15 **Abstract:**

16 Sill intrusions emplaced in organic-rich sedimentary rocks trigger the generation and
17 migration of hydrocarbons in volcanic sedimentary basins. Based on seismic and geological
18 observations, numerical modeling studies of hydrothermal flow around sills have shown that
19 thermogenic methane is channeled towards the intrusion tip, where it rises to the surface in a
20 hydrothermal vent. However, these models typically assume impermeable sills and ignore
21 potential effects of permeability evolution in cooling sills, e.g., due to fracturing. To address
22 this issue, we combine a geological field study of a volcanic basin (Neuquén Basin,
23 Argentina) with hybrid FEM/FVM numerical modeling of hydrothermal flow around a sill,
24 including hydrocarbon generation and transport. Our field observations show that graphitized
25 bitumen veins and cooling joints filled with solid bitumen or fluidized shale are common
26 within the studied sills. Raman spectroscopy indicates graphitization at temperatures between
27 350-500°C, evidencing fluid flow within the intrusions shortly after solidification. This
28 finding motivates our modeling study, which investigates flow patterns around intrusions that
29 become porous and permeable upon solidification. The results show three distinct flow
30 phases affecting the transport of hydrocarbons generated in the contact aureole: (1) Contact-
31 parallel flow toward the sill tip before solidification, (2) upon complete solidification, sudden
32 vertical “flushing” of overpressured hydrocarbon-rich fluids from the lower contact aureole
33 through the hot sill, and (3) slow rise of hydrocarbon-rich fluids above the sill center, and
34 backward-downward flow near the sill tip. We conclude that permeability creation within
35 cooling sills may be an important factor for hydrothermal flow and hydrocarbon transport in
36 volcanic basins, as it considerably alters the fluid pressure configuration and flow patterns by
37 dissipating overpressure below the sills. This could, for instance, lead to a reduced potential
38 for hydrothermal venting.

39

40 1 Introduction

41 Sill intrusions emplaced in sedimentary rocks strongly influence the generation and migration
42 of hydrocarbons and greenhouse gases in volcanic sedimentary basins. If sill intrusions are
43 emplaced in organic-rich strata, they trigger contact-metamorphic reactions (e.g., organic
44 matter transformation), overpressure generation, and hydrothermal fluid flow in the
45 surrounding strata (Einsele et al., 1980; Aarnes et al., 2012). Many recent studies of volcanic
46 sedimentary basins investigate how such processes may cause the formation of hydrothermal
47 vent complexes, which facilitate greenhouse gas release to the atmosphere and can thus drive
48 global climate change (Svensen et al., 2004; Aarnes et al., 2010; Aarnes et al., 2012; Iyer et
49 al., 2013; Iyer et al., 2017; Galerne and Hasenclever, 2019). Additionally, the same processes
50 can be critical factors for hydrocarbon generation and migration in igneous petroleum
51 systems containing sills emplaced within shale formations (Senger et al., 2017; Spacapan et
52 al., 2020).

53 Hydrothermal flow in response to the intrusion of magma into sedimentary host rocks has
54 been investigated for decades. The magmatic heat input leads to several temperature-
55 dependent processes that promote strong fluid pressure increase, which drive fluid flow
56 (Einsele et al., 1980; Delaney, 1982). These processes include for instance thermal fluid
57 expansion, mineral dehydration, organic matter transformation into hydrocarbon generation,
58 and pore space reduction due to mineral precipitation (Einsele et al., 1980; Delaney, 1982;
59 Aarnes et al., 2010; Townsend, 2018). When the rate of overpressure generation is larger than
60 flow-driven pressure dissipation, e.g. in low-permeable rocks like shale, hydraulic fractures
61 form and locally enhance fluid flow and pressure release (Aarnes et al., 2012; Kobchenko et
62 al., 2014; Panahi et al., 2018; Rabbel et al., 2020). This process may lead to explosive
63 hydrothermal vents, which are present in several volcanic basins (Nermoen et al., 2010;
64 Aarnes et al., 2012; Iyer et al., 2017).

65 Numerical models simulate these coupled processes to understand hydrothermal flow
66 dynamics and the associated hydrocarbon migration (usually represented as methane carried
67 in the hydrothermal fluids), typically in the context of vent formation around sills emplaced
68 in organic-rich sediments. Such simulations assume that sills are impermeable and show that
69 vents seem to preferentially form at the inclined tips of large “saucer-shaped” sills because
70 this situation favours both fast fluid pressure build-up below the sills and focussed fluid

71 migration towards the tips (Iyer et al., 2013, Iyer et al., 2017; Galerne and Hasenclever,
72 2019).

73 However, observations from several volcanic sedimentary basins indicate that the assumption
74 of impermeable sills is not generally valid. Sills often host fracture networks including
75 different fracture types. These form shortly after solidification of the magma and may include
76 columnar cooling joints or fractures related to hydraulic fracturing during hydrothermalism
77 (Senger et al. 2015, Witte et al. 2012, Rabbel et al., 2021). Multiple studies have provided
78 evidence that such fracture networks may be open and can contain water (Chevallier et al.,
79 2004) or hydrocarbons and act as fluid pathways or even fractured reservoirs (Mark et al.,
80 2018; Schofield et al., 2020; Spacapan et al., 2020). However, it is currently unknown to
81 which extent the generation of fractures during the cooling phase of sills affects hydrothermal
82 flow and associated hydrocarbon migration in volcanic basins.

83 To address this issue, we present a geological case study from the northern Neuquén Basin,
84 Argentina, combined with numerical hydrothermal simulations. The northern Neuquén Basin
85 provides particularly well-documented examples of sills with extensive cooling joint
86 networks emplaced in organic-rich shale because the fractured sills represent the main
87 reservoirs in several commercially producing oil fields (Rodriguez Monreal et al., 2009;
88 Witte et al., 2012; Spacapan et al., 2020). Additionally, numerical modeling and subsurface
89 data demonstrate the strong thermal impact of intrusions on host rock maturation in these
90 systems (Rodriguez Monreal et al., 2009; Spacapan et al., 2018). We first present geological
91 evidence from outcropping sills to provide evidence for hydrocarbon transport through
92 fractured sills in a hydrothermal environment. Our field observations motivate the
93 implementation of numerical modelling to test the influence of cooling joint formation, i.e.
94 permeable sills, on the hydrothermal flow patterns and hydrocarbon migration. We performed
95 a parameter study, in which we test this effect for sills of varying thickness and emplacement
96 depth. By integrating the simulation results with geological evidence, we show how
97 permeable sills affect hydrothermal flow in volcanic sedimentary basins as well as the fate of
98 hydrocarbons generated by contact metamorphism.

99

2 Geological observations

2.1 Geological setting

The study area is located around the Río Grande Valley (RGV) in the northern Neuquén Basin, Argentina, about 100 km south of the town of Malargüe (Figure 1). The Neuquén Basin initially formed as a series of isolated half-grabens during the late Triassic to early Jurassic (Howell et al., 2005). During the middle Jurassic to early Cretaceous, these depocenters coalesced during thermal subsidence, forming a large shallow-marine basin. This phase included the deposition of the Vaca Muerta and Agrío formations, which comprise several hundreds of meters of calcareous, organic-rich shale and form two important source rock formations for presently exploited petroleum systems (Kietzmann et al., 2014). From the early Cretaceous, the basin developed into a foreland basin in response to the compressive tectonic regime of the Andean orogeny. This led to inversion of the Triassic normal faults and

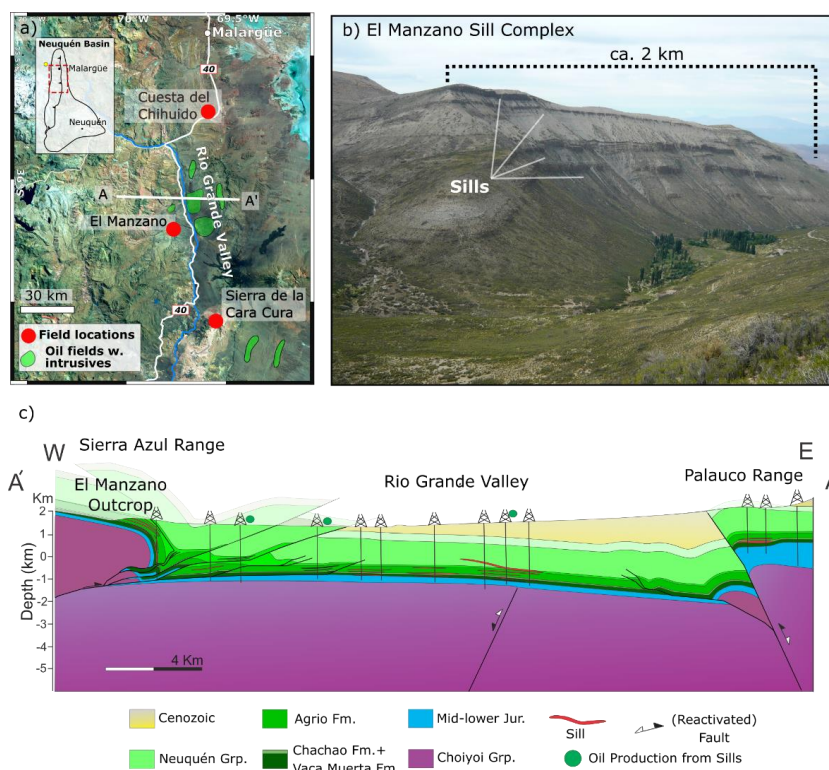

Figure 1. (a) Satellite image of the study area in the northern Neuquén Basin including field localities (red dots) and producing igneous petroleum systems (green areas). (c) E-W structural geological section illustrating the relation between subsurface and outcropping sill complexes (courtesy. J. B. Spacapan)

112 generation of a series of fold-thrust belts along the western basin boundary (Manceda and
 113 Figueroa, 1995; Yagupsky et al., 2008).

114 In addition to tectonic deformation, the northern Neuquén Basin experienced intense
 115 magmatic activity that formed a series of volcanic plateaus and widespread magmatic
 116 intrusions within the sedimentary succession (Kay et al., 2006). In the study area, two main
 117 eruptive cycles, termed Molle and Huincán eruptive cycles, occurred in the late Oligocene-
 118 mid Miocene and the late Miocene-Pleistocene, respectively (Combina and Nullo, 2005).
 119 These events lead to the emplacement of extensive andesitic and basaltic sill complexes
 120 predominantly in the Vaca Muerta and Agrío Formations, but also in overlying gypsum and
 121 sandstone units (Spacapan et al., 2020).

122 In the RGV, heavily fractured sills emplaced in the Vaca Muerta and Agrío formations
 123 constitute the reservoirs in an actively producing igneous petroleum system (Schiuma, 1994;
 124 Witte et al., 2012). Spacapan et al. (2020) reported 2 to 27 m thick sills in these shale
 125 formations, but up to 54 m within shallower clastic sediments of RGV. Other studies from the
 126 northern Neuquén Basin report thick laccolith intrusions (>100 m) acting as reservoirs
 127 (Rodríguez Monreal et al., 2009). Spacapan et al. (2018) showed that the heat input provided
 128 by the sills matured the Vaca Muerta and Agrío shale formations, which otherwise show very
 129 low thermal maturity at burial depths of ca. 2-2.5 km. The established model for the
 130 formation of these igneous reservoirs includes that the intrusions developed interconnected
 131 cooling joint networks, which subsequently stored the generated hydrocarbons (Witte et al.,
 132 2012; Spacapan et al., 2020).

133 In addition to the subsurface sill complexes, thrust tectonics brought to surface exceptional
 134 outcrop analogues in the surrounding mountain ranges including the Sierra Azul, Sierra Cara
 135 Cura, and Cuesta del Chihuido (Figure 1). Several studies describe these localities, which
 136 offer easy access to sills emplaced in the Vaca Muerta and Agrío formations (Spacapan et al.,
 137 2017; Rabbel et al., 2018; Rabbel et al., 2021). Especially the km-scale outcrops at El
 138 Manzano (Figure 1b) and Sierra Cara Cura constitute direct analogues to the subsurface sill
 139 complexes of the RGV igneous petroleum system (Palma et al., 2019; Rabbel et al., 2021).
 140 These three field localities are ideal case studies to reveal the interactions between igneous
 141 intrusions and the petroleum system.

142

2.2 Field methods

The fieldwork conducted for this study aims to document evidence of hydrothermal flow and hydrocarbon transport related to permeable intrusions in the study area. During three field campaigns, we collected an extensive dataset at the outcrops in El Manzano, Sierra de la Cara Cura, and Cuesta del Chihuido (Figure 1). We gathered ground-based and drone digital photographs to document outcrop observations. Additionally, we collected over 100 rock samples from the intrusions, surrounding shale as well as various types of veins for geochemical analyses. Here, we focus on presenting field evidence for hydrothermal flow of hydrocarbon-bearing fluids both around and within the sills, which then motivates the numerical study. Note that a more comprehensive description of the field study is presented by Rabbel et al. (2021).

2.3 Observations of hydrocarbons inside and around sills

Outcropping sills in all three localities feature solid bitumen and black shale inside the fracture network of the sills. At Cuesta del Chihuido, both the side and roof of thin sills are exposed, and the side view reveals upwelling dykelets of black shale (Vaca Muerta Formation) entering the sill from the bottom contact (Figure 2a). The top view of the same sill shows the entire polygonal cooling joint network with a black fill of the same material (Figure 2b). Brecciated igneous material often surrounds the dykelets where they enter the intrusion.

The larger sills at El Manzano (Sierra Azul) and Sierra Cara Cura also show widespread bitumen in the fracture network of the sills, but at a much larger scale (Figure 3). We observe arrays of 1-up to 50 cm thick and >10 m high bitumen dykes or veins (Figure 3a). Here, the bitumen dyke cuts across the contact aureole and enters the sill intrusion. We find exposures of similar structures where the sill interior is accessible (Figure 3b). The sill appears heavily fractured in addition to preexisting cooling joints, and solid bitumen or calcite fill nearly all fractures. On closer inspection, the bituminous material in these veins has a shiny and fibrous texture.

At an exposed sill tip at El Manzano, we also observe that thick bitumen veins appear to be concentrated along the tip contact, where they mutually cross-cut with calcite veins of at least similar thicknesses (Figure 3c,d). These calcite veins have cm-scale pores, which occasionally

174 contain solid bitumen themselves and release a strong hydrocarbon smell when the vein is
175 broken up.

176

177 **2.4 Bitumen characterization**

178 The fibrous texture of the observed bitumen within the sills is intriguing and suggests that it
179 partly experienced graphitization, i.e. it is much higher-grade bituminous material than that
180 described in the Neuquén basin by Cobbold et al. (1999) and Zanella et al. (2015).

181 In the field, we tested this hypothesis by measuring the resistivity of the fibrous bitumen with
182 a hand-held multimeter. Graphitization of bitumen significantly changes the electric
183 resistivity of the material: amorphous solid bitumen is very resistive and used as an electric
184 insulator in industry applications (Hays et al., 1967), while graphite is an excellent conductor.
185 Qualitative on-site resistivity measurements showed that the fibrous bitumen conducts
186 electric currents well, i.e., within the detection limit of a standard multimeter, suggesting
187 significant graphitization.

188 In addition, we applied Raman spectroscopy to better constrain the nature of the solid
189 bitumen and its thermal history. Raman spectroscopy provides positions and relative
190 intensities of spectral peaks characterizing carbonaceous materials like bitumen, including D
191 (“disorder”) and G (“graphite”) peaks at 1345 cm^{-1} and 1585 cm^{-1} , respectively (Potgieter-
192 Vermaak et al., 2011; Rantitsch et al., 2016). The shape of the spectra and the D/G peak and
193 area ratios allow classification of high-grade alteration of the bitumen to anthracite or (semi-
194)graphite and may serve as a geothermometer for high-temperature regimes (Beyssac et al.,
195 2002; Rantitsch et al., 2016). Due to the high temperatures within and around igneous
196 intrusions, we expect this method to indicate the degree of thermal alteration and thus
197 temperatures that the hydrocarbons experienced. Since Raman spectra can show varying
198 absolute intensities, we normalized each spectrum to the intensity of the respective G peak
199 (I_G) for visualization purposes.

200

201

Figure 2. Field observations of upwelling dykelets of liquefied shale and bitumen entering the cooling joint network of a thin sill at Cuesta del Chihuido (ca. 30 cm thick). (a) Side view showing the sediment-intrusion contact and dyke (Photo: D. Michelon), (b) top view demonstrating black bituminous fill in the polygonal cooling joints.

202

203 Raman spectrograms of the **sampled bitumen veins** show very clearly developed G and D1
 204 peaks and I_{D1}/I_G **ratios of 0.6 and 0.9**, respectively. The D3 band between the peaks is nearly
 205 absent in the sample from Sierra de la Cara Cura, while it is visible at low intensity in the
 206 presented sample from El Manzano (Figure 4).

Figure 3. Examples of dykes or veins of solid bitumen associated the sill intrusions. (a) Bitumen dyke at El Manzano of >10 m height and up to 0.5 m thickness originating in the aureole of Agrío Fm. and entering the sill through the bottom contact. (b) Fractured zone inside a sill at Sierra de la Cara Cura exhibiting many cm-scale veins of solid bitumen. (c, d) Exposed sill tip at El Manzano showing high concentration of fibrous bitumen and calcite veins in the contact in front of the tip.

207 2.5 Composition and thermal implications of bitumen samples

208 We compare our Raman results with those measured in carbonaceous material from several
 209 studies, where increased graphitization and metamorphism lead to well-developed, narrow
 210 graphite (G) and disordered carbon (D1) peaks, weak or absent D3 bands, and I_G/I_D peak
 211 ratios of <1 (Beyssac et al., 2002; Kwiecinska et al., 2010; Rantitsch et al., 2016). Although
 212 we did not perform quantification via peak-fitting, a qualitative comparison of our results
 213 with highly metamorphosed sediments presented by Beyssac et al. (2002, Fig. 6 and 11

214 therein) leads to estimated temperatures of 350-500°C for our samples (Figure 4).
215 Hydrothermal graphitization can occur along intrusion-sediment contacts at relatively
216 shallow crustal levels and requires temperatures of $\geq 400^\circ\text{C}$ (Buseck and Beyssac, 2014).
217 Hydraulic fracturing focuses the flow of hydrothermal fluids oversaturated with CH_4 and/or
218 CO_2 from which crystalline graphite may precipitate (Rumble, 2014). This fits well with the
219 observations that the bitumen dykes in our study area consist of pure, often crystalline
220 graphitic material and occupy fractured zones in the aureole, **around the tip**, or within the sills
221 themselves (Figure 3). In a previous summary of fracture types present in the sills of the study
222 area, Rabbel et al. (2021) interpreted these features as hydraulic fractures. Thus, evidence
223 from graphitized bitumen in the fractures in the aureole and the sills themselves points to
224 hydrocarbon transport in a high-pressure, high-temperature environment in which at least part
225 of the mobilized carbon transforms to graphitic carbonaceous material.

226 Our field and sample results strongly suggest that significant volumes of hydrocarbons
227 circulated through the sills when the temperature at their margins was 350-500°C. The
228 temperature was thus likely much higher in the interior of the sills. We infer that
229 hydrothermal flow also occurred along cooling fractures within the sill, i.e., the sill developed
230 some permeability while still hot (cf. Figure 2). This interpretation challenges the
231 assumptions of **previous models of hydrothermal circulation around cooling sills, in which**
232 **the sills remain impermeable during cooling** (Aarnes et al., 2012; Iyer et al., 2017, Galerne &
233 Hasenclever, 2019). To which extent permeability creation within hot sills affects
234 hydrothermal flow and the associated hydrocarbon transport around sills is not known. In the
235 following section, we therefore present numerical simulations to test the effects of
236 permeability increase associated with fracturing within the sills on hydrothermal circulations,
237 and how this affects hydrothermal transport of hydrocarbons around sills.

238
239

Figure 4. (a) Raman spectra from two bitumen vein samples at Sierra de la Cara Cura and El Manzano, respectively. Both samples include well-developed and narrow graphite and disordered carbon (G, D1) peaks as well as weak or absent D3 band. (b) Reference Raman spectrum to illustrate spectra decomposition of carbonaceous material after Beyssac et al. (2002).

3 Numerical Simulations

3.1 Model description

We employ the two-dimensional (2D) finite element model of Galerne and Hasenclever (2019), who applied it to quantify degassing through sill-related hydrothermal vents. As this complex model is presented in detail in Galerne and Hasenclever (2019), we will limit our discussion to the main features and point out the key adjustments for this study. In short, the model simulates hydrothermal flow around a cooling sill but is also coupled to a model for the heat-driven chemical transformation of organic matter into hydrocarbons (represented by methane). This allows us to investigate not only hydrothermal circulation around sills as such but also how this affects the transport of the hydrocarbons generated in the aureole.

The model considers single-phase hydrothermal flow of a compressible fluid in a porous medium following Darcy's law. Temperature calculations comprise heat diffusion, heat advection and heat sources/sinks related to latent heat of magma crystallization, dehydration, thermal cracking of organic matter as well as internal fluid friction and pressure-volume work. Fluid density varies with temperature and pressure according to the equation of state of pure water. The pore pressure equation also contains source terms representing fluid release due to temperature-dependent, irreversible contact metamorphic reactions, including (i) organic matter transformation into methane and (ii) clay mineral dehydration.

To calculate organic matter transformation to methane, the model uses the EASY%Ro method (Sweeney and Burnham, 1990), which quantifies the converted fraction of organic

261 matter and thermal maturity through vitrinite reflectance R_o . We monitor transport and
 262 accumulation of the released methane due to hydrothermal flow using a finite volume
 263 advection scheme, but do not consider buoyancy effects resulting from the addition of
 264 methane to the pore fluid. Clay mineral dehydration follows the maximum storable weight
 265 fraction of water in the stable mineral assemblage at a given temperature, which is predicted
 266 by phase equilibria (Connolly, 2009). This process not only produces additional pore fluid,
 267 but also causes a permanent porosity increase in the affected host rock to ensure mass
 268 conservation of rock and fluid. Note here that while the model uses the properties of methane,
 269 the results can be used to understand transport of (light) hydrocarbons around sills in general.
 270 We thus use “methane” and “hydrocarbons” interchangeably in the context of this study.

271 The model provides time series of the 2D fields of all relevant rock properties in the model
 272 domain and physical quantities related to metamorphism and hydrothermal flow. Since we
 273 investigate the impact of permeable sills on the fluid and hydrocarbon circulation, our
 274 analysis focuses on visualization of the flow fields and methane accumulation during cooling.

275 **3.2 Adjustments for this study**

276 We adjusted two aspects of the original model to honor geological observations in the study
 277 area. First, we limit the permeability increase in the host rock due to rock fracturing to tensile
 278 hydraulic fracturing, but do not consider shear failure. At sufficiently high pore fluid
 279 overpressure, i.e., if pore pressure exceeds the sum of lithostatic stress and tensile strength,
 280 we assume that hydrofracturing occurs and increases permeability. Here, we consider
 281 hydrofracturing of the aureole only, not within sill.

282 Second, we approximate the process of joint formation within the sill through a linear porosity-
 283 permeability increase that is a function of temperature. Geological observations from the
 284 Neuquén Basin suggest that an open (cooling) joint network developed in the sills through
 285 which hydrocarbon-bearing hydrothermal fluids entered the sill while it was still hot enough to
 286 cause graphitization (Figure 2, Figure 3, Figure 4). Cooling joints form as a result of bulk volume
 287 reduction of the cooling and crystallizing magma, which induces thermal stresses that lead to
 288 the formation of a cooling joint network, creating primary porosity and permeability inside the
 289 intrusion (e.g., Petford, 2003; Hetényi et al., 2012). The overall pore-space gained in the model
 290 is set to equate 8% volume loss, occurring during the transition from a melted to crystallized
 291 magma (between the liquidus and solidus temperature), based on reported fracture porosities
 292 from fractured sill reservoirs in the study area (Witte et al., 2012; Spacapan et al., 2020). To be

293 consistent with the crystal-mush model described by Marsh (2002), the onset of the pore
 294 opening should be when 50-55% of the magma has crystallized. Here we take a value of
 295 1000°C as the onset of the brittle-ductile-transition (BDT) temperature. Using a linearized,
 296 temperature-dependent definition of the melt fraction, $(T-T_S)/(T_L-T_S)$, with $T_L = 1100^\circ\text{C}$ and
 297 $T_S = 900^\circ\text{C}$ being liquidus and solidus temperatures, resp., the set value for the BDT in our
 298 simulations implies that cooling joint creation starts when, at any distance from the sill margins,
 299 50% of the sill has crystallized.

300 Note that in this way, we limit the model's representation of fracturing in the sill to cooling
 301 joints and thus perform a strong simplification compared to the complex interplay of fracturing
 302 mechanisms observed in the field (cf. section 3 and Rabbel et al, 2021). However, the goal is
 303 to study the general impact of permeable sills on hydrothermal flow and the associated
 304 hydrocarbon transport, which should be possible even with this limitation.

305

306 **3.3 Modeling setup**

307 We designed our modeling study to approximate the conditions of our study area, although
 308 we simplified the setup for the sake of a well-constrained parameter study. Figure 5 and Table
 309 1 show the model setup and the list of important model parameters, respectively.

310 The model domain extends from the surface to 500 m below the emplacement depth of the
 311 sill. We assume instantaneous sill emplacement at 1100°C, corresponding to the inferred
 312 liquidus temperatures of andesitic magma in the study area (Spacapan et al., 2018). Since
 313 flow patterns around idealized flat sills tend to be symmetric, we limited our studies to a 500
 314 m long “half”, flat sill intrusion (Figure 5a). This allows to evaluate processes around and
 315 within the sill at very high resolution of 0.5 m. The left and right boundaries are insulating
 316 and impermeable, and we calibrated the temperature at the bottom boundary to create a
 317 geothermal gradient of around 30°C/km. The top boundary mimics the behaviour of the sea
 318 floor with free in- and outflow. Otherwise, initial conditions consider no basin history such as
 319 uplift and erosion, and no pre-existing thermal maturation before sill emplacement. We
 320 justify this by low background maturity values reported in the study area (Spacapan et al.,
 321 2018; Palma et al., 2019; Rabbel et al., 2021)

For the sediments, we chose a homogenous material with 5% TOC and ca. 5 weight percent bound water, as well as exponential decay of porosity with depth (Figure 5b). Permeability is porosity-dependent and follows a Kozeny-Carman relationship. All values are calibrated to local organic-rich shale, i.e. low porosity and low permeability rocks (Figure 5b). We chose the specific values to match properties of Agrio and Vaca Muerta formations at 2-3 km depth

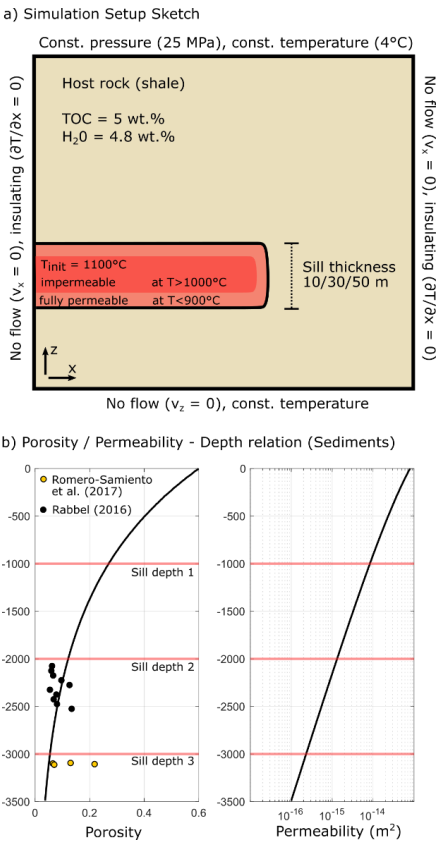

Figure 5. Illustration of the numerical modelling setup. (a) Sill geometry, boundary and initial conditions (not to scale). (b) Left: Porosity-depth relationship calibrated using reported data from the Vaca Muerta formation from various depths (Rabbel 2017, Romero-Samíento et al. 2017). Right: Permeability as a function of depth-

327

328 in the northern Neuquén Basin, which corresponds to emplacement depths for the igneous
329 petroleum systems present in both subsurface and outcrop.

330

331

332

3.4 Parameter sensitivity study

In total, we ran 27 simulations to investigate the effects of

- porosity and permeability generation within sills
- emplacement depth, i.e., sediment permeability and porosity (1, 2, 3 km)
- intrusion thickness (10, 30, 50 m)

We first conduct a series of reference setups including permanently impermeable sills but allowing hydraulic fracturing of the host rock. All combinations of emplacement depth and sill thickness lead to a total set of 9 reference simulations. Subsequently, we use the same setups but activate temperature-dependent porosity and permeability generation for the sills.

Table 1. Material properties used for hydrothermal simulations

Fixed rock parameters	Value	Unit
Fluid Properties	Follow eqn. of state for pure water (IAPS-84)	
Magma / Sill Properties (representing andesite)		
Specific heat capacity ^{1,2}	900	J kg ⁻¹ K ⁻¹
Latent heat of crystallization ^{1,2}	320	kJ/kg
Initial sill temperature ^{3,4}	1100	°C
Liquidus temperature ³	1100	°C
Solidus temperature ⁴	900	°C
Brittle-Ductile-Transition (permeability creation)	1000-900	°C
Permeability range in sill ⁴	10-20 – 10-15	m ²
Sill thickness ⁴	10, 30, 50	m
Magma density ^{2,6}	2830	kg/m ³
Thermal conductivity	2.51	W m ⁻¹ K ⁻¹
Host Rock Properties (representing shale)		
Density ⁶	2600	kg/m ³
Specific heat capacity ⁵	960	J kg ⁻¹ K ⁻¹

344 3.5 Numerical Simulation: results

345 3.5.1 Impermeable sill: Flow focusing and methane plume

346 We first present the results of the reference simulation of a 50 m thick, impermeable sill
 347 emplaced at 3 km depth. Figure 6 displays the evolution of temperature, vitrinite reflectance
 348 (Ro) as a proxy for thermal maturity, permeability and methane concentrations in the model
 349 1, 64 and 1000 years after the sill is emplaced. In the first few years after emplacement (left
 350 column in Figure 6), the sill is still over 1000°C hot and only the host rock very close to the sill
 351 is heated to temperatures of >350°C. Within the thin, barely visible thermal aureole, thermal
 352 maturity increases strongly and mineral dehydration takes place. In the dehydrated area,
 353 permeability increases from initial values of around 10^{-16} to 10^{-15} m² (Figure 6g). Figure 6g also
 354 shows a wider area of increased permeability indicated by the white dotted outline, which
 355 corresponds to the extent of hydrofracturing. The organic matter in the shale close to the
 356 contact shows a strong initial methane release, which travels toward the tip, where a small
 357 initial methane plume rises above the intrusion (Figure 6j).

358 After 64 years (central column in Figure 6), the high-temperature aureole in the surrounding
 359 host rock has expanded as the sill progressively cools down (Figure 6b). Within a distance of
 360 about 50 m around the sill, thermal maturity has reached Ro values above 2, which indicates
 361 the gas window or overmaturity (Figure 6e). Permeability in the same region is visibly
 362 elevated because the clay minerals are partly or fully dehydrated (Figure 6h). However, no
 363 more hydrofracturing occurs, since overpressures have dissipated and no longer exceed the
 364 tensile failure criterion. Methane concentrations now show a wide plume of methane rising
 365 on top of the sill and especially over its tip, but also a sizable accumulation remaining below
 366 the sill (Figure 6k).

367 The right column in Figure 6 represents the end of the simulation after 1000 years. The
 368 temperatures throughout the model are still elevated with respect to the initial geotherm but
 369 are now below 200°C everywhere. The dehydration-related permeability increase has not
 370 expanded significantly, but a second plume of very high methane concentrations is rising
 371 above the sill, but at some distance to its tip. The peak of the first plume has reached ca. 300

372 m above the sill at this point. The aureole below the sill has also accumulated high methane
 373 concentration of up to 800 kg per m³ of water, which remain trapped below the impermeable
 374 sill.

375

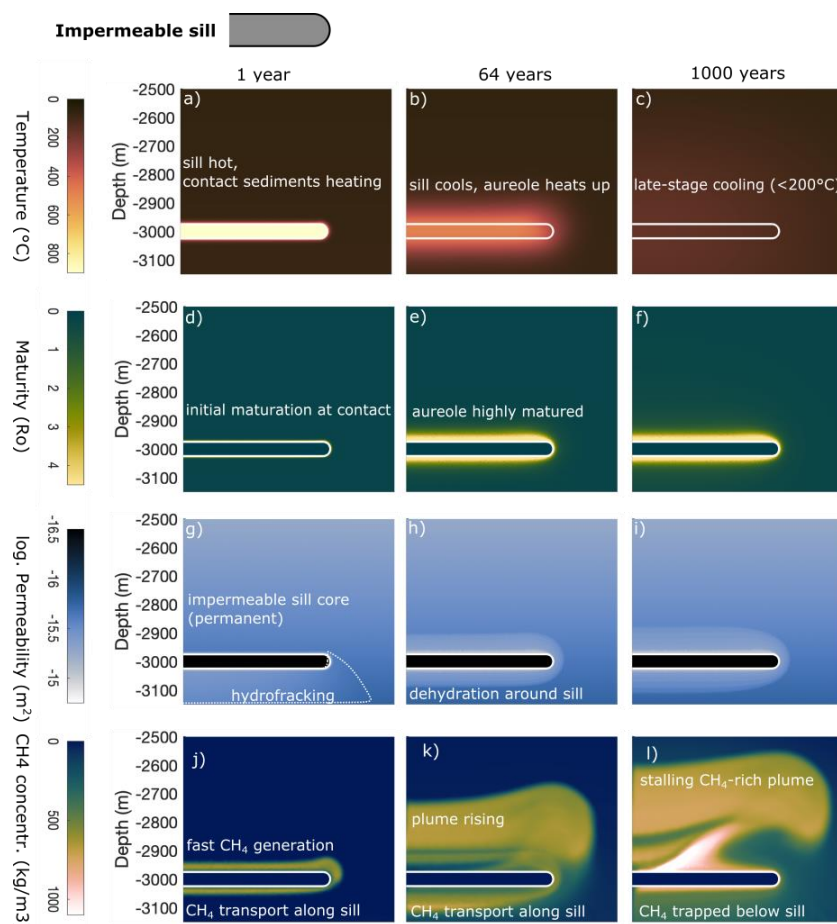

Figure 6. Reference simulation results for an impermeable sill of 50 m thickness at 3 km depth. The columns correspond to 1, 64 and 1000 years of simulated time after emplacement, respectively. The rows represent four parameters characterizing thermal state, contact metamorphism and hydrothermal transport of methane: (a-c) Temperature, (d-f) thermal maturity / organic matter transformation as vitrinite reflectance Ro, (g-i) permeability, (j-l) methane concentration.

376 3.5.2 Permeable sill: Pressure release and flow reversal

377 The introduction of cooling-related permeability generation in the sill profoundly changes the
 378 development of hydrothermal flow and methane transport patterns. We show identical

parameters and time steps as for the reference simulations, i.e. temperature, vitrinite reflectance (thermal maturity), permeability and methane concentrations in the model area around the permeable sill (Figure 7). To describe the details of the evolving flow patterns, we add close-up figures for methane concentration and flow velocities displaying flow vectors as well as the accumulation of methane and average temperature in the permeable and porous sill (Figure 8).

In the early phase, initial cooling of the sill leads to a progressing permeability front where the temperatures approach the solidus defined as 900°C. At this stage, the simulation closely resembles the reference run (Figure 7, left column). Temperatures in the sediments are elevated only very close to the intrusion, where the sediments almost instantly produce gas or become thermally overmature, i.e. vitrinite reflectance is larger than 1.5 (Figure 7a, d). Permeability in the sediments increases due to dehydration near the intrusion contact and hydrofracturing in the area within the dotted line below the sill (Figure 7g). Although large-scale methane concentrations appear nearly identical to the reference scenario, the detailed view shows that the onset of porosity and permeability generation in the sill's outermost regions allows some limited methane transport into the sill (Figure 8a.1). Nevertheless, most fluid flow and methane transport occur parallel to the sill contact and only rise upward around the sill tip (Figure 8a.1, a.4). Since methane generation in the aureole continues but transport is directed sideways within the host rock, the fraction of methane stored in the sill itself reduces (Figure 8b).

However, after the entire sill has become fully permeable, the flow direction along the sill center suddenly changes from horizontal, contact-parallel to near-vertical (Figure 7h, k, Figure 8a.2, a.5). The hydrothermal fluids transport the high methane concentrations from the lower aureole directly through the sill and into the upper aureole (Figure 7h, Figure 8a.2). In the upper aureole temperatures and thermal maturity are now higher than in the lower aureole (Figure 7b, e). At the same time, the flow directions at the intrusion tip also change and a circular flow pattern develops centered around a vortex located at the top of the intrusion tip (Figure 8a.2, a.5). This vortex initiates a downward directed flow that transports some of the methane from the flat rising plume above the sill back towards and into the sill tip (Figure 7k). During this phase of "methane flushing", more methane enters the sill from below and through the tip than is lost through the top contact, and thus both absolute and fractional methane stored in the intrusion rises until ca. 90 years of simulation (Figure 8b). Interestingly, the average temperature in the sill during this stage is still between 400-800°C (Figure 8b). The flow of

412 fluids through the sill also leads to an increased cooling rate from the moment when the sill
413 becomes fully permeable, as is indicated by the “kink” of the temperature curve at ca. 20
414 years (Figure 8b). Note also that the flow velocities drop by about 2 orders of magnitude
415 compared to the initial years and are now on the order of 10 cm/year after 64 years of
416 simulation.

417 In the following phase until the end of the simulation, the sill and sediments cool down to
418 below 200°C, and thermal maturity and permeability only increase marginally (Figure 7c, f, i).
419 The release of methane previously trapped under the sill creates a slowly rising band of very
420 high methane concentrations above the sill (Figure 7l). At the tip, continuous circular flow
421 creates a spatially confined area of very high methane concentration (Figure 8a.3, a.6).
422 However, flow velocities have further reduced by another 2 orders of magnitude (Figure 8a.6).
423 Overall, the sill maintains the total amount of stored methane due to approximately equal
424 inflow and outflow (Figure 8b). However, since methane generation continues in the shale, the
425 fraction of total methane stored in the sill reduces to ca. 5% from 500 years of simulation and
426 onwards.

427 In summary, we identify three hydrothermal flow phases in the case of a sill with
428 permeability evolution due to cooling joints. These include (i) pre-fracturing contact-parallel
429 flow and methane transport, (ii) post fracturing methane-flushing and partial backflow and
430 (iii) stabilization of methane in sill and late-stage methane generation.

431

432

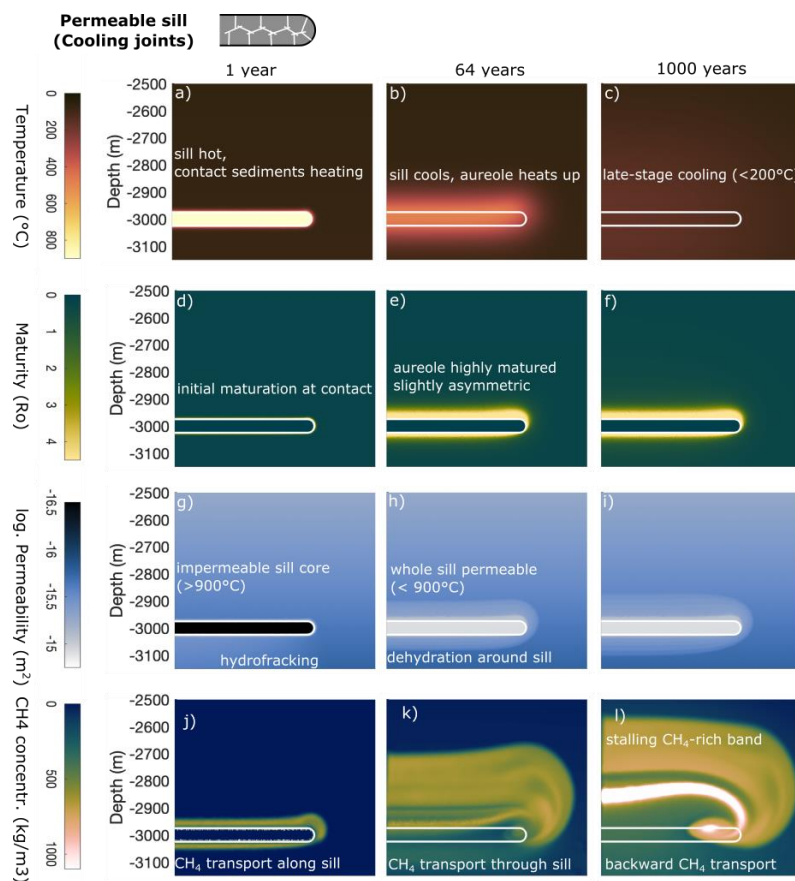

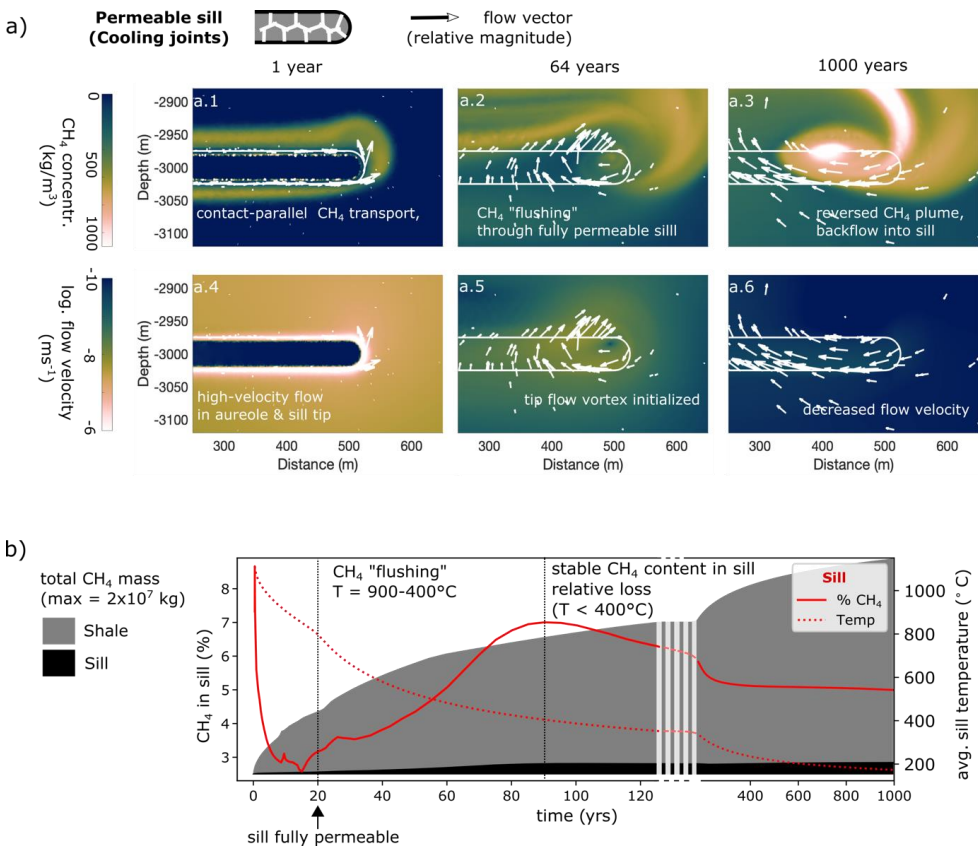

Figure 7. Simulation results for identical conditions as the reference case in Figure 6 (50 m thick, 3 km depth), but the sill develops porosity and permeability with cooling. The columns correspond to 1, 64 and 1000 years of simulated time after emplacement, respectively. The rows represent four parameters characterizing thermal state, contact metamorphism and hydrothermal transport of methane: (a-c) Temperature, (d-f) thermal maturity / organic matter transformation as vitrinite reflectance Ro, (g-i) permeability, (j-l) methane concentration.

Figure 8. (a.1-a.6) Detailed view of the simulation of a permeable sill (50 m thick, 3 km depth, cf. Figure 7). The columns correspond to 1, 64 and 1000 years after emplacement, respectively. The rows show methane concentration (a.1-a.3) and flow velocity (a.4-a.6). The arrows represent flow vectors, with length differences representing relative magnitudes. Note that irregular arrow spacing is due to increased mesh fineness in and around the sill. (b) Fraction of total methane stored in the sill (solid line) and average temperature inside the sill (dotted line) throughout the simulation displayed above. Note that x-axis scaling is changed after 125 years, as indicated visually.

3.5.3 Effects of emplacement depth and sill thickness

Finally, we explore the influence of emplacement depth and sill thickness on the resulting hydrothermal flow and methane transport pattern in case of a permeable sill (Figure 9). **Not surprisingly**, deeper and larger sills lead to more methane generation, but the transport of methane differs significantly because the flow patterns are affected in several ways. First, backward flow toward the intrusions similar to that described in the former section occurs only for **deep emplacement depths**, i.e. generally low permeability of the host rock due to burial, and for **relatively thick intrusions** (Figure 9a, d, g). **In contrast, very thin intrusions** (10 m) mainly generate a **thick band of rising methane** but little to no backflows at this depth (Figure 9f, i).

Figure 9. Parameter study results for the effect of varying emplacement depths and sill thicknesses on the final methane distribution after 1000 years, assuming a permeable sill. The columns represent different thicknesses of 50 m, 30 m and 10 m, respectively. The rows show emplacement depths of 1 km, 2 km, and 3 km, respectively, and thus include associated changes in host rock porosity and permeability as displayed in Figure 2b.

At 1km depth, however, the characteristics of the hydrothermal flow patterns change drastically. Although some methane remains inside and below the sill tip, the backflow around a tip-vortex is no longer the dominant feature. Instead, hydrothermal convection cells develop above the intrusion and a methane plume rises towards the surface (Figure 9a,b). After 1000 years, the plume generated by the 50 m thick sill has risen by 500m, which is more than double compared to the 30 m thick sill at the same depth, or a 50 m thick sill at 2 km depth (Figure 9a, b, d).

4 Interpretation and discussion

4.1 Hydrocarbon transport through hot sills

Outcrop data strongly suggests that transport of hydrocarbons generated around the sills in the northern Neuquén Basin occurs both vertically through the igneous intrusions as well as around their tip. Importantly, geochemical data from the study area suggests that the sills are responsible for most, if not all, organic matter transformation in the host rock, because background maturity between the sills is essentially zero (Spacapan et al., 2018; Rabbel et al., 2021). We thus interpret the observed hydrocarbons in the field to result from magmatic and hydrothermal activity rather than burial-related maturation.

Cooling joints and veins or dykes filled with black shale and bitumen are pervasive throughout the fracture networks of sills in our study area (Figure 2 and Figure 3). The example shown in Figure 2 is particularly clear in showing the relationship between upwelling fluidized structures and the fill of the cooling joints. Note that similar observations have been documented in other outcrops at larger scales (Rabbel et al., 2021). We therefore propose that the flow of hot fluids and fluidized sediments through sills is a common occurrence in the northern Neuquén Basin. We thus provide solid outcrop evidence that sills can become a preferred hydrocarbon transport pathways upon cooling. In contrast, this finding contradicts the widespread assumption of impermeable intrusions in modeling studies of hydrothermal fluid flow in volcanic basins (e.g., Iyer et al., 2013; Iyer et al., 2017; Galerne and Hasenclever, 2019).

Our observations complement numerous growing evidence of hydrocarbons or fluidized sediments within sills of widely different sizes exist for instance in the Faroe-Shetland Basin (Rateau et al., 2013; Schofield et al., 2020), Karoo Basin (Svensen et al., 2010) and Guyamas

Basin (Teske et al., 2021). Svensen et al. (2010) found metamorphosed sandstone dykes within dolerite sills in the Karoo Basin with mineral assemblage indicative of temperatures >300°C. They proposed that strong pressure gradients between the overpressured host rocks and the solidifying and contracting sill intrusions are likely responsible for liquefied sediments entering the intrusions shortly after cooling. Similar to this study, Svensen et al. (2010) based this interpretation on coupled thermo-hydraulic models, but explicitly considered thermal contraction of the magma. Although our approach of adding porosity to the sill is a simplification of this process, the general mechanism of hydrocarbon-rich fluids and sediments entering the cooling joint network in the intrusions in the Neuquén Basin is similar. We thus infer that our observations of hydrocarbon flow through hot sills in the Neuquén Basin are widespread in volcanic basins worldwide.

4.2 Impact of permeable sills on hydrothermal flow

Our numerical simulations allow us to assess the effects of implementing porosity and permeability increase due to fracturing when the sill has reached the solidus temperature. In simulations with an impermeable (i.e., unfractured) sill, the intrusion acts as a constant barrier for the hydrothermal flow and methane transport, and only the aureole shows permeability evolution due to fracturing and dehydration (Figure 6a, d, g). In this configuration, an upward-rising methane plume initiates from the top contact of the sill. In addition, large amounts of methane are trapped below the sill, since no vertical pathways are available through the sill (Figure 6g, j).

In contrast, a permeable sill introduces drastic changes in the flow and methane transport patterns, and results in three distinct phases with very different characteristics.

Phase 1: Impermeable sill and contact-parallel flow. Prior to complete solidification, the sill acts as a flow boundary and the flow patterns are essentially the same as in the reference simulation, i.e., rising methane above the sill and contact-parallel flow and extensive hydrofracturing below the sill (Figure 6g, j; Figure 7g, j, Figure 8a.1, a.4). Hydraulic fractures in the aureole and around the sill edge initiate in this early phase, which may lead to the formation of the large bitumen dykes and calcite veins observed in the field (Figure 3).

Phase 2: Hydrothermal “flushing” through solidified, permeable sill. The generation of cooling-related porosity and permeability inside the sill initiates the abrupt change from

512 contact-parallel flow towards the intrusion tip to vertical uprising through the sill (second
 513 column of Figure 7, Figure 8a.2, a.5). This effect is responsible for a rush of hydrocarbon (here:
 514 methane) -rich fluids through the sill at average temperatures of 400-800°C (Figure 8b),
 515 because the large overpressure below the sills can now drive fluid flow straight upwards and
 516 dissipate instead of supplying a steady flow toward the sill tip. In addition, porosity
 517 generation inside the sill creates a suction effect that drives fluids into the intrusion (cf.
 518 Svensen et al., 2010). Considering flow velocities after 64 years (Figure 8a.2, a.5), the model
 519 shows that fluids flowing through a 50 m thick sill are exposed to this environment for tens of
 520 years, which could be sufficient for graphite generation and therefore seems to fit well with
 521 outcrop data and models for hydrothermal graphite generation (Figure 4; Rumble, 2014).

522 *Phase 3: Vortex phase and reversed flow.* The sudden change in the pore pressure
 523 distribution due to permeability creation within the sill also initiates the vortex observed
 524 above the sill tip and leads to the observed flow reversal and methane transport towards the
 525 sill tip (right column Figure 7; Figure 8a.3, a.6). However, in the long run the amount of
 526 methane influx toward the sill approximately equals the loss through upward flow so that the
 527 amount of methane is stable within the sill, and the fraction of total methane stored in the sill
 528 reduces after the “flushing” phase (Figure 8b). Hydrocarbons entering the sill in this last phase
 529 does not experience the extreme temperatures and have better chances of survival.

530 **4.3 Impact of depth and thickness of permeable sills on hydrothermal flow**

531 The first two phases, i.e. contact-parallel flow followed by methane “flushing”, occur in all
 532 simulations with permeability creation within the cooling sill in a very similar fashion, which
 533 fits well with the fact that we observe graphitic material in sills of all sizes in the field.
 534 However, the final flow configuration and methane distribution shows important differences
 535 with intrusion thickness and emplacement depth (Figure 9). At depths of at least 2 km, i.e.,
 536 emplacement depths approximately corresponding to the Agrio and Vaca Muerta formations
 537 in the study area, the dominant feature is the backflow at the sill tip from an otherwise evenly
 538 rising band of very high methane concentration (Figure 9d, g). Conversely, for the shallowest
 539 case (1 km), higher background permeability now allows the formation of large convection
 540 cells that transport methane towards the surface, while accumulation in the sill itself is very
 541 limited (Figure 9a). Thus, shallow permeable sills seem to favour hydrothermal upward
 542 transport of methane. This conclusion corresponds well with the results of Iyer et al. (2013)
 543 who found that in shallow, high permeability settings, release of fluids through permeable

544 sills could be an important factor for greenhouse gas emissions from contact aureoles of sill
545 intrusions.

546 Furthermore, the **thinnest sills modelled** do not have sufficient thermal energy to create the
547 required pressure anomaly to sustain a flow vortex and backward flow of methane similar to
548 the larger intrusions (Figure 9c, f, i). This is especially true for the deeper intrusions, where
549 lower permeability of the host rock generally inhibits fluid flow. Since most of the sills
550 emplaced in our study area are less than 30 m thick, we expect that only few sills create
551 significant backflow.

552 **4.4 Implications for fluid flow and methane transport**

553 The strong contrast between the simulations with permeable and impermeable sills has
554 important implications for the understanding of hydrothermal flow in volcanic basins, and
555 notably on the formation of hydrothermal vent complexes and gas release to the atmosphere.
556 Permeable sills strongly favor upward vertical flow and fluid pressure dissipation, especially
557 in low-permeability host rocks, whereas impermeable sills favor fluid pressure build-up and
558 contact-parallel flow towards sill tips. These latter mechanisms are the main responsible for
559 the formation of hydrothermal vent complexes at sill tips (Iyer et al., 2017; Galerne and
560 Hasenclever, 2019). Conversely, since the opening of vertical pathways through the sills due
561 to cooling joints efficiently dissipates overpressure, permeable sills could potentially inhibit
562 vent formation, or at least reduce atmospheric degassing.

563 Although we do not attempt to model vent formation here, our study can serve as a starting
564 point to investigate the favorable conditions for hydrothermal vent formation. Our findings
565 suggest that imposing impermeable sills in hydrothermal models is a strong assumption that
566 may artificially ease the formation of hydrothermal vent complexes. Although there are good
567 arguments to assume that massive, unfractured and impermeable intrusions dominate in many
568 volcanic basins, the growing evidence of permeable sills during cooling (see section 6.1)
569 suggests that this assumption should be critically evaluated on a case-by-case basis, and
570 might explain the lack of hydrothermal vent complexes in some volcanic basins, like in the
571 Neuquén Basin. **We argue that future hydrothermal modelling studies of intrusion in
572 sedimentary basins need to include sound justification for the chosen permeability and
573 porosity evolution of the sills.**

574 **Additionally**, the occurrence of graphitic bitumen in dykes and as filling of cooling joints
575 indicates that part of the carbon gases rising through permeable sills could be reduced to

576 graphite and be stored as solids (Figure 2, Figure 3, Figure 4). This fraction of carbon is
 577 strapped permanently underground and is not available for degassing in the atmosphere. The
 578 widespread observations of graphite in the field suggests that a significant fraction of
 579 hydrocarbons matured in the sills metamorphic aureoles may not be mobilized. **Currently,**
 580 **the fraction of methane transformed to immobile graphite, and so how much this reduced**
 581 **methane transport, is not known.**

582

583 **4.5 Implications for igneous petroleum systems in the Río Grande Valley**

584 Our study also provides further insight into the evolution of the igneous petroleum systems in
 585 the Río Grande Valley, in particular with respect to the timing of the charging of the igneous
 586 hydrocarbon reservoirs. The current conceptual models comprise three main phases after sill
 587 emplacement into the previously immature shale formations (Witte et al., 2012; Spacapan et
 588 al., 2018; Spacapan et al., 2020). During the initial “thermal stage”, the heat input from the
 589 sills generates liquid and gaseous hydrocarbons. During the second so-called “cooling stage”,
 590 hydrocarbons hydrothermally migrate into the sill once cooling joints form. The last stage
 591 comprises tectonic fracturing and late-stage migration of hydrocarbons into the sills.

592 In this model, a significant part of the producible hydrocarbons migrates into the sill during
 593 the cooling stage, after the formation of colling joints. However, our study shows that
 594 hydrocarbons indeed migrate into the intrusions when the cooling joint network has formed,
 595 but experience far too high temperatures (at least 400°C) for them to survive as producible
 596 liquids or gases. In addition, regardless the scenarios tested in our simulations, temperatures
 597 during the main phase of accumulation of hydrocarbons in the intrusion still exceed 300°C
 598 (Figure 8b). Therefore, a survival of hydrocarbons entering the cooling joint network shortly
 599 after its creation seems highly unlikely. This result suggests that the charging of the igneous
 600 reservoirs occurs during the late-stage cooling of the sills, and after significant amounts of
 601 hydrocarbons has flowed through the sills at high temperature. The cooling stage of the
 602 models proposed earlier thus needs to be revised and split into two sub-stages: (1) a first
 603 influx of hydrocarbons through still hot sills, **with no survival hydrocarbons**, and (2) a later
 604 migration of hydrocarbons within the cooled sill, where the hydrocarbons can survive and be
 605 trapped to form producible reservoirs.

606 **4.6 Study limitations and future recommendations**

607 Finally, we present selected recommendations for future work arising from the limitations of
 608 our study. Despite the complexity of the current numerical model, some known processes are
 609 not yet considered. First, mineral precipitation at high temperatures can occur at non-
 610 negligible rates and lead to fast porosity-decrease, causing pore pressure increase and
 611 possibly fracturing (Townsend, 2018). Fracturing in the aureole may not be reversible but
 612 permanently increase porosity and permeability, which has been documented in systematic
 613 core studies of contact aureoles in the RGV (Spacapan et al., 2019). These features should be
 614 included in future research, and the model predictions tested against field and laboratory
 615 studies. Finally, due to the strong effect on hydrothermal flow, it is critical to investigate
 616 under which circumstances cooling joints, which exist in many sheet intrusions, become
 617 available flow pathways.

618

619 **5 Conclusions**

620 In this study, we integrate geological field data with numerical models to investigate
 621 hydrothermal transport of hydrocarbon-rich fluids around fractured igneous sills. We use
 622 outcrops of fractured sills emplaced in organic-rich shales in the northern Neuquén Basin to
 623 establish that sills can become permeable fluid pathways upon solidification, which affects
 624 the fate of locally generated hydrocarbons. The numerical modelling study allows us to
 625 understand the main phases of hydrothermal flow and the kilometre-scale flow patterns in
 626 response to porosity and permeability generation inside a sill intrusion. This provides new
 627 insights into hydrothermal flow in volcanic sedimentary basins, because previous studies
 628 commonly assume that sills represent permanently impermeable bodies. The main
 629 conclusions of this study are as follows:

- 630 1. Widespread occurrence of veins with solid, strongly graphitized bitumen as well as
 631 cooling joints filled with solid bitumen or organic-rich shales evidence transport of
 632 hydrocarbon-rich fluids and liquefied sediments into the sill in a high-temperature
 633 (probably >350°C), high-pressure environment.

634

- 635 2. Numerical modelling indicates three distinct flow phases around sills that become porous
636 and permeable upon solidification, which affects transport of hydrocarbons generated in
637 the contact aureole:
 - 638 (1) Contact-parallel flow toward the tip prior to solidification, creating an early
639 plume above the sill tip
 - 640 (2) Sudden change to vertical flow upon complete solidification and “flushing” of
641 hydrocarbons from the lower contact aureole upwards through the sill. This almost
642 instantly dissipates much of the overpressure below the sill.
 - 643 (3) “Post-flushing” flow regime with slow rise of hydrocarbon-rich fluids above
644 the sill center, and backward-downward flow towards the sill tip due to a vortex
645 initialized by the sudden pressure reconfiguration
- 646 3. Simulations indicate that “flushing” of methane through the sill occurs at temperatures
647 $>400^{\circ}\text{C}$, which meets the conditions for hydrothermal graphitization. This may explain
648 field observations of graphitic bitumen dykes.
649
- 650 4. Migration via reverse flow through a tip vortex during the post-flushing phase is very
651 limited or absent for thin sills ($< 30\text{m}$) in low-permeable host rocks, which applies to
652 many sill in the study area.
653
- 654 5. Permeability creation with the cooling sills may considerably reduce pressure build-up
655 below the sills, and thus reduce the potential for hydrothermal venting. With growing
656 evidence for permeable sills in volcanic basins globally, the permeability evolution of
657 sills should be addressed in future modelling studies focused on sill-related venting.
658
- 659 6. In contrast to proposed conceptual models, flow of hydrocarbons into newly formed
660 cooling joints is likely not a viable migration mechanism for igneous sill reservoirs in the
661 northern Neuquén Basin, as the intrusions are too hot for survival of liquid hydrocarbons.
662
