9 **Short summary**

10 The South Vietnam Upwelling develops in summer along and off the Vietnamese coast. It brings cold and nutrient-
11 rich waters to the surface, allowing photosynthesis essential to marine ecosystems and fishing resources. We show
12 here that its daily variations are mainly due to the wind, thus predictable, in the southern shelf and coast regions.
13 However, they are more chaotic in the offshore area, and especially in the northern area, due to the influence of
14 eddies of a highly chaotic nature.

15

Abstract

16 The South Vietnam Upwelling (SVU) develops off the Vietnamese coast (South China Sea) during the southwest
17 summer monsoon over four main areas: the northern coastal upwelling (NCU), the southern coastal upwelling
18 (SCU), the offshore upwelling (OFU) and the shelf off the Mekong River mouth (MKU). An ensemble of ten
19 simulations with perturbed initial conditions were run with the fine-resolution SYMPHONIE model (1 km
20 inshore) to investigate the daily to intraseasonal variability of the SVU and the influence of the ocean intrinsic
21 variability (OIV) during the strong SVU of summer 2018.

22 The intraseasonal variability is similar for SCU, MKU and OFU, driven to the first order by the wind variability.
23 MKU and SCU are induced by stable ocean dynamics (the northeastward then eastward boundary current) and
24 have very little chaotic variability. The OIV has a stronger influence on OFU. In July, OFU mainly develops along
25 the northern flank of the eastward jet. The influence of OIV is strongest and related to the chaotic variability of
26 the meridional position of the jet. In August this position is stable and OFU develops mainly in the area of positive
27 wind curl and cyclonic eddies north of the jet. The influence of OIV, weaker than in July, is related to the
28 organization of this mesoscale circulation. NCU shows a behavior different from what observed in the other areas.
29 In the heart of summer, a large-scale circulation formed by the eastward jet and eddy dipole is well established
30 with an alongshore current preventing NCU development. In early and late summer, this circulation is weaker,
31 allowing a mesoscale circulation of strongly chaotic nature to develop in the NCU area. During those periods, the
32 OIV influence on NCU is very strong and related to the organization of this mesoscale circulation: NCU is favored
33 (annihilated) by offshore-oriented (alongshore) structures.

34

35 1. Introduction

36 The summer general circulation in the central South China sea is largely induced by the prevailing southwest
37 monsoon winds (Wang et al., 2004; Wyrski et al., 1961). It is characterized by the development off the central
38 Vietnamese coast of an anticyclonic (AC) gyre in the south and a cyclonic (C) gyre in the north (forming an eddy
39 dipole referred to as the ACC dipole) and of the South Vietnam upwelling, hereafter referred to as the SVU, that
40 develops over four main areas. First, the convergence of two gyres creates an eastward jet departing from the
41 southern part of the central coast of Vietnam between 11°N and 12°N. This convergence gives rise to an Ekman
42 current-induced coastal upwelling (Dippner et al., 2007; Chen et al., 2012), hereafter referred to as SCU. Second,
43 Ekman pumping-induced upwelling (OFU hereafter) develops offshore in the area of strong positive wind and
44 surface current vorticity (Liu et al., 2012; Da et al., 2019; Ngo and Hsin, 2021). Third, recent studies have revealed
45 that coastal upwelling (NCU hereafter) can develop along the northern part of the central Vietnamese coast (Da
46 et al., 2019; Ngo and Hsin, 2021; To Duy et al., 2022). Last, To Duy et al. (2022) showed for the first time that
47 upwelling develops off the Mekong Delta behind Con Dao islands (see Fig. 1b, MKU hereafter). SVU participates
48 to the nutrient enrichment of the surface layer, hence plays an important role in the biological productivity and in
49 the halieutic resources of the region (Bombar et al., 2010; Liu et al., 2012; Loick-Wilde et al., 2017; Lu et al.,
50 2018; Loisel et al., 2017). Some authors also showed that the SVU may influence the functioning of local and
51 regional climate (Xie et al., 2003; Zheng et al., 2016). Understanding precisely the functioning and variability of
52 the SVU and its response to long-term changes is therefore an important issue.

53 The interannual variability of the SVU has been investigated in numerous previous studies. In the SCU, OFU and
54 MKU regions, the interannual variability of summer wind intensity is related to and in phase with the intensity of
55 the summer monsoon, and is the main driver of the interannual variability of upwelling intensity (Wang et al.,
56 2006; Chen et al., 2014; Li et al., 2014; Da et al., 2019; Ngo and Hsin, 2021; To Duy et al., 2022). ENSO (El Niño
57 Southern Oscillation) also impacts the upwelling in those regions, due to its influence on summer monsoon wind
58 (Wang et al., 2006; Kuo et al., 2004; Loick-Wilde et al., 2017; Da et al., 2019). Some studies (Li et al., 2014; Da
59 et al., 2019) then revealed that ocean intrinsic variability (OIV) influences the interannual variability of the
60 eastward jet and of the OFU. OIV, as opposed to the forced variability, corresponds to the unpredictable part of
61 ocean variability, not induced by the variability of external forcing factors but by the chaotic behavior of ocean
62 dynamics. Most studies have shown that mesoscale to submesoscale structures are a major source of OIV (Penduff
63 et al., 201; Sérazin et al., 2016; Waldman et al., 2018; Da et al. 2019). This influence of OIV is related to the
64 spatial distribution of summer averaged surface current vorticity associated with eddies: cyclonic (anticyclonic)
65 eddies located in the area of positive wind stress curl enhance (weaken) the Ekman pumping-induced OFU. The
66 interannual variability of NCU shows a completely different behavior. Ngo and Hsin (2021) and To Duy et al.
67 (2022) concluded that wind conditions favorable to SCU, MKU and OFU were unfavorable to NCU, and vice
68 versa. To Duy et al. (2022) moreover showed that the influence of wind is weaker for NCU than for the other
69 areas. In contrast, the influence of circulation, in particular of the spatial organization of the chaotic submesoscale
70 to mesoscale circulation that prevails over the area, was found to be stronger: on a seasonal average, NCU is
71 inhibited when alongshore currents prevail, and enhanced when offshore circulation prevails.

72 The daily to intraseasonal variability of the SVU was much less studied. Available studies, all based on satellite
73 data, focused on the SCU and OFU. Xie et al. (2007) showed that the upwelling in those areas does not develop
74 smoothly during the summer, but shows a strong intraseasonal variability related to the wind variability and
75 Madden Julian Oscillation (MJO). They suggested that SVU experiences two to four events of development and
76 decay during the summer, in response to the wind fluctuations. Isoguchi and Kawamura (2006) and Liu et al.
77 (2012) confirmed respectively for the period 2000-2002 and for summer 2007 that the MJO is a strong driver of
78 the events of southwesterly wind intensification within the season and of the resulting upwelling. They moreover
79 revealed the effect of tropical storms that can reinforce the southwesterly wind, hence the SVU.

80 To better understand the functioning and variability of the SVU, it is therefore necessary to investigate in detail
81 the functioning of its daily to intraseasonal variability over its four areas of development (SCU, NCU, OFU and
82 MKU) and to identify the driving factors. Previous studies mentioned above revealed the role of wind for SCU
83 and OFU, which should be examined for the other areas. The role of OIV in the interannual variability of the
84 upwelling, related to mesoscale circulation and eddies in the coastal and offshore area, was highlighted for OFU
85 and suggested for NCU. It should be examined at the intraseasonal scale, and requires an ensemblist approach as
86 used by Waldman et al. (2017a, 2018). Chen et al. (2012) also showed from idealized simulations that tides and
87 river plumes could be also involved in SVU variability, however, to our knowledge, only very few models used
88 for the SVU study included the effect of tides, and none of them investigated their impact.

89 The present paper focuses on the daily to intraseasonal variability of the SVU over its four areas of development,
90 examining in particular the role of atmospheric forcing, in particular wind, and the role of ocean dynamics and
91 their intrinsic variability. The effect of tides and rivers will be examined in a future study. A fine-resolution

92 realistic model including tides and already presented and evaluated in To Duy et al. (2022) for the period 2009-
93 2018 is used. Ensemble simulations with perturbed initial conditions are performed to study the case of summer
94 2018, which was an exceptionally strong summer of upwelling for SCU, OFU and MKU (Ngo and Hsin, 2021;
95 To Duy et al., 2022).

96 The fine-resolution model and ensemble simulations and the definition of study areas, upwelling indicators and
97 OIV indicators are presented in Part 2. The intraseasonal variability of the oceanic circulation and of the SVU,
98 including the role of OIV, are examined respectively in Part 3 and Part 4. Results are summarized and future work
99 is discussed in Part 5.

100

101 **2. Methodology**

102 **2.1. The 3-D hydrodynamical ocean model SYMPHONIE**

103 To Duy et al. (2022) built a fine-resolution configuration of the 3-D ocean circulation model SYMPHONIE
104 (Marsaleix et al., 2008, 2019) over the Vietnam coastal region (VNC hereafter for VietNam Coast), based on a
105 horizontal polar grid with a resolution decreasing linearly seaward, from 1 km at the Vietnamese coast to 4.5 km
106 offshore, and with 50 vertical levels. They used the GEBCO_2014 dataset released in April 2015 at a 30 seconds
107 interval (~0.9 km) and available from www.gebco.net. We use exactly the same configuration here and show
108 VNC domain in Figure 1a,b. The atmospheric forcing is computed from the 3-hourly output of the European
109 Center for Medium-Range Weather Forecasts (ECMWF) 1/8° atmospheric analysis, distributed on
110 <http://www.ecmwf.int>. Initial and lateral ocean boundary conditions are prescribed from the daily outputs of the
111 global ocean 1/12° analysis PSY4QV3R1 distributed by the Copernicus Marine and Environment Monitoring
112 Service (CMEMS) on <http://marine.copernicus.eu>. The implementation of tides follows Pairaud et al. (2008, 2010)
113 and considers the 9 main tidal harmonics, provided by the 2014 release of the FES global tidal model (Lyard et
114 al., 2006). Freshwater discharge is provided for 36 river mouths. More details about the model, its configuration
115 and the forcings are provided in To Duy et al. (2022). They performed and evaluated a 10-year simulation over
116 the period 2009-2018, hereafter called LONG, showing that it reproduces realistically the temporal (seasonal to
117 interannual) and spatial variability of the SCS ocean dynamics and water masses. In the LONG simulation, a very
118 strong SVU developed during summer 2018, in particular due to strong July-August northeastward wind (To Duy
119 et al., 2022).

120 **2.2. Ensemble simulations**

121 We performed an ensemble of ten simulations with perturbed initial conditions between January 1st, 2017 and
122 December 31st, 2018. For that we used ten different initial conditions for temperature, salinity, sea surface
123 elevation and currents fields. Most of the OIV develops at mesoscale (Sérazin et al., 2015, Waldman et al., 2018),
124 we therefore only perturbed the mesoscale field, following the same methodology as Waldman et al. (2017a,
125 2017b, 2018): for the ten simulations of the ensemble, the large-scale state of the initial field is identical, and the
126 small-scale of the initial field state differs. The common large-scale state is equal to the large-scale state of January
127 1st, 2017 of the LONG simulation, computed using a 100 km low-pass filter. For XX going from 09 to 18, the
128 small-scale state of January 1st, 20XX of the LONG simulation is computed using a 100 km high-pass filter. The

129 initial state of member XX of the simulation ensemble is then computed by adding this small-scale state to the
 130 common large-scale state.

131 **2.3. Definition of upwelling areas**

132 Figure 1c,d shows the SST averaged over June-September (JJAS) 2018 for the ensemble average and for OSTIA
 133 (Operational Sea Surface Temperature and Sea Ice Analysis) reanalysis outputs, available at
 134 <ftp://data.nodc.noaa.gov/pub/data.nodc/ghrsst/L4/GLOB/UKMO/OSTIA/>. Simulated SST is in good agreement
 135 with observations, showing a large area of colder surface water corresponding to the strong SVU that developed
 136 during summer 2018. We show in Figure 1b,c,d the four boxes used by To Duy et al. (2022), that correspond to
 137 the four main areas of SVU development: boxSC and boxNC for respectively the southern (SCU) and northern
 138 (NCU) coastal upwelling, boxOF for the offshore upwelling (OFU), and boxMK for the upwelling offshore the
 139 Mekong delta (MKU).

140 **2.4. Indicators of upwelling intensity**

141 We compute a SST-based index of upwelling intensity following exactly the same methodology as Da et al. (2019)
 142 and To Duy et al. (2022). The daily upwelling index UI_d is computed every day t at each point (x,y) of the study
 143 area that verifies $SST(x,y,t) < T_o$ as:

$$144 \quad UI_d(x, y, t) = T_{ref} - SST(x, y, t) \text{ for } (x,y,t) \text{ where } SST(x,y,t) < T_o \quad (1)$$

145 The reference temperature $T_{ref} = 29.2^\circ\text{C}$ is computed as the SST averaged over JJAS and over boxT_{Ref}, the area
 146 east of the upwelling region that is the least impacted by upwelling (see Figure 1c,d), in the LONG simulation.
 147 The threshold temperature under which upwelling occurs, $T_o = 27.6^\circ\text{C}$, is defined as the optimal upwelling
 148 threshold that covers the largest number of upwelling occurrences but avoids to include cold water horizontally
 149 advected between upwelling areas.

150 For each box $boxN$, the daily intensity of upwelling integrated over $boxN$ is quantified at day t by the daily
 151 upwelling index $UI_{d,boxN}$, computed as:

$$152 \quad UI_{d,boxN}(t) = \frac{\iint_{(x,y) \text{ in } boxN \text{ so that } SST(x,y,t) < T_o} (T_{ref} - SST(x,y,t)) . dx . dy}{A_{boxN}} \quad (2)$$

153 where A_{boxN} is the size of $boxN$.

154 Last, to quantify the intensity of upwelling integrated over boxN and over the summer, we define the summer
 155 upwelling index $UI_{JJAS,boxN}$, computed over JJAS as:

$$156 \quad UI_{JJAS,boxN} = \frac{\int_{JJAS} UI_{d,boxN}(t) dt}{ND_{JJAS}} \quad (3)$$

157 where $ND_{JJAS} = 122$ days is the JJAS duration.

158 2.5. Indicators of OIV impact

159 Following Waldman et al. (2018), we introduce two indicators to quantify the contribution of OIV on a given
160 variable X : one at the daily scale and one at the average scale over a given period. $X(t,i)$ at time t and for ensemble
161 member i can be any time-dependent (space-dependent or not) variable characterizing the ocean circulation or
162 upwelling intensity. In the following, σ_i is the ensemble standard deviation (that quantifies the time-dependent
163 intrinsic variability), σ_t temporal standard deviation, m_i the ensemble average and m_t the temporal average.

164 We quantify the effect of OIV at the daily scale by computing IV_d , the contribution of intrinsic variability to the
165 total daily variability of $X(t,i)$. For each day of JJAS 2018, it is computed as the ratio between the time-dependent
166 intrinsic variability and the total temporal variability over JJAS 2018:

$$167 \quad IV_d(X(t)) = \frac{\sigma_i(X(t,i))}{\sqrt{m_i(\sigma_t(X(t,i))^2)}} \quad (6)$$

168 We quantify the contribution of OIV at the average scale over a given period by computing the relative intrinsic
169 variability of the temporal mean state of X over the period, IV_m . For that, we compute the ratio between the
170 ensemble standard deviation and the ensemble average of temporal average of $X(t,i)$:

$$171 \quad IV_{tm}(X) = \frac{\sigma_i(m_t(X(t,i)))}{m_i(m_t(X(t,i)))} \quad (5)$$

172 To investigate the effect of OIV on surface circulation and upwelling, we apply in the following those indicators
173 on the upwelling indices (UI_d , $UI_{d,boxN}$ and $UI_{JJAS,boxN}$) and on the surface current vorticity.

174 3. Intraseasonal variability of wind and ocean circulation

175 Figure 2 shows for each upwelling area the daily time series of wind stress, of $UI_{d,boxN}$ for each simulation and for
176 the ensemble average, and of $IV_d(UI_{d,boxN})$. The southwest summer monsoon wind blows from June to September
177 over the SCS with three main peaks of strong northeastward wind during mid-June, beginning to mid-July and
178 beginning of August, associated with three peaks of OFU, SCU and MKU that will be examined into details in
179 Section 4 (see the daily time series of $UI_{d,boxN}$ and wind stress averaged over boxOF, boxSC and boxMK, Figure
180 2a,b,c). To study the development of upwelling and the ocean circulation over those areas, we define three periods
181 that fully cover OFU development (from a value of $UI_{d,boxOF}=0$ to a maximum value): June (9th-18th June, 10
182 days), July (28th June-18th July, 21 days) and August (1st-13th August, 13 days), highlighted in blue in Figure 2.
183 The development of OFU, SCU and MKU follows a similar chronology and the exact choice of each periods did
184 not modify our conclusions, as long as those periods cover the upwelling development and strong monsoon wind
185 periods. For the sake of readability and simplicity, we therefore use the three periods defined above for the
186 diagnostics used to study OFU, SCU and MKU. Figure 3a,b,c,d shows for each period the maps of ensemble
187 average of wind stress and wind stress curl, of surface current speed and of surface current vorticity averaged over
188 the period, and the maps of relative intrinsic variability (IV_m) of surface current vorticity over the period. A high
189 (low) value of IV_m of current vorticity indicates a strong (weak) OIV and a chaotic (stable) circulation. To quantify
190 the strength of the eastward jet, we calculate the ensemble mean of the average surface current speed through the
191 meridional transect at 109.9°E, between 9.5 and 12.2°N (red line in Figure 3a) during the three periods.

192 During the June period, the area of strong positive wind stress curl extends from the coast to $\sim 113^\circ\text{E}$, with a
 193 narrow meridional coverage (Figure 3a). The ACC dipole is not clearly formed (Figure 3b,c). The weak eastward
 194 jet is located in the south with a maximum speed of $0.5\text{-}0.7\text{ m.s}^{-1}$ around $10\text{-}11^\circ\text{N}$, and a mean speed of 0.51 m.s^{-1} .
 195 The circulation is stable in the coastal jet area (IV_{im} of current vorticity $<50\%$, Figure 3d), but much more chaotic
 196 over most of the offshore area ($IV_{im} >200\%$). During the July period, the area of strong positive wind stress curl
 197 is larger than in June (from 10.5°N to 13°N , extending to 112°E). The eastward jet strengthens, with a mean speed
 198 of 0.78 m.s^{-1} , and is more in the north, with a speed of about $0.8\text{-}1.1\text{ m.s}^{-1}$ near $11\text{-}12^\circ\text{N}$. The ACC dipole, with an
 199 anticyclonic (cyclonic) circulation in the south (north), is more pronounced than in June. The circulation is more
 200 stable than in June in the coastal zone and in the cyclonic and anticyclonic areas (IV_{im} of current vorticity $\sim 100\%$).
 201 It is less stable in the northeastern region of boxOF, where IV_{im} exceeds 200% . During the August period, the area
 202 of strong positive wind stress curl has the largest meridional and zonal extension, to 114°E . The eastward jet is
 203 still stronger, with velocities reaching $1.2\text{-}1.5\text{ m.s}^{-1}$ around $10.5\text{-}11.5^\circ\text{N}$ and a mean speed up to 0.88 m.s^{-1} . The
 204 ACC dipole is also stronger, with a well-established and large cyclonic gyre. The surface circulation is more stable
 205 compared to June and July, with a larger area of low IV_{im} of current vorticity ($<100\%$) covering boxOF. In
 206 September, the summer monsoon and the large-scale jet/ACC circulation begin to weaken (not shown).

207

208 4. Intraseasonal variability of upwelling

209 Here we examine the upwelling intraseasonal variability and its intrinsic variability for each upwelling area. Table
 210 1 shows for the four areas the value of yearly upwelling index $UI_{JJAS,boxN}$ for each member and for the ensemble
 211 average, and its relative intrinsic variability $IV_{im}(UI_{JJAS,boxN})$. It also shows the values of the correlation coefficients
 212 between the daily time series of the ensemble mean of $UI_{d,boxN}$ and of the wind stress components and intensity.
 213 Figure 3e,f shows for each period defined in Section 3 the maps of UI_d on the day of maximum $UI_{d,boxN}$ over each
 214 period and the maps of its relative intrinsic variability $IV_{im}(UI_d)$.

215 4.1. The southern coastal upwelling (SCU)

216 For SCU, $UI_{d,boxSC}$ time series show a similar daily chronology for each member and for the ensemble mean
 217 (Figure 2b). SCU begins to develop during the first half of June, lasts during the whole summer with a strong
 218 intraseasonal variability, and disappears during the first half of September. We obtain three peaks of similar
 219 intensity, near June 19th, July 15th and August 16th, in phase with the wind forcing over the area: the correlation
 220 between the time series of $UI_{d,boxSC}$ and of the daily averaged wind stress intensity over boxSC is equal to 0.64
 221 ($p < 0.01$, Table 1). The correlation with the wind stress eastward component, i.e. the component nearly parallel to
 222 the south coast, that favors the SCU, reaches 0.71 ($p < 0.01$).

223 Over the summer, $IV_d(UI_{d,boxSC})$ varies between 10% when SCU is weak and 40% during periods of strong SCU,
 224 showing similar values for the three upwelling peaks (Figure 2e). The yearly upwelling index $UI_{JJAS,boxSC}$ shows a
 225 weak ensemble standard deviation (7% relative to the mean, Table 1). This intrinsic variability of the SCU summer
 226 strength is much weaker than its interannual variability: in the 2009-2018 LONG simulation analyzed by To Duy
 227 et al. (2022), $UI_{JJAS,boxSC}$ shows a 53% interannual standard deviation relative to its interannual mean. SCU
 228 develops in the same area for the ten members, in the coastal zone of the ACC dipole convergence, as shown by

229 the very low values of $IV_{im}(UI_d)$ (<50%) over this area (Figure 3e,f). Higher $IV_{im}(UI_d)$ values are obtained at the
230 periphery of this area, along the northern and southern flanks of the eastward jet. They are related to the variability
231 of the meridional position of the jet: a jet located further north (south) induces a SCU further north (south).

232 SCU daily to intraseasonal variability is therefore mostly driven by the wind. The OIV is mainly related to the
233 meridional position of the jet which does not vary much, thus affecting the SCU at a second order at the
234 intraseasonal scale.

235 **4.2. The Mekong delta shelf upwelling (MKU)**

236 For MKU, time series of $UI_{d,boxMK}$ are almost identical for each member and for the ensemble mean (Figure 2c).
237 They also show a strong intraseasonal variability, with three peaks of varying intensity following the three wind
238 peaks. The July peak is the strongest, followed by the August peak, then the June peak. The daily chronology of
239 MKU also strongly follows the wind chronology, with a correlation of 0.65 ($p < 0.01$) with the wind stress intensity
240 averaged over MKU, and of 0.59 (0.61) with the wind stress eastward (northward) component (Table 1).

241 MKU is very weakly influenced by the OIV: $IV_d(UI_{JJAS,boxMK})$ never exceeds 30% (Figure 2e) and $IV_{im}(UI_{JJAS,boxMK})$
242 is equal to 6% (Table 1). Again, this intrinsic variability of MKU summer strength is negligible compared to its
243 interannual variability: the interannual standard deviation of $UI_{JJAS,boxMK}$ is equal to 85% in the LONG simulation
244 (To Duy et al., 2022). Spatially, MKU is also very stable. As shown by To Duy et al. (2022), it develops along
245 the northeastward current, behind Con Dao islands (Figures 1, 3e). For the 3 periods of MKU development, Figure
246 3d,f shows extremely very weak values of IV_{im} both for the surface current vorticity and for the spatial upwelling
247 index. The circulation is therefore extremely stable in this area, explaining the spatial stability of MKU.

248 The daily chronology and intensity of MKU are thus mainly driven by the wind, and its position is determined by
249 non-varying factors, presumably bathymetry, that still need to be investigated, and not by chaotic factors like
250 (sub)mesoscale circulation. As a result, MKU is almost not affected by OIV.

251 **4.3. The offshore upwelling (OFU)**

252 Again, the daily chronology of OFU is very similar for the ten members and the ensemble mean (Figure 2a), and
253 in phase with the wind chronology (correlation of 0.65, $p < 0.01$ with the daily wind stress intensity over boxOF,
254 Table 1). However, contrary to SCU, the intensity of OFU peaks varies throughout the season, though wind stress
255 intensity is similar during those peaks. We obtain two strong peaks ($\sim 1.0^\circ\text{C}$) in the heart of summer on July 19th
256 and August 13th, a moderate peak ($\sim 0.6^\circ\text{C}$) at the end of August, and two small peaks ($\sim 0.2^\circ\text{C}$) at the beginning
257 and end of summer, on June 18th and September 16th. $IV_d(UI_{d,boxOF})$ also varies a lot seasonally, and is maximum
258 and much stronger than for SCU and MKU during OFU peaks (Figure 2e): it reaches 90% for the July peak, 70%
259 during the August peaks, and respectively 30% and 50% during the small June and September peaks. On the
260 summer average, $IV_{im}(UI_{JJAS,boxOF})$ is equal to 18% (Table 1), again stronger than for SCU and MKU, but still
261 much lower than the interannual variability (126%, To Duy et al., 2022). The regional daily wind stress therefore
262 drives the daily to intraseasonal variability of OFU at the first order. However, OIV also significantly influences
263 this daily variability, and this influence varies intraseasonally.

264 To understand the mechanisms that explain the intraseasonal variability of OFU intensity, we examine its
265 functioning during its three main periods of OFU development (June, July and August, highlighted in blue in
266 Figure 2). Da et al. (2019) and To Duy et al. (2022) showed that OFU is mainly induced by Ekman pumping and
267 develops in the area of strong positive wind stress curl and current vorticity. The eastward jet and ACC dipole
268 that favor the development of OFU are much stronger and well established in the heart of summer than at the
269 beginning and end of the summer monsoon (Figure 3bc and Part 3). Northeastward wind intensity is stronger in
270 July and August than in June and September (Figure 2) with a larger area of positive wind curl (Figure 3a).
271 Moreover, positive current vorticity developing in boxOF in the area of positive wind curl is much higher in July
272 and August, which further enhances Ekman pumping (Figure 3e). The intraseasonal variability of OFU peaks is
273 thus explained by the intraseasonal variability of wind and large-scale circulation.

274 We then examine the mechanisms that explain why the July and August peaks show different intrinsic variability
275 but similar ensemble mean of OFU intensity (Figure 2a). Figure 4a shows the maps of UI_d on the day of maximum
276 $UI_{d,boxOF}$ over the July OFU development period and the maps of average surface current vorticity during the this
277 period for 2 members of strong OFU (13, maximum $UI_{d,boxOF} = 1.53$ °C; 17, maximum $UI_{d,boxOF} = 1.42$ °C, Figure
278 2a) and 2 members of weak OFU (15, maximum $UI_{d,boxOF} = 0.77$ °C; 18, maximum $UI_{d,boxOF} = 0.65$ °C). In July,
279 the eastward jet is much stronger than in June (Figure 3b,c and Section 3 above). OFU develops mainly in the
280 area of positive wind stress curl and current vorticity along the northern flank of the jet (Figures 3c,e and 4). When
281 the position of the eastward jet is located more to the south than average, as for members 13 and 17, the area of
282 positive current vorticity northern of the jet in BoxOF coincides with the area of positive wind curl. This
283 combination of positive current vorticity and positive wind curl enhances Ekman pumping induced upwelling
284 (Figure 4) and results in a strong OFU covering a large area. This is the opposite when the position of the eastward
285 jet is more to the north than average (members 15 and 18) : the area of positive current vorticity located in the
286 positive wind curl region is smaller, not enhancing the Ekman pumping induced upwelling (Figure 4). Figure 3d,f
287 shows strong values of IV_m of current vorticity and upwelling intensity ($> 100\%$) along the eastward jet and in
288 the northeast area of boxOF. This confirms that OFU intrinsic variability in July is related to the effect of eastward
289 jet meridional position variability on the circulation and on the upwelling that develops along the northern flank
290 of the jet. Figure 4b shows the maps of UI_d on the day of maximum $UI_{d,boxOF}$ over the August OFU development
291 period and the maps of average surface current vorticity and average wind stress curl during this period for 2
292 members of strong OFU (14, maximum $UI_{d,boxOF} = 1.65$ °C; 13, maximum $UI_{d,boxOF} = 1.20$ °C, Figure 2a) and 2
293 members of weak OFU (10, maximum $UI_{d,boxOF} = 0.82$ °C; 16, maximum $UI_{d,boxOF} = 0.89$ °C). In August, part of
294 OFU still develops in the area of positive surface current vorticity along the northern flank of the eastward jet, but
295 to less extent than in July (Figures 3e, 4). The meridional position of the jet does not vary a lot from one member
296 to another (Figure 4b), as confirmed by the lower values of IV_m of current vorticity in the jet area (Figure 3d).
297 The eastward jet is thus stronger and more stable than in July (Figure 3b,c and Part 3), and does not induce a
298 strong intrinsic variability of OFU. Instead, August OFU mainly develops in the area of positive vorticity north
299 of the jet associated with the cyclonic eddy of the ACC dipole (Figures 4b,3e). Variations of zonal position of this
300 eddy explain the variability of OFU intensity. From members 14, to 13, 10 and 16, this eddy is located more and
301 more to the east, i.e. further and further away from the area of strong positive wind stress curl, resulting in a
302 weaker and weaker OFU (Figures 4b). The variability of circulation in the northern part of boxOF therefore
303 explains OFU intrinsic variability in August. This variability is moreover lower than in July: IV_m of current

304 vorticity and of UI_d in this northern part (highlighted by the black triangle in Figure 3d,e,f) is lower in August
305 than in July. The more stable jet in August, that results in a smaller intrinsic variability of OFU along the jet, and
306 smaller intrinsic variability of current vorticity in the northern cyclonic part, where OFU mostly develops,
307 therefore explain the intrinsic variability of OFU in August and the fact that it is smaller than in July.

308 In OFU, MKU and SCU areas, the effect of intrinsic variability on UI_d and the surface current vorticity therefore
309 shows similar spatial patterns (Fig. 3d,f) and the influence of OIV on upwelling is directly linked to the influence
310 of OIV on the circulation.

311 **4.4. The northern coastal upwelling (NCU)**

312 The ten members and the ensemble mean simulate NCU with a strong intraseasonal variability and a similar
313 chronology (Figure 2d), completely different from the chronology obtained for the three other areas. A strong
314 NCU develops at the beginning of summer (from June 10th to July 4th, reaching $\sim 1.2^\circ\text{C}$ for the ensemble average),
315 and a weak NCU develops at the end of August (August 26th to 31st, reaching $\sim 0.2^\circ\text{C}$). During those periods,
316 highlighted in green in Figure 2, NCU chronology follows the wind chronology for the ten members: $UI_{d,boxNC}$
317 peaks correspond to peaks of northward (i.e. alongshore) wind favorable to NCU, around June 18th and 25th, July
318 2nd, and August 28th and 29th. There still a significant correlation between the time series of $UI_{d,boxNC}$ and the time
319 series of wind stress northward component over boxNC, that favors the Ekman upwelling in this area (0.37,
320 $p < 0.01$, Table 1). It is however much weaker than correlations obtained for the other areas (at least 0.64).
321 Moreover, although northward wind peaks occur during the whole summer (e.g July 17th - 22nd, highlighted in
322 green in Figure 2) NCU does not develop from mid-July to mid-August.

323 NCU shows the strongest OIV of the four areas. $IV_d(UI_{d,boxNC})$ reaches 170% during the June-July peak, and is
324 much smaller during the rest of the summer, reaching at most $\sim 80\%$ during the short late August peak (Figure 2e).
325 The strong OIV in June explains the strong OIV at the summer scale (Table 1): $IV_m(UI_{JJAS,boxNC})$ is equal to 37%,
326 that is twice larger than for OFU and ~ 6 times larger than for SCU and MKU. It is twice smaller than the
327 interannual variability of MKU summer strength (72% in the LONG simulation, To Duy et al., 2022).

328 These results suggest that the daily to intraseasonal chronology of upwelling in boxNC is partly driven by wind,
329 but to less extent than in the other areas. Therefore other factors are involved that induce a strong intrinsic
330 variability of NCU both at the daily and summer scales. To identify those factors, we use the three periods
331 identified above : the period of strong wind over boxNC and strong NCU in June (June 10th – July 4th), the period
332 of strong wind but no NCU in July (July 17th - 22nd), and the period of strong wind and weak NCU at the end of
333 August (August 26th - 31st). We show in Figure 5 the maps of ensemble average of average surface current, current
334 vorticity and IV_m of current vorticity over each period, and the maps of UI_d and $IV_m(UI_d)$ on the day of maximum
335 $UI_{d,boxNC}$ over each period.

336 During the June period, ensemble average circulation in and around boxNC is globally offshore oriented. This
337 favors the Ekman transport, hence the development of NCU. The ensemble spreading of NCU strength is very
338 strong: $IV_m(UI_d)$ spatially exceeds 300% in the eastern part of boxNC (Figure 5e), and $IV_d(UI_{d,boxNC})$ reaches 170%
339 (Figure 2e). Figure 6 shows the maps of wind speed and curl, current speed and vorticity and UI_d on the day of
340 maximum $UI_{d,boxNC}$ over the June period for two members of strong NCU (10 and 16) and two members of weak

341 NCU (09 and 11). A cyclonic gyre in the north and anticyclonic gyre in the south meet in boxNC for members 10
342 (between 13°N and 14°N) and 16 (between 14°N and 15°N). This induces a convergence and an offshore current
343 resulting in a strong upwelling, following the same mechanism as for SCU. For members 09 and 11, cyclonic and
344 anticyclonic gyres do not meet in boxNC, but either north or south of boxNC, not inducing offshore oriented
345 current over boxNC. Instead a weak NCU is induced by a favorable northward alongshore current in the northern
346 part of boxNC (Figure 6). As already observed at the interannual scale by To Duy et al. (2022) for the interannual
347 variability, mesoscale circulation of strongly chaotic nature in and around boxNC therefore drives the NCU
348 development and explains its high intrinsic variability during the June period. The effect of intrinsic variability on
349 NCU is not related to the intrinsic variability of current vorticity, but of current direction relative to the coast.

350 Between mid-July and mid-August, the large-scale circulation (ACC dipole and eastward jet) is strongly
351 established (see Section 3). The western part of the cyclonic eddy covers boxNC and induces a strong southward
352 alongshore current over this region. Close to the coast, this alongshore current is associated with a divergent
353 circulation, hence with a coastward component and a coastal downwelling which inhibits the NCU (see the high
354 negative vorticity in this area during the July period in Figure 5b). This large-scale ocean circulation is common
355 for the ten members and systematically prevents the NCU to develop (see the weak IV_m of current vorticity and
356 the weak upwelling in Figure 5). This explains the very weak $UI_{d,boxNC}$ and $IV_d(UI_{d,boxNC})$ during this period (Figure
357 2e).

358 During the August period, the average circulation is similar to the mid-July and mid-August circulation described
359 above (Figure 5a,b). However, with the weakening of the summer monsoon, the ACC dipole structure
360 progressively weakens, the negative vorticity is less strong and the current is a bit more offshore oriented: NCU
361 is not as strong as in June, but it can develop easier than in the middle of the summer. $IV_d(UI_{d,boxNC})$ consequently
362 increases, but stays smaller than in June.

363 Our results therefore show that the development of NCU at the intraseasonal scale is first related to the large-scale
364 circulation, which prevents it during the heart of summer and allows it at the beginning and end of summer. Inside
365 those periods of “allowed NCU development”, it is first driven by wind, then by the mesoscale circulation that
366 explains its very strong intrinsic variability.

367 **5. Conclusion and future work**

368 An ensemble of ten fine-resolution simulations with perturbed initial conditions was performed and analyzed in
369 this paper to represent and investigate the daily to intraseasonal variability of ocean circulation and of SVU over
370 its different areas of development and the influence of OIV.

371 The ensemble was used to examine the seasonal variability and intrinsic variability of the circulation in the SVU
372 region during summer 2018. In June, the eastward jet is weak and mainly located in the south, the ACC dipole is
373 not formed and the circulation is only stable in the coastal area. In July, the jet is stronger and the ACC dipole is
374 clearly formed. The circulation in the area of positive vorticity north of the jet is more stable. In August southwest
375 monsoon wind is the strongest and has the largest area of influence, inducing an even stronger eastward jet and a
376 pronounced ACC dipole. In August, the circulation is stable over a larger area than in July.

377 We then examined the seasonal variability and intrinsic variability of the upwelling.

378 For SCU, MKU and OFU, the daily chronology and intraseasonal variability of the upwelling are quite similar
379 and mainly driven by the summer monsoon wind, with upwelling maxima in phase with strong southwest wind
380 periods. Their intrinsic variability is much weaker than their interannual variability.

381 The development of MKU and SCU is related to ocean circulation processes, respectively the northeastward
382 current and eastward jet, that are spatially quite stable. As a result, MKU and SCU show a very weak (less than
383 10%) intrinsic variability in space and time, both at daily scale and on average over summer. Peaks of OIV are
384 related to peaks of upwelling intensity. SCU develops as long as wind conditions are favorable over the area of
385 the ACC dipole convergence, that does not vary much spatially. MKU develops along the northeastward current
386 that flows offshore the Mekong delta and is spatially very stable.

387 OFU shows stronger intrinsic variability (18%), both at daily scale and for the whole summer period, and also in
388 space. The seasonal variability of OFU intensity and intrinsic variability are not only driven by the wind, but also
389 related to the period of the season. The large-scale circulation (ACC dipole and eastward jet) that enhances the
390 Ekman pumping – induced OFU is weak in June and September, whereas it is strongly established in the heart of
391 summer in July and August. This explains the stronger OFU intensity and OIV during the July-August period.
392 Moreover, for similar OFU intensity, the impact of OIV is weaker in August than in July. In July, OFU mainly
393 develops along the northern flank of the eastward jet. The meridional position of this jet is quite variable,
394 explaining the strong intrinsic variability of the July OFU: a southern (northern) position of the jet induces a larger
395 (smaller) common area between positive curl of wind stress and current, hence induces a stronger (weaker)
396 upwelling. In August, this position is much more stable. Moreover, OFU mainly develops in the area of cyclonic
397 activity north of the jet, related to mesoscale eddies of strong chaotic nature. OFU intensity depends on the zonal
398 position of this cyclonic activity with respect to the wind curl: a cyclonic eddy (not) located in the area of strong
399 positive wind stress curl results in stronger (weaker) OFU. The circulation in this area is moreover more stable
400 than in July, explaining the weaker intrinsic variability in August.

401 NCU daily chronology and the intraseasonal variability is completely different from that found in the three other
402 areas, and its intrinsic variability is much higher. At the intraseasonal scale, the development of NCU is driven by
403 the large-scale circulation. During the heart of summer, from mid-July to end of August, the eastward jet and ACC
404 dipole are strongly established, inducing a strong southward alongshore current over boxNC which annihilates
405 NCU, explaining its very low intensity and intrinsic variability. At the beginning and, to less extent, end of
406 summer, the large-scale ACC dipole structure and associated eastward current are weaker, allowing offshore
407 current to develop. Inside these periods, NCU chronology is driven by the wind but also by the development (or
408 not) of offshore oriented currents related to the spatial organization of coastal eddies. NCU shows a strong intrinsic
409 variability related to strong chaotic variability of mesoscale structures with the order of magnitude similar to
410 interannual variability (37%).

411 We investigated here the effect of OIV on the circulation and upwelling in the SVU region, confirming that this
412 chaotic part of ocean variability here is mainly related to the small-scale structures, as previously shown for other
413 and larger areas. Following this study as well as those of Da et al. (2019) and To Duy et al. (2022), we can draw
414 some perspectives on the application of research regarding the predictability of SVU at the intraseasonal to
415 interannual scale. The development of MKU and SCU, which is little affected by OIV, could be largely predicted

416 using wind forecasts, provided of course that these forecasts are reliable. At first order, OFU can be partially
417 predicted from wind forecasts, but with uncertainties in its daily to summer integrated magnitude that can vary by
418 a factor of 1.5 to 2 (see Figure 2 and Table 1). Wind forecasts could identify favorable/unfavorable periods for
419 NCU development. However, favorable periods would be associated with a high uncertainty rate in terms of NCU
420 intensity, given the strong impact of OIV on NCU during these periods. Further studies are underway to investigate
421 the influence of other factors, including rivers and tides. Chen et al. (2012) indeed suggested that tides could
422 influence the SVU development. Tidal amplitude is particularly strong over the shallow Mekong shelf region
423 (Phan et al. 2019), moreover submitted to the influence of the Mekong river waters. Both factors may therefore
424 affect SVU development and variability, in particular over the MKU and SVU areas. We moreover developed an
425 ocean-atmosphere regional coupled model that will allow to study the impact of upwelling on atmosphere and
426 climate, at local and regional scales, that was studied until now using satellite data and an atmosphere-only model
427 (Xie et al. 2003; Zheng et al., 2016; Yu et al., 2020). The impact of upwelling on the marine ecosystem should
428 also be studied, using for example the dynamical-biogeochemical coupled model developed by Ulses et al. (2016)
429 and Herrmann et al. (2017). Finally, the long-term evolution of the upwelling should be studied, in particular since
430 Herrmann et al. (2020,2022) showed that summer monsoon winds may weaken in response to climate change.
431 Last, the upwelling that develops offshore the Mekong Delta, MKU, was revealed by To Duy et al. (2022) and
432 confirmed by the present study, and the northern coastal upwelling, NCU, was revealed by Da et al. (2019) and
433 confirmed by Ngo and Hsin (2021). Extremely few in-situ observations are available over these two areas, and
434 field campaigns are therefore necessary to better understand their functioning. This study explored the impact of
435 OIV on the South Vietnam Upwelling, but is more generally of interest for the scientific community working on
436 the functioning and variability of upwellings and on the effect and modeling of OIV.

437

438 **Code and data availability**

439 The SYMPHONIE model is available on the webpage of the SIROCCO group, <https://sirocco.obs-mip.fr/>. Sea
440 surface temperature, currents and windstress simulated by the ensemble over summer 2018 are freely available
441 on <https://doi.org/10.5281/zenodo.7504087>.

442

443 **Authors Contribution**

444 Marine Herrmann, To Duy Thai and Claude Estournel designed the experiments and To Duy Thai carried them
445 out. Marine Herrmann prepared the manuscript with contributions from all co-authors.

446

447 **Competing interests**

448 The authors declare that they have no conflict of interest.

449

450 **Acknowledgements**

451 This work is a part of LOTUS international joint laboratory (lotus.usth.edu.vn). PhD studies of To Duy Thai were
452 funded through an IRD ARTS grant and a “Bourse d’Excellence” from the French Embassy in Vietnam.
453 Numerical simulations were performed using CALMIP HPC facilities (project P13120) and the cluster OCCIGEN
454 from the CINES group (project DARI A0080110098). This paper is a contribution to celebrate the 100 years
455 Anniversary of the Institute of Oceanography, Vietnam Academy of Science and Technology. The authors warmly
456 thank both reviewers for their constructive comments.
