22 **Abstract.** The Mediterranean Forecasting Systems produces operational analyses, reanalyses and 10-day forecasts for many
23 Essential Ocean Variables (EOVs), from currents, temperature to wind waves and pelagic biogeochemistry. The products are
24 available at a horizontal resolution of 1/24 degrees (approximately 4 km) and 141 unevenly spaced vertical levels.

25 The core of the Mediterranean Forecasting System is constituted by the physical (PHY), the biogeochemical (BIO) and the
26 wave (WAV) components coupled offline, consisting of both numerical models and data assimilation modules. The 3
27 components together constitute the so-called Mediterranean Monitoring and Forecasting Center (Med-MFC) of the Copernicus
28 Marine Service.

29 Daily 10-day forecasts are produced by the PHY, BIO and WAV components as well as analyses, while reanalyses are
30 produced for the past 30 years about every ~3 years and extended (yearly). The modelling systems, their coupling strategy and
31 evolution is illustrated in detail. For the first time, the quality of the products is documented in terms of skill metrics evaluated
32 on a common three-year period (2018-2020), giving the first complete assessment of uncertainties for all the Mediterranean
33 environmental variable analyses.

34 **1 Introduction**

35 Ocean analysis and forecasting systems are now available for the global and world ocean regional seas at different spatial
36 scales and with different numbers of Essential Ocean Variables (EOV) considered (Tonani et al., 2015). The societal drivers
37 for the operational products stemming out of the ocean analysis and forecasting products are the safety of maritime transport,
38 multiple coastal hazards and climate anomalies. Moreover, the operational products are at the basis of new understanding of
39 the dynamics of the ocean circulation (Pinardi et al., 2015), its linked biogeochemical cycles, among others, carbon uptake and
40 eutrophication (Melaku Kanu et al., 2015, von Schuckmann et al., 2020) and extreme storm surge events (Giesen et al., 2021).
41 The ocean analysis and forecasting system for the entire Mediterranean Sea was set up in the past 15 years (Pinardi and
42 Coppini, 2010; Pinardi et al., 2017; Lazzari et al., 2010; Salon et al., 2019; Ravdas et al., 2018; Katsafados et al. 2016). In this
43 paper we give an overview of the “core” components of the system, i.e., the numerical models and the data assimilation
44 modules that represent the eddy-resolving ocean general circulation, the biogeochemical tracers and the wind waves.
45 Furthermore, we will document the quality EOV products using goodness indices (Brassington et al., 2017). The core
46 components constitute the so-called Mediterranean Monitoring and Forecasting Center (Med-MFC) of Copernicus Marine
47 Service (Le Traon PY et al., 2019). The integrated approach of MED-MFC system represents a unique opportunity for the
48 users who are able to access state-of-the-art data coupled and provided in a uniform manner (e.g., same grid, unique format,
49 unique point of access).

50 This ocean analysis and forecasting system, hereafter Med-MFC, produces analyses, 10 days forecasts and reanalysis (Adani
51 et al., 2011; Pinardi et al., 2015; von Schckumann et al., 2016; von Schckumann et al., 2018; von Schckumann et al., 2019;
52 Terzic et al., 2021, Simoncelli et al., 2016; Simoncelli et al., 2019; Ravdas et al., 2018, Escudier et al., 2020; Escudier et al.,
53 2021).

54 The Mediterranean Sea is a semi-enclosed basin with an anti-estuarine circulation corresponding to a 0.9/0.8 Sv baroclinic
55 inflow/outflow at the Strait of Gibraltar, positive energy inputs by the winds, net buoyancy losses inducing a vigorous
56 overturning circulation (Cessi et al., 2014; Pinardi et al., 2019). The basin scale circulation is dominated by mesoscale and
57 sub-mesoscales variability (Pinardi et al., 2016; Bergamasco et al., 2010; Pinardi et al., 2006; Robinson et al., 2001; Ayoub et
58 al., 1998), the former subdivided into semi-permanent and synoptic mesoscales with a spatial scale larger than 4-6 times the
59 local Rossby radius of deformation (Terzic et al., 2021). The stratification is large during the summer in the first 50 meters
60 and during winter the water column is practically unstratified. The Mediterranean Sea is an oligotrophic basin (Siokou-Frangou
61 et al., 2010) with a west-to-east decreasing productivity gradient (Lazzari et al., 2012) and relatively high primary productivity
62 in open ocean areas where winter mixing increases surface nutrients (Cossarini et al., 2019). The wave conditions are driven
63 by the winter storminess, while summer is characterised by low significant wave height values and higher value scatter (Ravdas
64 et al., 2018). Mean wave periods are around 5 s and mean significant wave height is 3 m.

65 In this paper we describe the final set up of the Med-MFC core components for the period 2017-2020: The PHY component
66 is offline coupled daily to the biochemical and wave components. This allows several model parametrizations to be calibrated

67 to obtain the best result in term of the specific environmental variable considered by each component. Furthermore, this weakly
68 coupled system ensures an efficient development of the data assimilation modules connected to each numerical model modules
69 and specific input data sets. It is a distributed system that shares information when and how it is required by relevant processes,
70 with efficiency and effectiveness. Due its rather unique structure and the quality of its products the system described could be
71 used as a basic standard for new systems to be developed.

72 The paper is organised as follows. Section 2 overviews the technical specifications of the Med-MFC components, Section 3
73 describes the quality of the system for a reference period from 2018 to 2020, Section 4 concludes the paper and presents future
74 perspectives.

75 **2. Description of the Med-MFC core components**

76 The structure of the Med-MFC core components is shown in Figure 1: the physical component (PHY) is composed of the
77 NEMO general circulation model (Madec et al., 2019) coupled to the WaveWatch-III (WW3) wave model (Clementi et al.,
78 2017a) and the ocean data assimilation OceanVar 3DVAR (ref); the biogeochemical component (BIO) is composed of the
79 Biogeochemical Flux Model (BFM), the tracer transport (OGSTM) and a data assimilation scheme (Lazzari et al., 2012;
80 Lazzari et al., 2016 Cossarini et al., 2015; Vichi et al., 2020), coupled daily to the daily mean of the PHY component fields;
81 the wave component (WAV) is composed of the wave model WAM (AMDI Group, 1988) and its assimilation scheme, coupled
82 daily to the daily mean of the PHY components fields. Daily 10 days forecasts are produced with all PHY, BIO and WAVE
83 components as well as analyses and reanalyses as described below.

84 **2.1. The general circulation model component**

85 **2.1.1. Numerical model description**

86 The PHY numerical model component comprises a two-way coupled current-wave model based on NEMO and WW3
87 implemented over the whole Mediterranean basin and extended into the Atlantic Sea in order to better resolve the exchanges
88 with the Atlantic Ocean (Figure 2). The model horizontal grid resolution is $1/24^\circ$ (ca. 4 km) and is resolved along 141 unevenly
89 spaced vertical levels (Clementi et al., 2017b; Clementi et al., 2019). The topography is an interpolation of the GEBCO 30arc-
90 second grid (http://www.gebco.net/data_and_products/gridded_bathymetry_data/gebco_30_second_grid/), filtered and
91 specifically modified in critical areas such as: the Eastern Adriatic coastal areas, Gibraltar and Messina straits, Atlantic external
92 border. All the numerical model choices are documented in Table A1.

93 The general circulation model considers the non-linear free surface formulation and vertical z-star coordinates. The numerical
94 scheme uses the time-splitting formulation to solve the free surface and the barotropic equations with a (100 times) smaller
95 time step with respect to the one used to evaluate the prognostic 3D variables (240 seconds). The active tracers (temperature
96 and salinity) advection scheme is a mixed up-stream/MUSCL (Monotonic Upwind Scheme for Conservation Laws; Levy et
97 al., 2001) as modified in Oddo et al. (2009). The vertical diffusion and viscosity terms are defined as a function of the

98 Richardson number, following Pacanowski and Philander (1981). The air-sea surface fluxes of momentum, mass, and heat are
99 computed using bulk formulae described in Pettenuzzo et al. (2010) and the Copernicus satellite gridded SST data (Buongiorno
100 Nardelli et al., 2013) is used to correct the non-solar heat flux using a relaxation constant of $110 \text{ Wm}^{-2}\text{K}^{-1}$ centred at midnight.
101 A detailed description of other specific features of the model implementations can be found in Tonani et al., (2008), Oddo et
102 al. (2009), and Oddo et al. (2014).

103 The wave model WW3 is discretized by means of 24 directional bins (15° resolution) and 30 frequency bins (ranging between
104 0.05 Hz and 0.7931 Hz) to represent the wave spectral distribution. The wave model is implemented using the same bathymetry
105 and grid of the hydrodynamic model and uses the surface currents to evaluate the wave refraction, but assumes no interactions
106 with the ocean bottom. The Mediterranean implementation of WW3 follows WAM cycle4 model physics (Gunter et al., 1993);
107 the wind input and dissipation terms are based on Janssen's quasi-linear theory for wind-wave generation (Jansen, 1989;
108 Jansen, 1991), the wave dissipation term is based on Hasselmann (1974) whitecapping theory according to Komen et al. (1984)
109 and the non-linear wave-wave interaction is modelled using the Discrete Interaction Approximation (DIA, Hasselmann et al.,
110 1985). The exchanges between the hydrodynamic and wave models are performed using an online hourly two-way coupling
111 which provides to WW3 the air-sea temperature difference and the surface currents evaluated by NEMO, while the neutral
112 drag coefficient estimated in WW3 is sent to NEMO to evaluate the surface wind stress.

113 The NEMO-WW3 coupled system is intended to provide the representation of current-wave interaction processes in the ocean
114 general circulation. At the moment the feedback is considered only for the surface wind stress drag coefficient and more details
115 on this wave-current model coupling can be found in Clementi et al. (2017).

116 **2.1.2. Model initialization, external forcing and boundary conditions**

117 The PHY component was initialised in January 2015 using temperature and salinity winter climatological fields from WOA13
118 V2 (World Ocean Atlas 2013 V2, <https://www.nodc.noaa.gov/OC5/woa13/woa13data.html>). The atmospheric forcing fields
119 for both NEMO and WW3 models are from 6 hours (3 hours for the first 3 days of forecast), 0.125° horizontal resolution
120 operational analysis and forecast fields from the European Centre for Medium-Range Weather Forecast (ECMWF); a higher
121 spatial (0.1° in horizontal) and temporal resolution dataset is used starting from year 2020.

122 The general circulation model lateral open boundary conditions (LOBC) in the Atlantic Ocean are provided by the Copernicus
123 Global Analysis and Forecast products (Lellouche et al., 2018) at $1/12^\circ$ horizontal resolution and 50 vertical levels. The
124 Dardanelles Strait boundary conditions (Delrosso, 2020) consist of a merge between the Copernicus global ocean products and
125 daily climatology derived from a Marmara Sea box model (Maderich et al., 2015). The WW3 model implementation considers
126 closed boundaries in both Atlantic Ocean and Dardanelles strait.

127 The river runoff inputs consist of monthly climatological data for 39 major rivers (characterised by an average discharge larger
128 than $50 \text{ m}^3/\text{s}$) with a prescribed constant salinity at river mouth (Delrosso, 2020) and listed in Table A.4.

129 2.1.3 The data assimilation component

130 A 3D-variational data assimilation scheme, called OceanVar, initially developed by Dobricic and Pinardi (2008)) and further
131 improved for a wide range of ocean data assimilation applications (Storto et al., 2015) is coupled to NEMO.

132 The OceanVar scheme aims to minimise the cost function as described in the following Eq. (1):

$$133 J = \frac{1}{2} \delta x^T B^{-1} \delta x + \frac{1}{2} (H \delta x - d)^T R^{-1} (H \delta x - d), \quad (1)$$

135 where $\delta x = x - x_b$, and x is the unknown ocean state, equal to the analysis x_a at the minimum of J , x_b is the background
136 state, $d = y - H(x_b)$ is the misfit between an observation y and its modelled correspondent mapped onto the observation
137 space to the observation location by the observation operator, H .

138 In OceanVar, the background error covariance matrix is considered as $B = VV^T$, where V is a sequence of linear operators:
139 $V = V_\eta V_H V_V$. Multivariate EOFs (Empirical Orthogonal Functions) (Dobricic et al., 2006; Pistoia et al., 2017) compose the
140 vertical component operator, V_V . EOFs are computed in every grid point for the sea surface height, temperature and salinity
141 using a three-year simulation in order to capture the mesoscale eddy variability that is assumed to represent the unbalanced
142 component of the background error covariance. The horizontal covariances, V_H , are modelled by an iterative recursive filter
143 (Dobricic and Pinardi, 2008, Storto et al., 2014). In order to assimilate altimeter observations, the dynamic height operator, V_η ,
144 developed in Storto et al., (2011) is used. A reference level of 1000 m is used for this operator so SLA along track observations
145 shallower than this depth are not assimilated.

146 The observational error covariance matrix, R , is estimated following Desroziers et al. (2005) relationship. The assimilated
147 observations include along-track altimeter sea level anomaly from six satellites and in-situ vertical temperature and salinity
148 profiles from Argo floats. A special quality control procedure is applied to the Argo data before they are assimilated. It consists
149 of removing not good quality profiles, rejecting observations with negative temperature and/or salinity, temperature higher
150 than 45°C and salinity higher than 45PSU, removing profiles with gaps in the observations of more than 40m in the first 300m
151 depth (to avoid possible inconsistencies in the thermocline), profiles with observations provided only below 35m depth and
152 observations in the 1st model layer (0-2m). Moreover, a background quality check is implemented to reject observations whose
153 square departure exceeds the sum of the observational and background-error variances 64 times in case of SLA and 25 times
154 in case of *in-situ* temperature and salinity.

155 The misfits are computed at the observation time by applying the FGAT (First Guess at the Appropriate Time) procedure and
156 the corrections to the background are applied once a day, using observations within a one-day time window.

158 **2.2. The wind wave component**

159 **2.2.1. Numerical model description**

160 The WAV component consists of two nested wave model implementations: the first grid covers the whole Mediterranean Sea
161 at $1/24^\circ$ horizontal resolution and it is nested within a coarser resolution wave model grid at $1/6^\circ$ horizontal resolution
162 implemented over the Atlantic Ocean (Figure 2).

163 The wave model is based on the state-of-the-art third generation WAM Cycle 4.6.2 which is a modernised and improved
164 version of the well-known and extensively used WAM Cycle 4 wave model (AMDI Group, 1988; Komen et al., 1994). WAM
165 solves the wave transport equation explicitly without any presumption on the shape of the wave spectrum. Its source terms
166 include the wind input, whitecapping dissipation, nonlinear transfer, and bottom friction. The wind input term is adopted from
167 (Snyder et al., 1981). The whitecapping dissipation term is based on (Hasselmann, 1974) whitecapping theory. The wind input
168 and whitecapping dissipation source terms of the present cycle of the wave model are a further development based on Janssen's
169 quasi-linear theory of wind-wave generation (Jansen, 1989; Jansen, 1991). The nonlinear transfer term is a parameterization
170 of the exact nonlinear interactions as proposed by (Komen et al., 1984) and (Hasselmann et al., 1985). Lastly, the bottom friction
171 term is based on the empirical JONSWAP model of (Hasselmann et al., 1973).

172 The bathymetric map has been constructed using the GEBCO 30arc-second bathymetric data set for the Mediterranean Sea
173 model and the ETOPO 2 data set (U.S. Department of Commerce, National Oceanic and Atmospheric Administration, National
174 Geophysical Data Centre, 2006. 2-minute Gridded Global Relief Data) for the North Atlantic model. In both cases mapping
175 on the model grid was done using bi-linear interpolation accompanied by some degree of isotropic Laplacian smoothing. This
176 bathymetry is different from the one used for the PHY component, optimized for the specific quality of the wave products.

177 The wave spectrum is discretized using 32 frequencies, which cover a logarithmically scaled frequency band from 0.04177 Hz
178 to 0.8018 Hz (covering wave periods ranging from approximately 1 s to 24 s) at intervals of $df/f = 0.1$ and 24 equally spaced
179 directions (15 degrees bin). The WAV model component runs in shallow water mode considering wave refraction due to depth
180 and currents in addition to depth-induced wave breaking. Modifications from default values of WAM 4.6.2 have been
181 performed in the input source functions as a result of a tuning procedure. Specifically, the value of the wave age shift parameter
182 (ZALP) in the wind input source function was set to 0.011 (0.008 is the default) for the Mediterranean model and the tunable
183 whitecapping dissipation coefficients C_{DS} and δ were altered from their default values to become $C_{DS}=1.33$ (2.1 default) and
184 $\delta = 0.5$ (default value was 0.6). Finally, a limitation to the high-frequency part of the wave spectrum corresponding to the
185 Cy43r1 ECMWF wave forecasting system (ECMWF, 2016) was also implemented and tested in order to reduce the wave
186 steepness at very high wind speeds.

187 **2.2.2. Model initialization, external forcing and boundary conditions**

188 The WAV component is forced with 10 m above sea surface wind fields obtained from the ECMWF Integrated Forecasting
189 System (IFS) at $1/8^\circ$ dissemination resolution. The temporal resolution of the wind forcing is 3 h for the first 3 days of the
190

191 forecast and 6 h for the rest of the forecast cycle. The wind is bi-linearly interpolated onto the model grids. Sea ice coverage
192 fields are also obtained from ECMWF at the same horizontal resolution ($1/8^\circ$) and are updated daily. With respect to currents
193 forcing, the WAV model is forced by daily averaged surface currents obtained from Copernicus Marine Service Med MFC at
194 $1/24^\circ$ resolution and the North Atlantic model is forced by daily averaged surface currents obtained from the Copernicus
195 Global wave model at $1/12^\circ$ resolution.

196 The Mediterranean Sea model receives a full wave spectrum at 5-min intervals at its Atlantic Ocean open boundary from the
197 WAM implementation in the North Atlantic. The latter model is considered to have all its four boundaries closed assuming no
198 wave energy propagation from the adjacent seas. This assumption is readily justified for the north and west boundaries of the
199 North Atlantic model considering the adjacent topography which restricts the development and propagation of swell into the
200 model domain.

201

202 **2.2.3 The wave data assimilation component**

203 The assimilation module of the WAV component is based on the data assimilation scheme of WAM Cycle 4.6.2 which consists
204 of an Optimal Interpolation (OI) of the along-track Significant Wave Height (SWH) observations retrieved by altimetry and
205 then re-adjusting the wave spectrum at each grid point accordingly. This assimilation approach was initially developed by
206 Lionello et al. (1992) and consists of two steps. First, a best guess (analysed) field of significant wave height is determined by
207 OI with appropriate assumptions regarding the error covariance matrix. One of the key issues is the specification of the
208 background error covariance matrix, for the waves called P , and the observation error covariance matrix, R . The first is defined
209 as in the following Eq. (2):

$$210 \quad P = \exp\left(\frac{d_{ij}}{l_c}\right), \quad (2)$$

211 while the second is Eq. (3):

$$212 \quad R = \frac{\sigma_o^2}{\sigma_b^2}, \quad (3)$$

213
214
215 where i and j are the model grid points in the longitudinal and latitudinal directions respectively, d is the distance of the
216 observation location to the grid point, l_c is the field correlation length, while σ_o^2 and σ_b^2 stand for the observation and model
217 errors, respectively. In the above expressions the error is considered as being homogeneous and isotropic. We use $R=1$ and the
218 correlation length l_c equal to 3 deg (~ 300 km).

219 Finally, the weights assigned to the observations are the elements of the gain matrix K as presented in Eq. (4):

$$220 \quad K = PH^T [HPH^T + R]^{-1}, \quad (4)$$

222

223 where H is the observation operator that projects the model solution to the observation location. For the current version of
224 Med-waves, the OI analysis procedure is applied only to altimeter along-track SWH measurements although wind at 10m
225 measurements can be assimilated as well.

226 During the second step, the analysed significant wave height field is used to retrieve the full dimensional wave spectrum from
227 a first-guess spectrum provided by the model itself, introducing additional assumptions to transform the information of a single
228 wave height spectrum into separate corrections for the wind sea and swell components of the spectrum. Two-dimensional wave
229 spectra are regarded either as wind sea spectra, if the wind sea energy is larger than 3/4 times the total energy, or, if this
230 condition is not satisfied, as swell. If the first-guess spectrum is mainly wind-sea, the spectrum is updated using empirical
231 energy growth curves from the model. In case of swell, the spectrum is updated assuming the average wave steepness provided
232 by the first-guess spectrum is correct, but the wind is not updated.

233 Prior to assimilation, all altimeter SWH observations are subject to a quality control procedure. Every day the system is
234 scheduled to simulate 264 hours: 24 hours in the past (analysis) blending through data assimilation model results with all
235 satellite SWH observations available followed by 240 hours forecast. The assimilation step adopted for the current version of
236 the Med-waves system equals to 3 hours.

237 **2.3 Mediterranean biogeochemical component**

238 **2.3.1. Numerical model description**

239 The BIO component consists of the Biogeochemical Flux Model (BFM, Vichi et al., 2007) coupled with the transport
240 (OGSTM) module (Salon et al., 2019). Advection, vertical and horizontal diffusion and the sinking term for the
241 biogeochemical tracers (Foujols et al., 2000) are solved by the OGSTM module that uses daily 3D velocity, diffusivities and
242 2D atmospheric fields provided by the PHY component through the offline coupling scheme (Figure 1). A source splitting
243 numerical time integration is used to couple advection and diffusion to the biochemical tracer rates.

244 BFM describes the biogeochemical cycles of carbon, nitrogen, phosphorus, silicon and oxygen through the dissolved inorganic
245 and the particulate living and non-living organic compartments (Lazzari et al., 2012; Lazzari et al., 2016). The model includes
246 four phytoplankton functional groups (i.e., diatoms, flagellates, picophytoplankton and dinoflagellates), four zooplankton
247 groups (i.e., carnivorous, and omnivorous mesozooplankton, heterotrophic nanoflagellates and microzooplankton) and
248 heterotrophic bacteria. Among the nutrients, dissolved inorganic nitrogen is simulated in terms of nitrate and ammonia. The
249 non-living dissolved organic compartment includes labile, semi-labile and refractory organic matter. A carbonate system
250 component (Cossarini et al., 2015) includes alkalinity (ALK), dissolved inorganic carbon (DIC) and particulate inorganic
251 carbon (PIC) as prognostics variables, computes CO₂ air-sea gas exchange according to Wanninkhof (2014) and provides
252 diagnostics variables such as pH, CO₂ concentration and calcite saturation horizon.

253 254 **2.3.2. Model initialization, external forcing and boundary conditions**

255 Climatological profiles from EMODnet (Buga et al., 2018) are used to initialize nutrients (nitrate, ammonia, silicate and
256 phosphate), oxygen and carbonate variables (DIC and alkalinity) in each of the areas represented in Fig. 3. The model has two
257 open lateral conditions: in the Atlantic Ocean and at the Dardanelles Strait. Nutrients, oxygen, DIC and alkalinity in the Atlantic
258 are provided through seasonally varying climatological profiles derived from World Ocean Atlas (WOA 2018) and literature
259 (Alvarez et al., 2014) and Newtonian dumping is applied. A Dirichlet-type scheme with constant concentration values of
260 nutrients, DIC and alkalinity derived from literature (Yalcin et al., 2017; Tugrul et al., 2002; Souvermezoglou et al., 2014;
261 Copin-Montegut, 1993; Schneider et al., 2007; Krasakopoulou et al., 2017) is applied at the Dardanelles Strait. The
262 concentrations are also tuned to provide input fluxes from Black Sea to the Mediterranean Sea consistent with published
263 estimates (Deliverable of Perseus, 2020; Yalcin et al., 2017; Tugrul et al., 2002; Copin-Montegut, 1993). A radiative condition
264 is set for the other BFM tracers.

265 Terrestrial inputs include 39 rivers consistently with the PHY component. Annual nutrients input are about $46500 \cdot 10^6$ molN/y
266 and $881 \cdot 10^6$ molP/y (Salon et al., 2019). Carbon and alkalinity inputs are 9300109 gC/y and $800 \cdot 10^9$ mol/y, respectively.
267 Estimates are derived considering typical concentrations per freshwater mass in macro coastal areas of the Mediterranean Sea
268 (Copin-Montegut, 1993; Meybeck and Ragu, 1995; Kempe et al., 1991) and the river water discharges from the PERSEUS
269 dataset (Deliverable of Perseus, 2012 as before). Annual atmospheric nutrient depositions are $81300 \cdot 10^6$ molN/y and $1194 \cdot 10^6$
270 molP/y for nitrogen and phosphorus, respectively (Ribera d'Alcalà et al., 2003). Atmospheric pCO₂ mean annual
271 concentrations are from the ENEA Lampedusa (Trisolino et al., 2021) station with the present-day values extrapolated by
272 linear regression.

273 **2.3.3 The biogeochemical data assimilation component**

274 The BIO component features a variational data assimilation scheme (3DVarBio) which is based on the minimization of the
275 cost function (Eq. 1) (Teruzzi et al., 2014). Minimization is computed iteratively in a reduced space using an efficient parallel
276 PETS_c/TAO solver (Teruzzi et al., 2019) and the background error covariance matrix, B, is factorised in a sequence of linear
277 operators, as in the PHY component, that accounts for the vertical error covariance of the biogeochemical fields, the horizontal
278 error covariance, and the error covariance among the biogeochemical variables.

279 The horizontal error covariance operator is a gaussian filter and includes non-uniform and direction-dependent length scale
280 correlation radius to account for anisotropic coastal assimilation (Teruzzi et al., 2018) and vertical profile assimilation
281 (Cossarini et al., 2019). The vertical error covariance operator is based on a set of vertical error profiles obtained using an
282 empirical orthogonal functions (EOFs) decomposition of a pre-existing biogeochemical simulation. EOFs are computed
283 monthly for the 16 subregions and rescaled at each grid-point considering the ratio between observation and model variances
284 (Teruzzi et al., 2018). The biogeochemical error covariance operator is designed to preserve the ratios among phytoplankton
285 functional types and their internal carbon to nutrient quotas (Teruzzi et al., 2014) and supports monthly and spatial varying
286 covariances between dissolved inorganic nutrients (Teruzzi et al., 2021).

287 In the most recent configuration (Teruzzi et al., 2021, Cossarini et al., 2019), the assimilated biogeochemical observations are
288 satellite multi-sensor (MODIS, VIIRS and OLCI) surface chlorophyll data (Volpe et al., 2019) and quality-controlled Argo-
289 BGC nitrate and chlorophyll profiles (Schmechtig et al., 2018; Johnson et al., 2018).

290

291 **2.4 Systems evolutions**

292 The Mediterranean has been the site of major forecasting research activities since the late nineties (Pinardi and Woods, 2001,
293 Pinardi et al., 2003, Pinardi and Coppini, 2010). Before 2008, only the PHY and BIO components were present. The PHY
294 component was based on the Ocean PARallelise (OPA) code (Madec et al., 1998) with the highest available horizontal and
295 vertical resolution of $1/16^\circ$ degrees (approx. 6.5 km) in horizontal and 72 vertical levels, with closed lateral boundaries, only
296 7 major rivers and implementing a weekly 3D-VAR assimilation scheme (Dobricic et al., 2007) assimilating temperature and
297 salinity vertical profiles, Sea Level Anomaly (SLA) along with track altimeter data, moreover a non-solar heat flux correction
298 was imposed through a nudging along the whole day with Sea Surface Temperature (SST) satellite gridded data.

299 A major upgrade of the PHY component was achieved in 2009 by implementing a version of the numerical model NEMOv3.1
300 including LOBC in the Atlantic Ocean (Oddo et al. 2009) and moving to a daily assimilation cycle. The first exchanges with
301 a wave model were implemented in 2010 when the PHY component was coupled hourly with WAM receiving the surface drag
302 coefficient to better represent the wind stress. In 2013 the whole operational modelling system was updated by implementing
303 an upgraded 2-way on-line coupled system based on NEMOv3.4 and WW3 (Clementi et al., 2017a) allowing for a more
304 consistent exchange between the two models. The following year the PHY general circulation module was improved by
305 accounting for the effect of atmospheric pressure effect (in addition to wind and buoyancy fluxes) and an explicit linear free
306 surface formulation using a time splitting scheme (Oddo et al., 2014), while the assimilation scheme was enhanced thanks to
307 the assimilation of Tailored Altimetry Products for Assimilation Systems (TAPAS) SLA data allowing for the application of
308 specific corrections of the altimetric original signal (Dobricic et al., 2012).

309 The PHY component delivered in 2015 included the nesting in the Atlantic Ocean through daily analysis and forecast fields
310 from the global system, while one year later the assimilation scheme was enhanced including the computation of monthly and
311 grid point EOFs and vertical observational errors varying with depth.

312 Another major PHY component evolution was achieved in 2017 when the resolution of the operational system was increased
313 to $1/24^\circ$ degrees (approx. 4 km) horizontal and 141 vertical levels using the z-star vertical coordinate system, a non-linear free
314 surface formulation and the NEMOv3.6 version and 39 rivers were introduced. From year 2019 the Dardanelles Strait inflow
315 was set as a lateral open boundary condition (instead as a river runoff climatological input) allowing for a daily update of the
316 fluxes, and an improved nudging with the satellite sea surface temperature was included by correcting the heat fluxes only
317 close to midnight.

318 The WAV component was developed and released for the first time in 2017 based on WAM Cycle 4.5.4 providing on a daily
319 basis 5 days wave forecasts and simulations for the Mediterranean Sea at $1/24^\circ$ horizontal resolution (Ravdas et al., 2018)

320 nested within a North Atlantic model at $1/6^\circ$ resolution and forced with ECMWF 10m winds and PHY component surface
321 currents. In March 2018 the system was upgraded by incorporating the data assimilation component to utilise available track
322 SWH satellite observations from Sentinel-3A and Jason-3. In 2019, the wave model was upgraded to Cycle 4.6.2 and the
323 duration of the forecasts were extended to 10 days. Additionally, a limitation to the high frequency part of the wave spectrum
324 was applied while modifications from default values were introduced in the input source and dissipation functions: ZALP was
325 set to 0.011 and C_{DS} and δ became 1.33 and 0.5 respectively.

326 In 2009, the first pre-operational version of the BIO component featured early versions of OGSTM transport model and BFM
327 model (Lazzari et al., 2010). The spatial resolution was $1/8^\circ$, which required a subsampling of the PHY component fields from
328 the $1/16^\circ$ resolution. The Atlantic boundary was closed with a nudging term for nutrients and the land nutrients input included
329 the three major Mediterranean rivers (i.e., Po, Rhone and Nile) and the Dardanelles was treated as a river. BFM used constant
330 daily averaged irradiance to force photosynthesis (Lazzari et al., 2010).

331 Horizontal resolution aligned with the physical model in 2013 and was refined to $1/24^\circ$ in 2017. Full alignment between The
332 PHY and BIO components in terms of same horizontal and vertical resolutions, bathymetry, boundaries (number and position
333 of rivers) was introduced in 2018 and remained a standard that mitigates possible approximation errors related to the use of
334 daily eddy-resolving ocean general circulation model to force the transport of tracers (Salon et al., 2019). Additionally, nutrient
335 and carbon land input from 39 rivers were introduced in 2017, open boundary conditions at Dardanelles Strait in 2019 and in
336 the Atlantic Ocean in 2020 (Salon et al., 2019).

337 Since 2008, three major improvements of the BFM model included the addition of the carbonate system to predict alkalinity,
338 ocean acidity and CO_2 air-sea exchanges in 2016 (Cossarini et al., 2015), the revision of nutrient formulation of phytoplankton
339 in 2018 (Lazzari et al., 2016) and, in 2020, the introduction of the day-night cycle in light-dependent formulation of
340 phytoplankton (Salon et al., 2019) and of the novel light extinction coefficient (Terzic et al., 2021).

341 A major system evolution and quality improvement was achieved in 2013 with the inclusion of the assimilation of satellite
342 chlorophyll through a variational scheme with prescribed background error covariance (Teruzzi et al., 2014). Assimilation
343 method was improved in 2018 to include coastal component (i.e., non-uniform and direction-dependent horizontal covariance;
344 Terruzzi et al., 2018) and in 2019 to integrate new observations (i.e., Argo-BGC float profiles) including new parameterization
345 for the vertical and biogeochemical background error covariance (Cossarini et al., 2019).

346 In terms of operational product delivery, the BIO component has produced daily 10-day forecasts and weekly 7-day analysis
347 since 2020, fully aligned with the PHY component (Salon et al., 2019). Before that, the system produced 7-day analysis and a
348 7-day forecast once per week since 2013, while a second cycle of 7-day forecasts was added each week in 2015.

349 3. Quality assessment

350 The evaluation of the quality of the Med-MFC is given here only for the analysis products, leaving the assessment of the
351 forecast skill for future work. One overarching driver for the Med-MFC evolution is the continuous improvement of the
352 numerical model and data assimilation modules with respect to a well-defined set of goodness indices established for all the
353 European regional Seas (Hernandez et al., 2009).

354 3.1. PHY component skill

355 The skill of the physical analysis fields is assessed over a 3 years period from 2018 to 2020 comparing model results (Clementi
356 et al., 2019) to satellite and in-situ observational datasets by means of root mean square differences (RMSD) and bias (model
357 minus observations) of daily mean analysis outputs, so called Estimated Accuracy Number (EAN) and misfits, calculated at
358 observation time during the forward model integration and evaluated on a sub-set of observations corresponding to the ones
359 assimilated by the system. In EAN, the daily mean analyses are interpolated on daily available observations: this goodness
360 score is somewhat approximated especially at the surface where daily variability is large, but this is a score used by many
361 forecasting systems (Ciliberti et al., 2022; Toledano et al., 2022; Sotillo et al., 2021, Najy et al., 2020) and we will show it for
362 reference purposes.

363 Table 2 summarises the EAN of 3D model temperature and salinity daily mean values compared to in situ observations, in
364 particular Argo floats and CTD profiles average over the three reference years. Model temperature is generally warmer than
365 observations, i.e., it shows a positive bias, with the largest error (maximum value of the period is 0.8°C) in the sub-surface
366 layers between 10 and 60 m, decreasing with depth. Salinity is characterised by a negative bias, meaning generally lower
367 salinities than measured, along the whole water column. The salinity RMSD yearly mean values is lower than 0.22 PSU, the
368 error is larger in the first layers and decreases significantly below 150 m. The comparison with other Copernicus Marine
369 Service forecasting systems EAN values presented in the Quality Information Document (QUID) considering that the
370 validation periods are different, shows that the Mediterranean temperature and salinity quality in terms of RMSD are aligned
371 with all the other Copernicus forecasting systems. In particular the SST averaged RMSD with respect to satellite data ranges
372 from 0.48°C in the North West Shelf (derived from the QUID of the product
373 NORTHWESTSHELF_ANALYSIS_FORECAST_PHY_004_013 <https://doi.org/10.48670/moi-00054>) to 0.8°C in the Baltic
374 Sea (derived from the QUID of the product BALTICSEA_ANALYSISFORECAST_PHY_003_006
375 <https://doi.org/10.48670/moi-00010>), while the 3D mean temperature RMSD with respect to *in-situ* data ranges from 0.4°C in
376 the Mediterranean and North West Shelf to 0.7°C in the Black Sea (derived from the QUID of the product BLKSEA
377 ANALYSISFORECAST_PHY_007_001 https://doi.org/10.25423/cmcc/blksea_analysisforecast_phy_007_001_eas4) and the
378 salinity mean RMSD varies from 0.1PSU in the Mediterranean and North West Shelf to 0.3PSU in the Iberia-Biscay-Ireland
379 area (derived from the QUID of the product IBI_ANALYSISFORECAST_PHY_005_001 <https://doi.org/10.48670/moi-00027>). The sea level anomaly skill is also aligned with the ones of other operational systems within the Copernicus Marine

381 Service when compared with satellite altimeter observations (from 2.2cm in the Black Sea to 9cm in the North West Shelf
382 area).

383 The other goodness index is computed as weekly mean root mean square error and bias using temperature and salinity misfits,
384 that are computed at FGAT. The misfits are more precise to account for surface errors since the observations are compared
385 with the model at the exact time of the day when observations are taken. This index is represented as a depth-time Hovmoller
386 diagram in Figure 4. The temperature error is seasonal (Figure 4a), with maximum values of $\sim 1.8^{\circ}\text{C}$ in the range of 30-60 m
387 depth corresponding to the depth of the mixed layer and the seasonal thermocline during the stratified season, from June to
388 November. The error is reduced to an average value of around 0.4°C during the vertically mixed season from December to
389 May. The temperature bias (Figure 4c), as already shown in Table 2 for EAN, indicates an overall overestimation of the
390 temperature except for the subsurface during winter and spring. The positive bias could be caused by an overestimation of the
391 downward shortwave radiation flux which is estimated according to Reed (1977) formula, as already discussed in (Byun et al.,
392 2007) and (Pettenuzzo et al., 2010).

393 The salinity error (Figure 4b) is defined by two main structures: one that is constant throughout the year down to about 150 m
394 and the seasonal amplification during summer, as for the temperature errors. The maximum errors reach values of 0.35 PSU
395 in the summer period and decrease to 0.025 PSU below ~ 150 m. We argue that the background error, uniform throughout the
396 year, could be due to inaccurate advection of salinity in different sub-areas of the Mediterranean Sea. Moreover, the model
397 salinity bias is negative, i.e., the model salinity is lower than the observations (Figure 4d). This could be related to the larger
398 Atlantic water inflow with respect to literature (Soto-Navaro et al., 2010) at Gibraltar as reported in Table 3 and to inaccurate
399 mixing at Gibraltar due to the lack of tides.

400 Sea surface temperature (SST) and sea level anomaly (SLA) skills are evaluated comparing them with satellite observations:
401 model daily mean SST is compared to SST satellite L4 gridded data at $1/16^{\circ}$ resolution (Buongiorno Nardelli et al., 2018)
402 while SLA is compared to along with track satellite altimeter observations (Taburet et al., 2019) in terms of model misfits.
403 Table 4 presents the EAN RMSD values computed for SST and misfit SLA RMSD averaged in the Mediterranean Sea and
404 over the 16 sub-regions, presented in Figure 3. Considering SST, the EAN RMSD values range between 0.47°C and 0.69°C
405 (mean Mediterranean Sea error of 0.54°C), while the SLA error ranges between 2.3 cm and 5.3 cm (mean error is 3.8 cm).
406 The quality of the analysis varies in different regions depending on the spatial distribution of the observations (for SLA) in
407 addition to the model inaccuracies.

408 The time variability of the model SLA accuracy is also provided by means of weekly model misfits evaluated for each available
409 satellite altimeter and averaged in the whole Mediterranean Sea as shown in Figure 5. The error ranges between 2.5 cm and
410 5.5 cm (maximum error with respect to Cryosat) with a large variability among the different satellites, with a generalised
411 increase of error during Autumn and Winter seasons.

412 3.2. WAV component skill

413 The quality of the wave analysis and forecast product is assessed over a three-year period from January 2018 to December
414 2020. Model analysis and first-guess (i.e. just before data assimilation) outputs are compared to in-situ and satellite
415 observations respectively.

416 Significant wave height (SWH) and mean wave period (MWP) measurements are used for data validation from 28 wave buoys
417 in the Mediterranean Sea (Figure 6 lower panel). Data quality control procedures have been applied to the in-situ observations
418 (Copernicus Marine In-Situ Team, 2020) and measurements associated with a bad quality flag are not taken into consideration.
419 Figure 6 depicts scatter plots of the evaluation of the observed SWH and MWP against measurements, obtained from the 28
420 buoys. The figure reveals small SWH underestimation by the model mainly for very small wave heights (< 0.6 m). A
421 prevalence of model overestimation is obtained for waves above about 2m, which becomes more pronounced for higher waves.
422 Regarding MWP, the model underestimates the observations for $MWP < 7$ s whilst model overestimation is observed for
423 higher periods. Equivalent seasonal results (not shown) revealed that the performance of the model is better in winter than in
424 summer which agrees with other studies (Cavaleri and Selavo, 2006; Ravdas et al., 2018).

425 The qualification metrics for the different buoy locations in Fig. 6 is plotted in Figure 7 (upper panel). RMSD at the different
426 buoy locations varies from 0.13 m to 0.31 m. Scatter Index (SI) varies from 0.17 at buoy 3732621 to 0.35 at the buoys of
427 Malaga and SARON (Aegean Sea). In general, SI values above the mean value for the whole Mediterranean Sea (0.24) are
428 obtained at wave buoys located near the coast, particularly if these are sheltered by land masses on their north-northwest (e.g.
429 western French coastline), and/or within enclosed basins characterised by a complex topography such as the Aegean Sea. As
430 explained in several studies (Ravdas et al., 2018), in these cases, the spatial resolution of the wave model is often not adequate
431 to resolve the fine bathymetric features whilst the spatial resolution of the forcing wind model is incapable to reproduce the
432 fine orographic effects, introducing errors to the wave analysis. The Correlation coefficient (CORR) mostly follows the pattern
433 of variation of the SI. It ranges from 0.87 at SARON in the Aegean Sea to 0.97 at the deep-water buoy 6100196 offshore Spain,
434 which is well exposed to the prevailing north-westerly winds in the region. The BIAS varies from -0.13 m at buoy 3732621
435 (located north of Crete) to 0.13 at buoy 6100021 located near the French coast. Its sign varies, with positive and negative
436 values computed at almost the same number of locations respectively. Overestimation at buoy 6100198 in the Alboran Sea is
437 part of a general overestimation of the wave heights in the Atlantic and Alboran regions as will be seen later in the comparison
438 with satellite observations.

439 Figure 8 (right) shows the scatter plot between the first guess SWH and satellite observations. Here the initial guess SWH
440 refers to the model SWH before data assimilation, thus meaning semi-independent model data. In addition, a scatter plot
441 resulting from the comparison of the ECMWF forcing wind speeds (U10) and satellite measurements of U10 is shown in
442 Figure 8 (left). It is seen that ECMWF is forcing underestimates observed U10 throughout the entire U10 range, even more so
443 at high wind speeds. An overall ECMWF overestimation of 3% is computed. On the other hand, the SWH model
444 underestimation is about 6%. The model underestimates SWH for the lower range (< 2.5 m) and overestimates SWH for larger

445 waves. Compared to the equivalent results obtained from the model-buoy comparison, a smaller scatter (by about 7%) with a
446 larger overall bias is associated with the model-satellite comparison, i.e. open ocean waves. SI values compare well at the more
447 exposed wave buoys in the Mediterranean Sea.

448 Figure 9 maps statistics of the comparison of model first-guess and satellite observations of SWH for the different sub-regions
449 of the Mediterranean Sea. The Aegean and Alboran Seas have relatively high SI values (0.21). The highest value of SI is
450 obtained for the North Adriatic Sea (0.26) followed by the South Adriatic (0.23). The lowest values (0.13-0.15) are found in
451 the Levantine Basin, the Ionian Sea, and the Southwest Mediterranean Sea. Relatively low values (0.16) are also found west
452 of the islands of Sardinia and Corsica. As discussed above, the error is due to inaccuracies associated with orographic winds
453 and/or local sea breezes and the missing representation of the complicated bathymetry in the fetch-limited, enclosed regions.
454 SWH negative bias is present in all sub-regions.

455 Finally, inter-compared to ECMWF, UK MetOffice and DMI (Danish Meteorological Institute) wave forecasting systems for
456 a different year (2014), Med-waves shows a better skill in terms of SWH with RMS errors for the Western Med buoys equal
457 to 0.227 m (0.234m for ECMWF; 0.281 for UK MetOffice) and 0.201m for the central and eastern Mediterranean (0.227m for
458 ECMWF; 0.268 for DMI).

459

460 **3.3. BIO component skill**

461 The BIO component state variables can be validated at three different uncertainty levels providing a “degree of confirmation”
462 (Oreskes et al., 1994) of different scales of variability based on the availability of reference data.

463 Near real time satellite and Argo float data provide a rigorous skill performance validation data set down to the scales of the
464 week and mesoscale dynamics for a limited set of variables: chlorophyll, nitrate and oxygen. Dataset of historical
465 oceanographic data (Socat dataset, Baker et al (2016); EMODnet data collection, Buga et al. (2018), Cossarini et al., (2017);
466 Lazzari et al., (2016)) are used to build a reference framework of sub-regions and annual and seasonal climatological profiles
467 to validate model performance to simulate the basin wide gradients, the mean vertical profiles and the seasonal cycle. For this
468 data set it is possible to have nutrients, such as nitrate, phosphate, ammonia and silicate, as well as dissolved oxygen, dissolved
469 inorganic carbon, alkalinity and surface pCO₂.

470 Lastly, a third level of validation regards those variables whose observability level is very scarce (e.g., phytoplankton biomass)
471 or based on indirect estimations (e.g., primary production, air-sea CO₂ fluxes). Only confirmation of the range of variability
472 and a general uncertainty estimation can be provided for those variables (see for example the validation of model primary
473 production in (von Schuckmann et al., 2020; Cossarini et al., 2020).

474 Considering the 2018-2020 reference period, the chlorophyll is very well reproduced by the BIO component, both in terms of
475 seasonal cycle and spatial gradient at surface (Figure 10) and in terms of vertical profiles at the Argo float positions (Table 5).
476 Uncertainty of surface chlorophyll is lower than 0.03 mmol/m³ with larger values registered in winter and western sub-regions
477 where the variability and the chlorophyll values are higher (Figure 10a and b). Regarding profiles, chlorophyll values and

478 vertical shapes driven by mesoscale dynamics are simulated with a high level of accuracy by the model (Salon et al., 2019;
479 Cossarini et al., 2019, 2021). Indeed, (Salon et al., 2019) show how, using novel metrics, the BIO component reproduces with
480 high level of accuracy not only the concentrations in the euphotic layer, but also the seasonal evolution of the shape of the
481 profiles. The depth of the deep chlorophyll maximum during summer and of the surface bloom during winter, as well as the
482 depth of the nitracline and the depth of the maximum oxygen layer, which results from the interaction of physical and
483 biogeochemical processes, are reproduced with an uncertainty of the order of a meter (Table 5). However, the conclusions
484 about mesoscale accuracy of the BIO component should be taken with caution since the observations are still relatively few in
485 number (about 1 over 8 w.r.t. the Argo floats have biochemical sensors) and unevenly spaced (e.g., southern Mediterranean
486 Sea is less observed than northern areas).

487 As explained above, an additional verification of biogeochemical variables can be achieved for additionally 7 variables (not
488 considering chlorophyll) and two other derived variables with climatological data. An example of such comparison is shown
489 in Figure 11 for the carbonate system variables. Average maps and profiles of Alkalinity and DIC in selected sub-regions in
490 the zonal directions (coloured lines) are well superimposed to the range of variability of the historical in-situ data (grey shaded
491 areas) demonstrating the capability of the BIO component to reproduce both horizontal basin-wide gradients and vertical
492 profiles in the different areas.

493 As a summary of the skill performance analysis, statistics based on RMSD for all the considered model variables (Table 6)
494 reports the model uncertainty in reproducing the basin-wide values and gradients for the selected layers. Generally, larger
495 errors are computed for the upper layers where the variability (both spatial and temporal) is higher. Ammonia reports high
496 errors also in subsurface layers, which is due to a possible incorrect initialization of deep layers since the lack of data in 9 out
497 of 16 sub-regions. These numbers, which respond to the request for a synthetic measurement of Copernicus Marine Service
498 product accuracy (Hernandez et al., 2018), are consolidated by in deep skill performance analysis of BFM model in reproducing
499 chlorophyll (Lazzari et al., 2012; Teruzzi et al., 2018), nutrients (Lazzari et al., 2016, Salon et al., 2019) and carbonate system
500 variables (Cossarini et al., 2015).

501 Chlorophyll from Ocean Color is the most common variable used for validation and near real time assessment of operational
502 biogeochemical models and allows for a comparison of the forecast skill performance among the Marine Copernicus systems.
503 Results of surface chlorophyll skill scores show that the quality of the first day of forecast of the BIO component is in line
504 with those of other Copernicus models¹ (Spruch et al 2020; Vandenbulcke et al 2022; McEwan et al, 2021; McGovern et al
505 2020). In particular, the two proposed accuracy indexes (i.e., one minus scatter index and one minus the root mean square error
506 normalised on variability) of the MED model equal to 34% and 47%, which are within the ranges of the other Copernicus
507 systems: 11%-38% and 13%-73% for the two skill scores, respectively (Spruch et al 2020; Vandenbulcke et al 2022; McEwan
508 et al, 2021; McGovern et al 2020).

¹ Product Quality Dashboard, Green Ocean section, <https://pqd.mercator-ocean.fr/>, accessed 15 July 2022.

509 For other biogeochemical variables, a direct comparison of the accuracy among Copernicus models is not straightforward,
510 given the different protocols for metrics computation, the representativeness of the available observations and the large range
511 of variability of observed values of biogeochemical variables among the European seas. Nevertheless, a rough comparative
512 assessment of the quality of Marine Copernicus biogeochemical models can be provided using published estimated accuracy
513 numbers (EANs) and the typical values of the variables (McEwan et al., 2021; Feudale et al., 2021; Spruch et al., 2020; Melsom
514 and Yumruktepe, 2021; McGovern et al., 2020; Vandembulcke et al., 2021) to derive a common index of relative uncertainty.
515 As for examples, relative uncertainty of oxygen of the MED system is of the order of 2% which is in line with the other
516 Copernicus systems, except for Baltic and Black Seas systems, which show slightly higher relative errors. For nutrients, nitrate
517 and phosphate uncertainties of the MED are about 50% and 35% which are similar or slightly better than most of the other
518 Copernicus marine biogeochemical systems (i.e., ranges of 30-75% and 30-50% for nitrate and phosphate, respectively).
519 Finally, the relative uncertainty of pH simulated by the MED system is less than 0.5% while other Copernicus systems report
520 relative errors of the order of 1-2%.

521 Beside the aforementioned comparison, it is worth to report that the MED biogeochemical system exhibits some
522 distinguishable features: the continuous monitoring of the forecast skill of surface chlorophyll since the beginning of the
523 operational biogeochemical system dating back to 2010 (Salon et al., 2019), a large number of validated variables with in-situ
524 data (i.e., up to 10 variables, Table 6), the thorough use of Argo-BGC observations for near real time validation (Salon et al.,
525 2019, Cossarini et al., 2021; <https://medeaf.ogs.it/nrt-validation>, last visit August 2022).

526 **4. Conclusions and Future Perspectives**

527 In this paper, the Med-MFC components, PHY, BIO and Wav have been described providing an overview of their technical
528 specifications. The system is offline coupled and the PHY component exchanges 3D currents, temperature, salinity with the
529 BIO and WAC components daily, with daily mean values. This approximation is flexible enough that improvements can be
530 carried out separately on the three components, considering different levels of maturity of the numerical modelling
531 parametrizations, the data assimilation components and the validation data sets. Three different data assimilation system are
532 run for each component making the best use of all available data from satellite and in-situ, the effort is to assimilate as much
533 data as possible and use background or model uncertainties to account for the missing couplings. The 3 components accuracy
534 has been evaluated for a common three-year period, from Jan 2018 to Dec. 2020.

535 The PHY component shows a warm bias at surface of +0.7°C compared to satellite SST. The RMSD has a clear seasonal
536 signal with the largest errors due to the depth of the surface mixed layer and the seasonal thermocline. The model salinity is
537 higher in the first layers and decreases significantly below 150 m. The analysis SLA presents an average error of 3.8cm on a
538 three-year average.

539 The WAV component was extensively validated for the 3-year period using all available in-situ and satellite observations in
540 the Mediterranean Sea. All statistical values calculated and presented here showed a very good system performance. It is

541 concluded that the Mediterranean SWH is accurately simulated by the WAV component. The typical SWH difference with
542 observations (RMSE) over the whole basin is 0.21 m (0.202 m for in-situ and 0.214 for satellite observations) with a bias
543 ranging from -0.004 m, when the comparison is against the in-situ observations, to -0.0031 m when the comparison is with
544 satellites. The scatter index (SI) exhibits low values (15%-17%) over the majority of the basin and relatively higher values
545 (21%-22%) over the Aegean, Alboran, Ligurian and South Adriatic Seas (highest SI equal to 28% occurs in the North Adriatic).
546 As explained, the occurrence of higher SI values is mainly related to the quality of ECMWF winds in fetch-limited areas of
547 the basin where the orographic effects play an important role and the difficulties of wave models to appropriately resolve
548 complicated bathymetry and coastline.

549 Overall, the quality of the WAV component stems out of the weakly coupled offline coupling between PHY and WAV. In
550 particular, the WAV component assimilates data with a well calibrated stand-alone OI scheme using satellite altimetry data
551 and implements regular updates and improved parameterization independently from the other components.

552 The BIO system has defined a validation framework (Salon et al., 2019) based on the near real time observations (i.e., satellite
553 and Argo) showing average errors in the 0-200m layer of 0.04 mg/m³, 0.4 mmol/m³ and 16.8 mmol/m³ for chlorophyll, nitrate
554 and oxygen, respectively.

555 Since 2008 the Med-MFC components have been continuously upgraded and substantially improved. The system evolution
556 will continue also in the future following the main drivers of the three components, the Copernicus Marine Service users.
557 Considering the PHY component, the user needs finer spatial scales and higher time frequencies of the products. User require
558 also higher accuracy in storm surge forecasting including tidal forcing and improved representation of lateral open boundary
559 conditions (e.g., rivers, nesting in the Atlantic and the Black Sea). The Med-MFC offers a unique opportunity to model the
560 coastal areas at the resolution of few hundred meters using nesting schemes (Federico et al., 2017, Trotta et al. 2021). Finally,
561 the future should consider ensemble forecasting to recast the deterministic forecast in within a probabilistic framework (Pinardi
562 et al, 2011, Millif et al, 2009, Thoppil et al, 2021; Barton et al., 2021). Another important goal for the future is to assimilate
563 Argo and drifter trajectories (Nelson et al., 2016) and gliders (Dobrici et al., 2009) as well as tidal coastal station at sea level.
564 User needs for the future evolution of the WAV component indicate the increase of the frequency of the wave analyses, making
565 available larger data sets such as the wave spectra and dedicated products (like the directional spread at peak frequency and
566 different parts of the wave spectrum). Extreme waves forecasting requires also a probabilistic approach. The required increased
567 accuracy can be achieved by improving the quality of the wind forcing using downscaled ECMWF forecasts and assimilating
568 additional satellite (wave spectrum from SAR) or higher frequency in-situ wave measurements. Also, for the WAV component,
569 the development of a WAB ensemble prediction system will be necessary.

570 In the light of the user needs and requirements, the BIO component validation framework helped to identify strengths and
571 weaknesses of the model system for future developments. In the BIO component case, future upgrades should be related to the
572 development of the BFM biogeochemical model process representations and model parameter estimation. This includes
573 increasing the number of phytoplankton functional types and zooplankton compartments to describe diversity of the plankton
574 community and the different energy and matter pathways across the ecosystem. Additionally, the integration of optics and

575 biogeochemistry including new coupled modelling and novel hyperspectral and high-resolution radiometric data will be
576 beneficial for calibrating parameters of key ecosystem processes (Lazzari et al., 2021).

577 Regarding the BIO component assimilation framework, the future developments should consider the assimilation of
578 biochemical variables from new sensors such as novel satellite and in situ Argo and Gliders (Cossarini et al., 2019) and the
579 evolution of the 3DVarBio towards hybrid-3Dvar or ensemble-3Dvar methods (Carrassi et al., 2018) and joint physical-
580 biogeochemical data assimilation.

581

582

583 **Author Contributions:** G.C. (Coppini) and E.C. coordinated the preparation of the paper in collaboration with G.C. (Cossarini), and G.K.

584 E.C., G.C. (Cossarini) G.K., P.L., A.T., G.B., J.P, A.C.G., A.A., R.E., A.C., D.D., S.M., A.N., N.P., M.R. contributed to the system and
585 models development; V.L., A.G., L.F., C.A., V.D., A.M., A.C.G, A.Z., C.O., E.C. contributed to the model validation and assessment; R.L.,
586 M.D., A.M., A.B., G.L.C., contributed to the operational activities. All authors contributed to the final version of the paper.

587 **Funding:** This work has been funded through the EU Copernicus Marine Med-MFC Service Contact n.74.

588 **Acknowledgments:** This study has been conducted using EU Copernicus Marine Service Information. Within the Copernicus Marine
589 Service of the MED-MFC CMCC is in charge of the coordination of the service and responsible for the Physics (ocean circulation)
590 Production Unit, OGS is responsible for the BIO (biogeochemical) Production Unit and HCMR is responsible for the WAVE Production
591 Unit. The authors thank CINECA (Italian supercomputer centre) for the technical support provided in the biogeochemical component
592 production workflow.

593 **Conflicts of Interest:** The authors declare no conflict of interest

596 **Appendix A**

597

598

Table A1. List of the NEMO and WW3 numerical setup for the PHY component

599

Parameter	Value
NEMO model version	3.6
Horiz. Resolution	1/24°
Vertical discretization	141 z levels with partial cells
Vertical coordinates	zstar
Time-step	240 s
Number of barotropic iterations	100
Free-surface formulation	Non-Linear free surface with split-explicit free surface
Air-sea fluxes	MFS-Bulk formulae
Atmospheric Pressure	Yes
Wave coupling	Neutral drag coefficient
Runoff	Surface boundary condition with specific treatment at river mouth and prescribed river salinity
Sea Surface Restoring T/S	only for temperature
Solar radiation penetration	2-band exponential penetration (insert the decay length and the transmission coeff)
Lateral momentum B.C.	No-slip
Lateral Open B.C.	Flather open boundary condition for barotropic currents, Orlansky for total currents and tracers
Bottom B.C	Non-linear friction with logarithmic formulation

Equation of State	EOS-80
Tracer Advection	Up-stream/MUSCL
Tracers Horiz. Diffusivity	Bi-Laplacian coeff = -1.2.e8 [m4/s]
Momentum Horiz. Viscosity	Bi-Laplacian coeff = -2e.8 [m4/s]
Momentum Advection	Vector form (energy and enstrophy cons. scheme)
Turbulent vertical viscosity scheme	Richardson number dependent formulation following Pacanowsky Philander (1981) and Lermousiaux (2001) adjustment
Background Vertical Visc.	1.2e-6 [m2/s]
Background Vertical Diff.	1.0e-7 [m2/s]
Vertical time stepping scheme	Implicit
WW3 model version	3.14
Horiz. Resolution	1/24o
Number of frequencies	30
Number of directions	24
Time-step (global)	240 s
Wind input term	Janssen's quasi-linear theory (Jansen, 1989; Jansen, 1991)
Wave dissipation term	Hasselmann (1974) according to Komen et al., (1984)
Non-linear wave-wave interaction term	Discrete Interaction Approximation (DIA, Hasselmann et al., 1985)
Coupling with NEMO	Sea surface currents, sea surface temperature

600

601

602

Table A2. List of the WAM model set up for the WAV component.

Parameter	Value
-----------	-------

WAM model version	Cycle 4.6.2
Horiz. Resolution	1/24°
Geographical domain	18.125°W - 36.2917°E 30.1875°N - 45.9792°N.
Depth map	GEBCO 30arc-second
Number of frequencies	32
Number of directions	24
Time-step (propagation)	60 s
Time-step (sources)	360 s
Deep/Shallow mode	Shallow
10m winds	ECMWF 10m analyses and forecast winds
C_{DS}, δ	1.33, 0.5
ZALP	0.011
Surface currents coupling	Offline coupled with Med-MFC NRT daily surface currents
Data assimilation	Optimal Interpolation method / Altimeter satellite data provided by Copernicus Marine Service are assimilated in the wave model.

603

604

605

606

Table A3. List of the OGSTM-BFM model set up for the BIO component.

Parameter	Value
OGSTM model version	4.1
BFM model version	5.0
3DVarBio version	3.3
Horiz. Resolution	1/24o
Geographical domain	9.0°W - 36.2917°E 30.1875°N - 45.9792°N.
OGSTM: physical forcing	U, V, W, eddy diffusivity, SSH
OGSTM: timestep	450 s
OGSTM: off-line coupling frequency	1 d
OGSTM: advection scheme	Smolarkiewicz
OGSTM: horizontal diffusion	Bi-Laplacian coefficient -3.e9 [m4/s]
OGSTM: vertical diffusion scheme	implicit 2nd order
BFM parameters for Phytoplankton, Zooplankton, Bacteria, DOM and POM formulation	as in (Lazzari et al., 2012) and 2016
BFM light: type of model	instantaneous light from short wave radiation, light at the centre of the grid cell
BFM light: Fraction of Photosynthetically Available Radiation	0.40
BFM light: conversion W/m2 to moli quanta/m2/s	1./0.217 Watt / umol photons
BFM light: background extinction coeff.	0.0435 1/m
BFM light: specific attenuation coefficient of particulate	0.001 m2/mgC

BFM carbonate system: solver using total alkalinity and DIC	SolveSAPHE v1.0.1 routines (Munhoven, 2013)
BFM carbonate system: K0, solubility of co2 in the water (K Henry)	Weiss 1974
BFM carbonate system: k1 and k2 constants for carbonic acid	Mehrbach et al. (1973) refit, by Lueker et al. (2000) (total scale)
BFM carbonate system: Kb constant for boric acid	Millero p.669 (1995) using data from Dickson (1990) (total scale)
BFM carbonate system: k1p, k2p and k3p constants of phosphoric acid	Millero (1974)
BFM carbonate system: Ksi constant of orthosilicic acid	Millero (1995)
BFM carbonate system: Kw of water dissociation	Millero (1995)
BFM carbonate system: ks of sulfuric acid	Dickson (1990)
BFM carbonate system: kf of folic acid	Perez & Fraga (1987) recom. by Dickson et al., (2007)
BFM carbonate system: air-sea exchange model	Wannikoff et al., 2014
3DVarBio: max depth of assimilation	200m
3DVarBio: n. of vertical EOFs	26
3DVarBio: horizontal correlation radius	variable in X and Y; average 15 km (Teruzzi et al., 2018)
3DVarBio: solver for cost function J	quasi-Newton L-BFGS minimizer
3DVarBio: Minimum gradient of J	1.0E-11
3DVarBio: Percentage of initial gradient	0.01
3DVarBio: n. of interactions of recursive filter	4

1155

Tables

Table 1 Changes in the Mediterranean forecasting components since 2008.

Year	Numerical Model Changes
<i>Physics component (PHY)</i>	
< 2008	1/16 deg., 72 vert. lev., OPA8.2 model (Madec et al., 1998) with closed lateral boundary conditions in the Atlantic (Tonani et al., 2008), 7 rivers (Ebro, Rhone, Nile, Po, Seman, Vjiose, Buna-Bojana), closed lateral boundary at Dardanelles strait, OceanVar (Dobricic et al., 2007) weekly assimilation
2009	As in 2008 with NEMOV3.1 with climatological lateral open boundary conditions in the Atlantic (Oddo et al., 2009), OceanVar with daily assimilation (Dobricic et al., 2007)
2010	As in 2009 with one-way offline coupling between NEMOV3.1 and WAM (wave)
2013	As in 2010 with two-way coupling between NEMOV3.4 and WW3 (Clementi et al., 2017a)
2014	As in 2013 but with surface atmospheric pressure forcing (Oddo et al., 2014), explicit linear free surface and SLA TAPAS(*) data assimilation (Dobricic et al., 2012)
2015	As in 2014 but with daily lateral open boundary conditions in the Atlantic
2016	As in 2015 but with monthly and grid point EOF and vertical observational error varying with depth in OceanVar
2017	1/24 deg., 141 vert. lev., NEMOV3.6 with nonlinear free surface and z-star coordinate system), 39 rivers (Table A.4)
2019	As in 2017 but with open lateral boundary conditions at the Dardanelles Strait, improved SST nudging
<i>Biogeochemistry component (BIO)</i>	
<2008	1/8 deg BFM offline coupled to PHY component
2009	Offline coupling to horizontal subsampled PHY component at 1/8 deg
2013	Coupling with 1/16 deg PHY component and Biogeochemical Data Assimilation (BDA) for Ocean Color derived Chlorophyll data (Teruzzi et al., 2014)
2015	Inclusion of the carbonate system in the model (Cossarini et al., 2015)
2017	Revision nutrient formulation in BFM (Lazzari et al., 2016) and coupling with 1/24 deg PHY component including z-star coordinate system
2018	BDA for Ocean Color coastal data (Teruzzi et al., 2018)
2019	Open lateral boundary condition at the Dardanelles Strait, revision daily light cycle in BFM (Salon et al., 2019)
2020	Open lateral boundary condition in the Atlantic Ocean and BDA with Argo biogeochemical data (Cossarini et al., 2019), and daily operational 10-days of forecast
<i>Wave component (WAV)</i>	
2017	1/24 deg WAM Cycle 4.5.4, one-way offline coupled to PHY component surface currents. Open boundary conditions from North Atlantic implementation of WAM model at 1/6 deg resolution.
2018	Implementation of data assimilation for along track Significant Wave Height (SWH) observations from Jason 3 and Sentinel 3a

2019	WAM Cycle 4.6.2; assimilation of Cryosat-2 and Saral/Altika SWH observations tuning of wave age parameter; imposition of a limitation to the high frequency part of the spectrum based on Phillips spectrum.
2020	Assimilation of Sentinel-3b SWH observations t

(*) the Sea Level Anomaly (SLA) TAPAS product is produced to give information about the different corrections of the altimetric original signal.

Table 2. EAN estimates with in-situ observations. The differences (BIAS) and their square values (RMSD) are then averaged over the whole Mediterranean Sea region and 9 vertical layers for years 2018-2020.

Layer (m)	Temperature RMSD (°C)	Temperature bias (°C)	Salinity RMSD (PSU)	Salinity bias (PSU)
0-10	0.54	0.02	0.19	-0.01
10-30	0.82	0.04	0.20	0.01
30-60	0.85	-0.04	0.19	0.01
60-100	0.58	-0.03	0.16	0.02
100-150	0.41	0.01	0.13	0.01
150-300	0.28	0.02	0.08	0.02
300-600	0.18	0.00	0.05	0.01
600-1000	0.09	0.02	0.03	0.00
1000-2000	0.05	-0.01	0.02	0.00

Table 3. Gibraltar mean and standard deviation volume transports [Sv] from the Med-PHY numerical system averaged in the period 2018-2020 compared to literature values (current meter observations from October 2004 to January 2009).

Gibraltar Transport	Model [2018-2020]	Literature	
		Soto-Navarro et al. (2010) [2004-2009]	Literature Candela (2001) [1994-1996]
Net	0.040±0.017	0.038 ± 0.007	0.04 (max: 0.26, min: 0.11)
Eastward	0.91±0.01	0.81 ± 0.06	1.01 (max: 1.12, min: 0.91)
Westward	0.087±0.06	0.78 ± 0.05	0.97 (max: 0.83, min: 1.11)
