Siberia, but the associated snow cover anomalies have the same amplitude in all three months, and are only located over eastern Europe in January. In November, the anticyclone is centered over the Nordic seas (Fig. 12a), while it extends from the Nordic Seas to Northern Siberia in January (Fig. 12b). In April, the snow anomalies cover the southern edge of the snow cover domain, and the anticyclone is centered over the eastern Arctic (Fig. 12c). EOF2_{int} is associated with a trough over the Ural Mountains in November and April, while the NAO and the associated temperature anomalies over southern Siberia dominate in January.

The comparison between Fig. 10 for observations and Figs. 11-12 for models suggests that the models reproduce fairly well the main mode of the observed variability. In both cases, the NAO is the dominant mode of variability during January. In January, the analysis of the second EOF from detrended observations (not shown) also shows that it is associated with patterns similar with that found in models (Figs. 11e and 12e). During November and April, the observed dominant mode of variability is a blocking pattern with a trough over the Ural region. This pattern also occurs in the models, but with less variance, as it is reproduced by EOF2 rather than EOF1. However, there is an important spread among observations in November and April, and the analysis of observation is based on detrended time series that still include the contribution from interannual SST variability and short-term fluctuations in the external forcing.

4.2 Climate influence of snow cover anomalies

Because of the limited intrinsic atmospheric persistence, the SLP and temperature lagging the snow cover by one month should reflect the snow cover influence in the absence of other concomitant forcings. It is
illustrated for observations in Fig. 10c,g,k and for models in Figs. 13-14. In observations, the November EOF1 is followed by negative SLP anomalies over the polar cap and some weak positive anomalies over Western Europe and the Bering Sea. This SLP pattern shares some similarities with that found at no lag, but with a smaller amplitude. In January, the negative NAO anomalies associated in phase with EOF1 are reduced by half but they persist the following month. In April, no clear SLP pattern emerges at a lag of one month. In all cases, the surface temperature is cold (warm) over positive (negative) snow cover anomalies, as expected, although their statistical significance is limited.

In models, no robust SLP or temperature anomalies follow the November snow cover EOF1\textsubscript{int} with a lag of one or two months (Fig. 13a,d). On the other hand, the January EOF1\textsubscript{int} (Fig. 13b) is followed by strong temperature and SLP anomalies at lag 1 (in February) with a strong anticyclonic anomaly over the polar cap extending toward central Eurasia, which is associated with cold continental air advection over northern Eurasia. The patterns are somewhat similar to those shown at lag 0 for January (Fig. 12b). Since they remain largely similar at lag 2 (Fig. 13e), albeit with smaller amplitude, this suggests that snow cover anomalies act as a positive feedback and amplify the AO one (in February) or two (in March) months later. However, it might also reflect an unusually large atmospheric persistence or the presence of a concomitant forcing. The May SLP and temperature anomalies lagging the EOF1\textsubscript{int} in April by one month (Fig. 13c) are also similar to the unlagged patterns, albeit smaller, and the air temperature remains cold over the land surfaces covered with positive snow anomalies in April. However, the anomalies are negligible at lag 2 (Fig. 13f). The pattern lagging the snow cover by one month is robust among models in January (Fig. 13h), but the agreement decreases in April (Fig. 13i) and more so in November (Fig. 13g). For the pattern following the January EOF1\textsubscript{int} by two months, the agreement among models is smaller than at lag 1, but it remains high in models with 30 members.

The temperature and SLP anomalies lagging the snow cover EOF2\textsubscript{int} by one month (Fig. 14a-c) are smaller than for EOF1\textsubscript{int} and they vanish at lag 2 (not shown). One month after January EOF2\textsubscript{int} there are substantial temperature and SLP perturbations (Fig. 14b), resembling a negative AO pattern as was the case of the forcing pattern (Fig. 12e), but weaker. Its polar center is rather located over Svalbard, and it
is less associated with an intensification of the Siberian anticyclone. Negative SLP anomalies are also found over East Asia. On the other hand, only small SLP and surface air temperature anomalies follow the November and April EOF2\textsubscript{int}.

The comparison of Fig. 10 with Figs. 12 and 13 shows a different relationship in models and observations for snow cover in November and April. However, in January, a more extended snow cover over Europe is followed in both models and observation by anticyclonic anomalies over Iceland and negative pressure anomalies over the mid-latitude Atlantic Ocean, as well as cold air temperature advection toward Europe. As the same relationship is found when the January land snow leads the atmosphere by two months in models, this might indicate a large-scale atmospheric response to the snow cover anomalies. However, an anomalous persistence of atmospheric anomalies can also be caused by troposphere-stratosphere interactions, increasing the memory of the atmosphere. This hypothesis is investigated in the next section.

### 4.3 Role of the stratosphere for the January snow cover variability

To understand the mechanism behind the statistical relationship between the January snow cover and the atmosphere, we focus on LMDZOR6 (the model #5 in Figs. 11g-i, 12g-i, and 13g-i.), as daily outputs and three-dimensional atmospheric fields are available. LMDZOR6 reproduces the links between the January snow cover EOF1\textsubscript{int} and the atmosphere one or two months later shown in Fig. 13, with nearly identical regression maps onto PC1\textsubscript{int} (not shown). Figure 15 shows the lag regression of the daily polar cap temperature (north of 60°N) onto the PC1\textsubscript{int} of the January snow cover. A significant lower-stratosphere warming is simulated from November to March. At 50-hPa, the temperature anomaly increases from 0.15°C in November to 0.3°C in December and 0.6°C in January. The stratospheric warming and polar vortex weakening thus precede the January snow cover anomalies. However, the stratospheric temperature shows another maximum anomaly of 1.0°C in February, suggesting that the snow cover has intensified the polar vortex weakening. The 50-hPa geopotential height anomalies associated to the snow cover show that the polar vortex weakening is widespread and affects the whole polar cap (Fig. S4).
The wave activity flux was calculated to investigate the propagation of the stationary waves (see Section 2.2). The regression of the wave activity flux on PC1\textsubscript{Int} shows an amplified upward component of the wave activity flux over eastern Eurasia and the western North Pacific (Fig. S5). This may weaken the polar vortex within 10 to 20 days. It is well established that such polar vortex weakening might then lead to a negative AO in the troposphere, with a lag of a few weeks (Baldwin and Dunkerton, 1999), and episodic downward propagations are indeed visible in Fig. 15 from mid-January to March. However, the role of the snow cover anomalies in this mechanism remains to be established.

To do so, we consider in the same model (e.g. LMDZOR6) an index of the stratospheric polar vortex, defined as the standardized January polar cap (north of 60°N) temperature anomalies at 50-hPa, hereinafter called PCT\textsubscript{50}. We also define an February AO index with the first PC of the SLP north of 20°N. The ensemble mean of that model is then removed from all time series. The correlation between PCT\textsubscript{50} and PC1\textsubscript{Int} is weak (0.09) but significant. Both the January PCT\textsubscript{50} and PC1\textsubscript{Int} are significantly correlated to the February AO, but the variance of the AO that is explained by PCT\textsubscript{50} is larger than the one associated with the snow cover index, PC1\textsubscript{Int} (Fig. 15b). Both polar vortex and snow cover remain significantly related to the AO when using a multi-variate regression (not shown). A similar analysis using composites confirms this result and shows that the relationships between both indices and the AO are mostly linear (Fig. S6). Therefore, the snow cover has a significant influence on the AO, but this influence is smaller than the one associated with the polar vortex.

Using regression onto PCT\textsubscript{50}, we found that the snow cover anomalies precede the stratospheric warming by 1 or 2 months (Fig. 16a,d), but not by more. The same regression using SLP (Fig. 16b,e) shows a dominant Ural blocking pattern in December increasing the snow cover anomalies by easterly cold air advection, and preceding by one month the January polar vortex anomaly. The Ural blocking is associated with negative SLP anomalies over Western Europe and the Aleutians, and thus projects onto the negative AO phase. Ural blocking can also amplify the stationary wave pattern and warm the stratosphere through intensified heat flux due to planetary waves (Martius et al., 2009; Peings, 2019). The regressions are weaker for lag -2, with only a small significant anticyclone east of Scandinavia. The Ural blocking pattern
over northern Siberia is consistent with positive snow anomalies south of it. The regressions obtained using PCT\textsubscript{50} (Fig. 16b,e) resemble the one obtained with PC1\textsubscript{Int} (Fig. 16c,f), even if the later anomalies are shifted toward the North Atlantic.

In summary, the snow cover and the polar vortex have a common driver, namely Ural tropospheric blocking. The snow cover and the polar vortex also have a similar influence on the AO one month later. Therefore, the lag relationship between January snow cover and the troposphere in February or March must be interpreted with caution, as causality cannot be firmly established. However, the polar vortex anomalies in Fig. 15 show a clear amplification in February, following the January snow cover anomalies. Although the snow cover influence is smaller than the one of the polar vortex, it remains significant when removing the concomitant effect of the polar vortex with a multivariate regression using snow cover and polar vortex indices. This suggests that snow cover anomalies act as a positive feedback for the AO variability, as they amplify the combined negative AO and Ural blocking pattern.

5. Discussion and conclusion

The land snow over the Northern Hemisphere is investigated in four observational datasets and two large multi-model ensembles of atmosphere-only experiments, one with prescribed SST, sea ice and external forcing during the 1979-2014 period, and the other in which sea ice variations are replaced by their climatology. Although models simulate different mean states for snow cover, the observations show an important spread as found by Mudryck et al. (2017), and both simulated trend and mean state are within the observational spread. In the multi-model ensemble mean, the trend is mainly driven by the external forcings and the associated SST warming. The sea ice loss only drives a small and insignificant fraction of snow cover trends. The sea ice loss only produces a decreasing snow cover trend located south and downstream of Scandinavia in January and April, and east of Scandinavia downstream of the Barents Sea in November. Cohen et al. (2014), among others, proposed that snow anomalies might amplify or damp the mid-latitude atmospheric circulation response to sea ice loss, but in our experiments, the SIC has little influence in driving the snow cover. However, the lack of two-way coupling between atmosphere, sea-
ice and the ocean in our experiments does not allow reproducing realistic links between snow and sea ice anomalies. Analogous analyses need to be conducted in AOGCMs to further investigate the links between SIC and snow cover.

The 1979-2014 investigated period shows a transition from a warm to a cold IPO phase and from a cold to a warm Atlantic multidecadal variability (AMV) phase (Luo et al. 2022). Our analysis suggests that the IPO has a consistent influence among models on the North American snow cover, through the PNA teleconnection pattern. The results for the Eurasian snow cover are ambiguous and cannot be specifically attributed to the SST anomalies or the external forcings. The investigation of simulations focusing on the role of external forcing, such as those realized in the RFMIP (Pincus et al., 2016) panel of CMIP6 would be necessary to distinguish between them. Sensitivity simulations using the observed changes in the AMV and IPO would also be helpful. In addition, including the period after 2014 would be important to understand the climate impacts of the observed reduction in spring snow cover (Mudryk et al. 2020). The simulations investigated here end in 2014 and cannot be used to fully understand this change. A similar multi-model investigation with simulation extended to present-day could be pursued in future works.

The snow cover variability due to internal atmosphere-land variability is analyzed in the large ensembles of simulation after removing the ensemble mean separately in each model. Lacking a better method, the internal variability is quantified in observations by removing the quadratic trend. We performed an EOF analysis of the Eurasian snow cover and used regression of atmospheric fields on the associated PCs to investigate the atmosphere-snow coupling. We found that the models reproduce well the main atmospheric modes responsible for the forcing of the snow cover in observations, with Ural blocking anomalies embedded with wave-like anomalies leading to dipolar snow cover anomalies in early spring and early winter. In mid-winter, the NAO has the dominant influence, increasing the snow cover over Europe and inducing a widespread Eurasian cooling for negative NAO phases. In both observations and models, we found no robust circulation pattern following November snow anomalies. This seems to contradict the results of Gastineau et al. (2017), where CMIP5 preindustrial control simulations were found to partly reproduce the observed influence of November Eurasian snow. This emphasizes the need
to better explore the observational uncertainties, using various data sets. However, sea ice concentration and SST anomalies are prescribed in our atmosphere-only simulations and cannot respond to the atmospheric forcing as in observations or coupled simulations, where snow cover, sea ice and SST are driven by the atmosphere, and provide concomitant forcings. Both models and observations show that January eastern European snow cover anomalies are linked to AO-like anomalies one month later. The relationship remains significant at a lag of two months in models. The outputs from one of the models reveal that the Ural blocking pattern acts as a common driver for the Eastern Europe snow and the polar vortex anomalies. A stratospheric warming (cooling) event and a polar vortex weakening (strengthening) are, therefore, found to precede by two months the snow cover and negative (positive) AO changes in January. The stratospheric warming is found to explain a larger AO variance fraction than the snow cover. The lead-lag relationship between snow cover and atmosphere might only stem from the internal atmospheric variability, as proposed by Blackport and Screen (2021) for the case of the sea-ice atmosphere interaction that shares a large similarity with the interaction discussed here. However, we note that polar vortex anomalies (Fig. 15) are reinforced in February, one month after snow cover anomalies, and are much weaker before January. Such asymmetry suggests that the snow cover intensifies the stratospheric warming and the resulting AO-like anomalies produced by downward propagation one month later. This mechanism is supported by the intensification of the upward propagating planetary waves following a larger snow cover extent in January, as found by Lü et al. (2020). This suggests a two-way coupling between the snow cover and the internal atmospheric variability, where the snow cover anomalies amplify the AO-Ural blocking anomalies that generated them, acting as a positive feedback in the land-troposphere-stratosphere system. This conclusion agrees with the results from subseasonal forecasts (Orsolini et al., 2015; Garfinkel et al., 2020), where the snow cover through troposphere-stratosphere interaction reinforces and prolongs the NAO. Further investigating causality and the specific role of the snow cover would require sensitivity experiments controlling the land snow cover, or the use of specific statistics to investigate the causation (San Liang, 2014; Runge et al., 2015).
Code and data availability
This study is based on publicly available data for observations. The climate model simulations are available upon request from the authors of this study. Matlab code for data analysis and scripts used to generate the map (ferret and python) can be obtained upon request from the corresponding author. The Plumb wave activity flux is calculated using the code from Kazuaki Nishii (http://www.atmos.rcast.u-tokyo.ac.jp/nishii/index.html).

Figure 1: (Top) Seasonal cycle of the area covered by snow, in $10^6$ km$^2$, in (a) North America and (b) Eurasia. (Bottom) Seasonal cycle of the Northern Hemisphere snow mass, in $10^{12}$ kg, in (c) North America and (d) Eurasia. Color curves show results from models. Thick black curves show observations. The grey shade provides the observational spread obtained from CanSISE.
Figure 2: (a) Mean January snow cover in CanSISE, in fraction. (b-i) Mean snow cover (color shade) bias in January, in fraction, calculated as the ALL ensemble mean minus CanSISE for each model. The contours indicate the mean snow cover fraction in CanSISE (contour interval 0.2) shown in (a).
Figure 3: Same as Fig. 2, but for the snow water equivalent, in m.
Figure 4: Time series of the anomalous area covered by snow in $10^6$ km$^2$ (first row) and anomalous snow mass in $10^{12}$ kg (second row) in winter (from November to April), in (right) North America and (left) Eurasia in observation and the simulation ALL. (Third row) Same as first row, but for ALL minus NoSICvar. (Fourth row) Same as the second row, but for the difference ALL minus NoSICvar. Note the different scale in the y-axis for (left axis, black line) models and (right axis, blue line) ERA5-Land and CanSISE observations. The grey shading indicates the range between the minimum and the maximum values among the eight models. The black curve is the multi-model ensemble mean. The correlation between the multi-model mean and ERA5-Land is given in the bottom left corner of each panel, the star symbol indicating a p-value below 5%.
Figure 5: Trend in Northern Hemisphere (a) snow mass and (b) snow extent. Correlation between ERA5-Land and simulated values for (c) snow mass and (d) snow extent. Red (blue) symbol denotes the simulation ALL (ALL minus NoSICvar) for 1979-2014. Grey symbol denotes the CanSISE observations for 1979-2010. Orange (blue sky) symbol is for the simulation ALL (ALL minus NoSICvar) when using linearly detrended fields. Northern Hemisphere trend in snow cover, in % per decade$^{-1}$, for the multi-model mean of simulations (e-g) ALL and (h-j) the difference of ALL minus NoSICvar; in (e) (h) November (f) (i) January and (g) (j) April. In (a-d), the size of the symbol is large (small) if the significance of the trends is below (above) 5%. In (e-j), black contours indicate where the p-values are lower than 5%. 
Figure 6: Variance fraction (in %) of the interannual snow cover anomalies explained by SST, external forcing and sea ice concentration; for (a) November, (b) January and (c) April. The thick black curve indicates where the p-value of the ANOVA test is lower than 5% for at least 5 models out of 8. Variance fraction (in %) of the snow cover area over Eurasia (Eur) and North America (NAm) calculated for each model separately for (d) November, (e) January and (f) April. The number from 1 to 8 designates the model (see table 1 for correspondence with model name). The symbol star indicates when 30 members are available for both ALL and NoSICvar. The factor $f$, representing the influence of SST and external forcings, is referred to as SST/ext. The factor $e$, representing the influence of SIC on the time mean snow, is referred to as SIC. The factor $te$, representing the influence of SIC on the time-varying snow, is referred to as SST/Ext:SIC. Numbers are given in bold font if the ANOVA test has a p-value below 5%.
Figure 7: (Left column) First and (center column) second EOFs of Northern Hemisphere snow cover anomalies in ERA5-Land during 1981-2014 for (first row) November, (second row) January and (third row) April. The variance explained by the EOFs is indicated. (Right column) Pattern correlation between the (blue bar) EOF1 and (orange bar) EOF2 of ERA5-Land and that found in other observational datasets MERRA2, NOAA-CDB and CanSISE.
Figure 8: (Left column) First EOF of the snow cover anomalies associated with sea surface temperature and external forcing anomalies and (center column) first EOF associated with sea ice concentration anomalies, for (first row) November, (second row), January and (third row) April. (Right column) Correlation between the observed snow cover PC1/2 and PC1 BC and between the observed PC1/2 and PC1 SIC, when using (blue and orange bars) ERA5-Land, (green cross) MERRA2, (blue cross) NOAA-CDR and (red cross) CanSISE. The blue (orange) bars and the associated crosses provide the results when using PC1 (PC2) from observations. The dashed line provides the 5% level of statistical significance for the correlation when using ERA5-Land, MERRA2 or NOAA-CDR in 1981-2014 (32 degrees of freedom). The dotted line is the same as the dashed line but when using CanSISE in 1981-2010 (28 degrees of freedom).
Figure 9: (a) (b) (c) Regression of the SST, in °C (gray contours and color shade) on PC1BC; (d) (e) (f) Regression of the SST, in °C (color shade) and sea level pressure, in hPa (black contour, contour interval 2 hPa; dotted contours for negative values), on PC1BC. (g) (h) (i) Regression of the SIC, in % (gray contours and color shade), and sea level pressure, in hPa (black contour, contour interval 2 hPa; dotted contours for negative values), on PC1IC. In all panels, color shade indicates p-value below 5% for the regression of the SST or SIC. Dots indicate p-values below 5% for the SLP regression in panels (d)-(i). Left panels are for November. Center panels are for January. Right panels are for April.
Figure 10: (First column from left) First EOF of the detrended Eurasian snow cover in ERA5-Land, shown as the regression of the snow cover, in %, onto the first PC. (Second column) Regression of the observed (color shade and grey contours) surface air temperature, in °C, and (black contour; contour interval 1 hPa) sea level pressure in hPa on PC1 at lag=0, and (third column) at lag = 1, i.e. for PC1 leading by one month the atmospheric fields. (Forth column) Pattern correlation of the EOF1s and of the regressions of surface air temperature or sea level pressure on the Eurasian snow cover PC1 between ERA-Land and other snow cover datasets. T2M_0 and SLP_0 designate the pattern correlation of the regressions at lag = 0; T2M_1 and SLP_1 designate the pattern correlation at lag = 1. The first row is for November, the second row for January and the third row for April. In the second and third columns, color shadings indicate p-value below 5% for the surface air temperature regression.
Figure 11: (First row) First and (second row) second EOF\textsubscript{Int} of the Eurasian snow cover, in %, associated with internal atmospheric variability in the simulations ALL and NoSICvar. The patterns are the average patterns of the eight models. The numbers displayed on top are the minimum and maximum variance explained by that EOF among the eight models. Dots indicate the locations where 7 models out of 8 have EOF\textsubscript{Int} anomalies with the same sign. (Last row) Spatial pattern correlation between the EOF\textsubscript{Int} obtained from each model and that of the model average. The blue (orange) bar shows the results when using the first (second) EOF. The numbers on the x-axis designate each model (see Table 1 for the corresponding model names). The symbol star indicates when 30 members are available for both ALL and NoSICvar; for (left column) November, (center column) January and (right column) April.
Figure 12: Regression of the (color shade) 2 m air temperature (T2m), in °C, and (black contour, contour interval 0.5 hPa) SLP, in hPa, on (a) (b) (c) PC1_int and (c) (d) (e) PC2_int, for (left) November, (center) January and (right) April. All regressions are calculated at no lag (lag = 0 mth), and only use the T2m and SLP anomalies associated with the internal atmosphere-land variability, after the removal of the corresponding multi-model mean. The regression shows the multi-model mean regression map, with dots indicating when the sign of SLP anomalies is consistent in at least 7 models out of eight. The color shades are masked if the sign of T2m is not consistent in at least 7 models out of eight.
Figure 13: Same as Fig. 12a-c, but at (a) (b) (c) lag 1 and (d) (e) (f) lag 2, when the atmosphere follows by one month the (left) November, (center) January and (right) April snow cover index, as provided by PC1_int. The last row shows the spatial pattern correlation north of 20°N between the SLP regression obtained from each model and that of the model average. The blue (green) bar shows the results at lag 1 (2). The numbers on the x-axis designate each model (see Table 1 for the corresponding model names). The symbol star indicates when 30 members are available for both ALL and NoSICvar; for (g) November, (h) January and (i) April.
Figure 14: Same as Fig. 12a-c, but using PC2_int instead of PC1_int at lag = 1 month, when the atmosphere follows by one month the (a) November, (b) January and (c) April snow cover. The last row shows the spatial pattern correlation north of 20°N between the SLP regression obtained from each model and that of the model average. The blue bar shows the results at lag 1. The numbers on the x-axis designate each model (see Table 1 for the corresponding model names). The symbol star indicates when 30 members are available for both ALL and NoSICvar; for (g) November, (h) January and (i) April.

Figure 15: (a) Regression of the daily air temperature anomalies over the polar cap (north of 60°N), in °C, onto the First PC of the snow cover internal atmospheric variability, PC1_int, in January and in LMDZOR6. The black line indicates the local statistical significance at the 5% level. The vertical dashed black line shows the days corresponding to January. (b) Explained variance fraction of the Arctic Oscillation defined as the first EOF of the sea level pressure north of 20°N, for a regression using PC1_int, PCT50 and both PCT_int and PCT50 as predictors. The explained variance fraction is significant at the 5% level in the three cases.
Figure 16: Regression of the (a,d) snow cover, in %, and sea level pressure (SLP; b,e) anomalies, in hPa, onto the January polar cap (north of 60°N) 50-hPa temperature anomalies in LMDZOR6. (c,f) Regression of the sea level pressure (SLP) anomalies, in hPa, onto the First PC of the snow cover internal atmospheric variability, PC1_int, in January and LMDZOR6. The lag indicated is negative and given in month, indicating that the polar cap 50-hPa geopotential height or the PC1_int lags. The color shades are masked if the local statistical significance is above 5%.
